Abstract. Monte Carlo results for the moments $\langle M^k \rangle$ of the magnetization distribution in a $L^d$ geometry, where $L$ (4 $\leq$ L $\leq$ 22) is the linear dimension of a hypercubic lattice with periodic boundary conditions in $d = 5$ dimensions, are analyzed in the critical region and compared to a recent theory of Chen and Dohm (CD) [X.S. Chen and V. Dohm, Int. J. Mod. Phys. C (1998)]. We show that this finite-size scaling theory (formulated in terms of two scaling variables) can account for the longstanding discrepancies between Monte Carlo results and the so-called “lowest-mode” theory, which uses a single scaling variable $tL^{d/2}$ where $t = T/T_c - 1$ is the temperature distance from the critical temperature, only to a very limited extent. While the CD theory gives a somewhat improved description of corrections to the “lowest-mode” results (to which the CD theory can easily be reduced in the limit $t \to 0$, $L \to \infty$, $tL^{d/2}$ fixed) for the fourth-order cumulant, discrepancies are found for the susceptibility ($L^d\langle M^2 \rangle$). Reasons for these problems are briefly discussed.

PACS. 05.70.Jk – 64.60.-i – 75.40.Mg

1 Introduction

Since about 15 years the five-dimensional Ising model is used as a “laboratory” [1–8] to test theoretical concepts about critical phenomena, in particular the concept of finite-size scaling [9–32], which has become an extremely valuable and indispensable tool for the study of phase transitions in condensed matter [22,33,34] and gauge theories of elementary particle physics [35,36]. In this context, $d = 5$ Ising model is of particular interest, since it exceeds the upper critical dimension, $d^* = 4$, and hence the Landau mean-field exponents exactly describe the critical behavior [37,38]. Also correction-to-scaling exponents [39] are known precisely [38] and fluctuations around the leading mean-field description can be dealt with by simple perturbation theory; a renormalization-group treatment of fluctuation effects is not required here [37,38]. While for $d > d^*$ the hyperscaling relation $d\nu = \gamma + 2\beta$ ($\nu$, $\gamma$, $\beta$ being the standard critical exponents for correlation length $\xi$, susceptibility $\chi$ and order parameter $M$, respectively) does not hold and hence finite-size scaling in its standard version (“the linear dimension $L$ scales with $\xi$” [9–12,16,20,23]) does not hold either [12–14], a simple extension was proposed [1,2,17,18] which can be phrased as [2] “the linear dimension $L$ scales asymptotically with a thermodynamic length $\ell_T = (M_b^2/\chi_b)^{-1/d} \propto t^{-2/d}$.

Moreover it was suggested that ratios of moments of the order parameter distribution, such as $Q \equiv \langle M^2 \rangle^2/\langle M^4 \rangle$ or $\langle M \rangle^2/\langle M^2 \rangle$ can easily be calculated from the so-called lowest-mode approximation [17], which was believed to be exact for the limit $L \to \infty$, $t \to 0$, $L/\ell_T$ fixed and should yield, apart from scale factors, universal finite-size scaling functions of $L/\ell_T$.

In view of these rather definite predictions [17], apparent discrepancies between the theoretical results and the Monte Carlo simulations [1–3] have been disturbing and it has been a matter of debate [27,4–8,29–31] whether the discrepancies reflect corrections to finite-size scaling. In Ref. [8] it was shown that the Monte Carlo data for $Q$ are indeed compatible with the predictions of Brézin and Zinn-Justin [17] if one takes into account two, theoretically predicted, corrections to scaling. However, this still left the very slow convergence of $Q$ as a function of $L$ toward its predicted asymptotic value as a remarkable feature (in Ref. [3] the data for $Q$ for the considered range of system sizes appeared to have a common intersection point unequal to this value). More importantly, the correctness of the treatment in Ref. [17] has recently been doubted [31] (see below). This controversy is cumbersome because the fact that it is apparently very difficult to disentangle the leading and subleading terms in finite-size scaling analyses even in a case where all involved critical exponents are known precisely naturally leads to some
doubt on analyses where one wants to extract unknown critical exponents from finite-size scaling [22, 23, 26, 34]. In addition, the problem also is of interest in the context of physical systems that are nearly described by Landau theory, such as systems with a long but finite range of interaction [25, 28], polymer mixtures near their critical point of unmixing [40], etc.

New light has been shed on this state of affairs by Chen and Dohm (CD) [29–31], who presented detailed arguments that for \( d > d^\ast \) the standard treatment of the \( \phi^4 \) field theory in continuous space [17, 18, 38] yields a misleading description of finite-size behavior, different from the finite-size behavior of a \( \phi^4 \) model on a lattice, which one believes to be equivalent to an Ising model [37, 38]. Chen and Dohm emphasized that therefore the justification given for the lowest-mode theory is invalid, and stated that the moment ratios mentioned above “do not have the universal properties predicted previously and that recent analyses of Monte Carlo results for the five-dimensional Ising model are not conclusive” [31].

In view of this criticism, a reanalysis of the available Monte Carlo results (including also some recent unpublished results [41] used in [42]) is clearly warranted. Such an analysis, where we compare the Monte Carlo data in detail with the result of the CD theory (which treats order parameter fluctuations perturbatively to one-loop order for the Ising case [31]) is given here. For the sake of a coherent presentation, we summarize the pertinent theoretical results in Sec. 2, while Sec. 3 gives a detailed comparison of the results for \( Q \) and for the susceptibility \( \chi = L^d(M^2) \) with the CD theory. Section 4 summarizes our conclusions.

## 2 Theoretical background

The singular part of the free-energy density \( f_L \) of a system with linear size \( L \) in an external field \( h \) is written as (see, e.g., Ref. [14])

\[
f_L = L^{-d} f(tL^h, hL^y, uL^u), \quad L \to \infty,
\]

where \( t = T/T_c - 1 \) and \( u \) is an irrelevant variable, in the renormalization-group sense (exponents \( y_t > 0, y_h > 0, y_u < 0 \)). Now for \( d > d^\ast = 4 \) we have \( y_t = 2, y_h = (d+2)/2 \) and \( y_u = 4 - d \), but \( u \) is a “dangerous irrelevant variable” (see, e.g., Refs. [43, 44]), which means that the scaling function \( f(x_2, x_3) \) is singular in the limit \( x_2 \to 0 \) and cannot simply be replaced by \( f(x_1, x_2, 0) \). In terms of the bulk correlation length \( \xi_b \),

\[
\langle |\rangle = \xi_b^{-\nu} \text{ (above } T_c \text{ in zero field),}
\]

the first argument of Eq. (1) can be interpreted as \( (L/\xi_b)^{2d} \). Taking suitable derivatives of Eq. (1) with respect to the field we can thus write for the order parameter, the susceptibility and the ratio \( Q \) (in zero field)

\[
\langle |\rangle = L^{-(d-2)/2} P_M \{ t(L/\xi_0)^2, (L/\xi_0)^{4-d} \},
\]

\[
\chi = \left( \frac{\partial^2 f_L}{\partial h^2} \right) = L^d \langle M^2 \rangle
\]

\[
= L^2 P_X \{ t(L/\xi_0)^2, (L/\xi_0)^{4-d} \}
\]

and

\[
Q = \langle | \rangle^2 = Q \{ t(L/\xi_0)^2, (L/\xi_0)^{4-d} \}.
\]

where \( P_M \), \( P_X \) and \( Q \) are the (universal [22]) finite-size scaling functions of the quantities \( \langle | \rangle \), \( \chi \) and \( Q \). The correlation-length amplitude \( \xi_0 \) of the bulk correlation length now appears as a scale factor for the variable \( x_1 \) and for the variable \( x_3 \) we have introduced the correlation-length amplitude \( \ell_0 \) of the bulk correlation length at \( T_c \) in a small field [31] as a scale factor. In this way, the arguments of the scaling functions \( P_M \), \( P_X \) and \( Q \) are dimensionless, as they should be. Note that \( u \propto \ell_0^{-4} \).

For large \( L \) the variable \( x_3 \propto (L/\ell_0)^{4-d} \) clearly becomes very small, and hence it is an obvious question to ask how all these functions \( f_L, P_M, P_X, Q \) behave in the limit \( x_3 \to 0 \). It was assumed in Ref. [1] that then the dangerous irrelevant variable \( x_3 \) enters in the form of multiplicative singular powers of \( x_3 \), e.g.,

\[
f_L(x_1, x_2, x_3) = x_3^2 f_L(x_1 x_3^2, x_2 x_3^2).
\]

This assumption was in the first place motivated by the fact that this is the mechanism that operates for the scaling in the bulk for \( d > 4 \) [44], and secondly by various phenomenological arguments. In particular, it was argued that standard thermodynamic fluctuation theory requires for \( T < T_c \) and sufficiently large \( L \) that the distribution function \( P_X(M) \) of the magnetization per spin for \( M \) near the spontaneous magnetization \( \pm M_0 \) is a sum of two Gaussians [1, 2, 12],

\[
P_L(M) = \frac{L_d^d/2}{2\sqrt{\pi}\chi_b} \{ \exp \left[ -(M - M_0)^2 L^d/2\chi_b \right] + \exp \left[ -(M + M_0)^2 L^d/2\chi_b \right] \}.
\]

Using \( M_0 = \tilde{M}_b |t|^{\beta} = \tilde{M}_b (t - t_0)^{1/2} \) and \( \chi_b = \chi_b(t - t_0)^{-\gamma} \) the arguments of the exponential functions have the form

\[
\frac{1}{2} \left[ (M/\tilde{M}_b)|t|^{-1/2} \mp 1 \right]^2 (L/\ell_0)^d,
\]

with \( \ell_0^d = M_0^2 \chi_b = M_0^2 (\chi_b - t_0)^{-2} t_0^{-2} \). Taking moments of this distribution one hence expects that the scaling functions in Eqs. (2)-(4) reduce to scaling functions of a single variable \( (L/\ell_T)^d/2 \propto tL^d/2 \) or, keeping the amplitudes \( \xi_0 \) and \( \ell_0 \) explicitly present, \( tL^{d/2}(\xi_0^{4-d})/2 \), i.e.,

\[
\langle |\rangle = L^{d/4} \tilde{P}_M \left( tL^d/2\xi_0^{4-d} \right),
\]

\[
\chi = L^{d/2} \tilde{P}_X \left( tL^d/2\xi_0^{4-d} \right),
\]

and

\[
Q = \tilde{P}_Q \left( tL^d/2\xi_0^{4-d} \right).
\]

Note that scale factors for the magnetization and the susceptibility have been absorbed in \( P_M \) (or \( \tilde{P}_M \)) and \( P_X \) (or
\[ \hat{P}_\lambda(x), \text{ respectively, while in ratios such as } Q \text{ (and hence in } P_Q \text{ and } \hat{P}_Q) \text{ such scale factors are divided out and fully universal functions remain.} \]

These arguments as they were presented in Refs. [1, 2] did not tell anything about the explicit form of the scaling functions \( \hat{P}_M(x) \), \( \hat{P}_\lambda(x) \) and \( \hat{P}_Q(x) \), however, and hence no prediction for the supposedly universal constant \( P_Q(0) \) was made. In fact, making the (premature!) assumption that linear dimensions \( L = 3 \) to 7 lattice spacings are already large enough to obtain the limit \( x_3 \propto (L/\xi_0)^{-1} \to 0 \) in \( d = 5 \) dimensions, it was argued that at \( T_c \) there occurs a distribution of the scaled order parameter \( P_L(\phi) \propto \exp(A\phi^d - \phi^4) \), which implies a shift of \( T_c \) as \( T_c(L)/T_c(\infty) \to 1 \propto AL^{-d/2} \), if \( T_c(L) \) is defined as the temperature where \( P_L(\phi) \) starts to develop a two-phase structure. However, the next step in the development, due to Brézin and Zinn-Justin [17], suggested that in the scaling limit \( P_L(\phi) \propto \exp(-\phi^4) \) at \( T_c \), since the shift of \( T_c \) as defined above should only exhibit a scaling with a higher power of \( L^{-1} \), namely \( T_c(L)/T_c(\infty) \to 1 \propto L^{-d-d} \), because it results from corrections to the scaling description given in Eqs. (8)–(10). According to Ref. [17], the asymptotic behavior is simply given by the homogeneous order parameter \( M \) in the finite system,

\[ P_L(M) = \exp \left[ -L^d \left( \frac{1}{2}M^2 + uM^4 \right) \right], \quad (11) \]

where \( r_0 = a_0t \) changes sign at \( T_c \), \( u \) is the dangerous irrelevant variable mentioned above, both \( a_0 \) and \( u \) being nonuniversal constants. From Eq. (11) it is straightforward to derive that [17]

\[ \hat{P}_Q(0) = 8\pi^2/\Gamma^4(1/4) \approx 0.456947. \quad (12) \]

However, the statements of CD imply that the continuum model considered in [17] actually leads to a behavior differing from Eq. (11) and thus at this point also Eq. (12) seems without safe foundation. CD obtain, in the large-\( n \) limit of the \( n \)-vector model on the lattice rather than in the continuum, a result for the scaling function \( P_M(x, y) \) [Eq. (3)]:

\[ P_M(x, y) = \frac{2}{J_0} \left[ \frac{\delta(x, y) + \sqrt{\delta(x, y)^2 + 4y}}{\sqrt{\delta(x, y)^2 + 4y}} \right]^{-1}, \quad (13) \]

where \( J_0 \) is the interaction range of the \( \phi^4 \) model on the \( d \)-dimensional hypercubic lattice (the lattice spacing being taken as unity here throughout),

\[ J_0 = \frac{1}{dL^d} \sum_{i,j} J_{ij} |r_i - r_j|^2, \quad (14) \]

and \( \delta(x, y) \) is given by

\[ \delta(x, y) = x - yI_1(\tilde{J}_0^{-1}P_\lambda)^{-1}, \quad (15) \]

with the function \( I_m(x) \), \( m = 1, 2, \ldots, \) being

\[ I_m(x) = \frac{1}{(2\pi)^{2m}} \int_0^\infty dy y^{m-1} \exp(-xy/4\pi^2) \times \left[ \left( \frac{\pi}{y} \right)^{d/2} - \left( \sum_{p=-\infty}^{\infty} e^{-yp^2} \right)^d \right] + 1. \quad (16) \]

In terms of the Hamiltonian of the \( n \)-vector model with \( n \)-component vectors \( \phi \) on the lattice,

\[ H = \sum_i \left[ \frac{r_0}{2} \phi_i^2 + u_0(\phi_i^2)^2 \right] + \sum_{i,j} \frac{J_{ij}}{2}(\phi_i - \phi_j)^2, \quad (17) \]

the characteristic lengths \( \xi_0, \xi_0 \) in Eqs. (2)–(4) are given by

\[ \xi_0^2 = \frac{J_0}{a_0}(1 + S_0^b), \quad \xi_0^{-d-4} = \frac{4u_0n}{J_0^2} \frac{1}{1 + S_0^b}, \quad (18) \]

with \( r_0 = r_0 + a_0t \) and

\[ S_0^b = u_0n \int dI [\delta(J(k))]^{-2}, \quad \delta(J(k)) = J(0) - J(k), \quad (19) \]

where \( J(k) \equiv L^{-d} \sum_{i,j} J_{ij} \exp[-ik \cdot (\mathbf{r}_i - \mathbf{r}_j)] \). For the \( n \)-vector model with \( n = 1 \), which is supposed to belong to the Ising universality class, comparable results are obtained only to one-loop order in perturbation theory [31]. Although the results are not exact, their scaling structure is analogous to Eqs. (13)–(16) and this structure is not expected to be changed by the higher-order terms of the loop expansion. Defining reduced moments

\[ \theta_m(Y) = \int_0^\infty d\phi \phi^m \exp \left[ -\frac{1}{2}Y\phi^2 - \phi^4 \right] \quad (20) \]

CD find [31, 45]

\[ P_M(x, y) = \frac{1}{J_0 \sqrt{y} + 36I_2(\tilde{r})y^2}, \quad (21) \]

\[ P_Q(x, y) = \frac{[\theta_2(Y(x, y))]^2}{\theta_4(Y(x, y))}, \quad (22) \]

with

\[ Y(x, y) = \left[ x - 12yI_1(\tilde{r}) - 144\theta_2(xy^{-1/2})I_2(\tilde{r})y^{3/2} \right] / \left[ y + 36I_2(\tilde{r})y^{3/2} \right]^{1/2}, \quad (23) \]

where \( \tilde{r} \equiv x - 12\theta_2(xy^{-1/2})y^{1/2} \). As should be clear from what has been said above, the results (21)–(23) should hold for sufficiently large \( L \).

Armed with these results we are now in a better position to reconsider the question already posed in Ref. [1], namely to take the limit \( y \to 0 \). For this purpose we first consider the large-\( n \) limit, where we can rewrite Eq. (13) as

\[ P_M(x, y) = \frac{1}{J_0 \sqrt{y}} \left[ \delta(x, y) + \sqrt{1 + [\delta(x, y)/(2\sqrt{y})]^2} \right]^{-1}. \quad (24) \]

In the limit \( y \to 0 \) we see from Eq. (15) that \( P_M(x, y) \) depends, apart from the prefactor, on \( x \) and \( y \) through
the variable
\[ \frac{\delta(x, y)}{2\sqrt{y}} = \frac{x}{2\sqrt{y}} - \frac{1}{2\sqrt{y}} \int_I (J_0^{-1} P_x) . \]

Thus we see that there exists a limit \( t \to 0, L \to \infty, tL^{d/2} \) fixed, where the susceptibility scales exactly as postulated in Eq. (9), since then the correction term of order \((L/\ell_0)^{(4-d)/2}\) in Eq. (25) clearly is negligible \((J_0^{-1} P_x^2)\) tends toward zero in this limit, so the function \( I_1 \) approaches a finite constant). Contrary to statements made by CD themselves, viz. that the structure of Eqs. (8)–(10) is incorrect for the \( \phi^4 \) lattice model, we rather think that they have proven(!) the correctness of Eq. (11), in the limit specified above, at least for the large-\( n \) limit, and gratifyingly there is no contradiction at all between Eqs. (13)–(19) and the ideas of Ref. [1] that led to Eqs. (8)–(10). Of course, the strong merit of the CD treatment is that it yields not only the scaling structure but also the explicit scaling function and a full description of the corrections due to the dangerous irrelevant variable \( \xi_0 \).

We arrive at similar conclusions in the case \( n = 1 \), though one must recall that these results are only based on a one-loop order approximation. In the considered limit \( y \to 0 \) the quantity \( Y(x, y) \) in Eq. (23) reduces to
\[ Y(x, y) = \frac{x}{\sqrt{y}} [1 - 18I_2(\bar{r})y] - 12I_4(\bar{r})\sqrt{y} \]
\[ = tL^{d/2} \frac{2}{t_0} (L/\ell_0)^{(4-d)/2} [1 - 18I_2(\bar{r})(L/\ell_0)^{4-d}] \]
\[ - 12I_4(\bar{r})(L/\ell_0)^{(4-d)/2} , \]
(26)

which is, apart from the additional \( O(L^{4-d}) \) correction, fully analogous to Eq. (25). In the limit of interest \( t \to 0, L \to \infty, tL^{d/2} \) fixed), \( \bar{r} \) vanishes and the functions \( I_1, I_2 \) take finite values, so we see again that Eqs. (9) and (10) hold. Moreover, one concludes that at the critical temperature \( Y(0, y \to 0) \to 0 \) and hence also Eq. (12) holds, as noted already by CD. It remains to be seen whether (12), which is less general than the scaling structure of Eqs. (8)–(10), holds to all orders in the loop expansion.

In order to compare Eqs. (20)–(23) to numerical Monte Carlo data, it is clearly of interest to consider simple limiting cases of the susceptibility, where then the nonuniversal parameters \( \xi_0 \) and \( \ell_0 \) can be extracted. Since accurate Monte Carlo estimations of correlation lengths are much more difficult to perform than estimations of the susceptibility we note that in the large-\( n \) limit [Eqs. (13)–(19)] the bulk susceptibility is [29]
\[ \chi_b = - \frac{\partial^2 f_0(t, h)}{\partial h^2} = \frac{\xi_0^2}{J_0} + \frac{1 + S_c}{a_0} , \]
(27)

where \( \xi_0 = \xi_0 t^{-\nu} \). The same result is obtained from Eqs. (3), (13) using that, at fixed small \( t, \delta(x, y) \approx x \) in the limit \( L \to \infty \) and hence
\[ P_\chi(x, y \to 0) \approx (J_0x)^{-1} \Rightarrow \chi = L^2/[J_0(L/\xi_b)^2] = \chi_b . \]
(28)

In contrast, at the critical temperature the result is
\[ J_0 \chi(T = T_c) = L^{d/2} \frac{t_0^{4-d/2}}{t_0} . \]
(29)

Thus, one can determine both parameters of interest, \( \xi_0 \) and \( t_0 \), from the behavior of \( \chi \) in two simple limits. The same procedure can also be carried out in the \( n = 1 \) case, considering the limit \( y \to 0 \) at fixed small \( t \),
\[ \chi(t) = \frac{\xi_0^2}{J_0} \frac{x}{\sqrt{y}} - \frac{18I_2(\bar{r})y^2}{J_0} \]
\[ = \frac{L^2}{\ell_0^{d/2}} \frac{1}{\ell_0} \theta_2(0) = \frac{L^{d/2}}{\ell_0^{d/2}} \frac{1}{\ell_0} \Gamma(\frac{3}{2}) \].
(30)

As we already noted, the interest of Eqs. (20)–(23) is not only the combination of the scaling structure, Eqs. (8)–(10), in the limit \( t \to 0, L \to \infty, tL^{d/2} \) const, but these equations also incorporate the effect of the corrections to the lowest-mode approximation, which we would recover if in Eq. (23) we had \( Y(x, y) = xy^{d/2} \).

3 Comparison of the Chen–Dohm predictions with simulation results for the \( d = 5 \) Ising model

In Ref. [8] only numerical data for the amplitude ratio \( Q \) have been considered, with \( 5 \leq L \leq 22 \). In order to estimate the scaling parameter \( \ell_0 \) we now analyze the corresponding data for the magnetic susceptibility. Thus, we apply a finite-size expansion similar to Eq. (3) in [8],
\[ \chi(T, L) = L^{d/2} \left( p_0 + p_1L^{\nu_y} + p_2L^{2\nu_y} + p_4L^{4\nu_y} \right) , \]
(32)

where \( \ell = t + \alpha L^{\nu - \nu_y} \) and \( y_b = y_b - y_b/2 \). So the term \( \ell L^{\nu_y} = \ell tL^{d/2} + \alpha L^{(4-d)/2} \) just corresponds to the scaling variable in (25) and (26). The additional term in Eq. (26) was already mentioned in [8] as the “cross term” \( \ell L^{\nu_y + \nu} \); in contrast to the analysis of \( Q \), it turns out to have a negligibly small coefficient in the analysis of the susceptibility. The leading power \( L^{d/2} \) in Eq. (31)) has been confirmed numerically within less than one percent in Ref. [42]. In our analysis we have kept this power as well as the irrelevant exponent \( y_b \) fixed. This yielded a critical coupling \( J/k_b T_c = 0.1139152(4) \), in excellent agreement with the value found in [8] from keeping \( Q \) fixed at the zero-mode prediction (12) viz. \( J/k_b T_c = 0.1139150(4) \) (numbers in parentheses denote the uncertainty in the last decimal places). Furthermore, we found \( y = 2.53(4) \), very close to \( d/2 \), and \( p_0 = 1.86(7) \). The quality of the fit in terms of the \( \chi^2 \) criterion was \( \chi^2/\text{DOF} = 1.06 \). In order to improve the accuracy of our estimate for \( p_0 \), we have repeated the analysis with \( y_b \) fixed at \( d/2 \), finding \( J/k_b T_c = \).
Rewriting this in terms of the reduced temperature $t \chi$, the scaling variable

$$L$$

is not this estimate for $\ell$ thus pertains to the thermodynamic limit and is not a finite-size quantity.

It is also possible to extract $\xi_0$ from the Monte Carlo data. However, here we use the series-expansion result from Ref. [46] for this purpose. Assuming the mean-field exponent $\gamma = 1$, it was found that asymptotically $\chi = A/(1 - \nu/\nu_c)$ with $A = 1.311$ (9) and $\nu = \tanh(J/k_B T)$. Rewriting this in terms of the reduced temperature $t$, we have $\chi = A[\cosh(J/k_B T_c) \sinh(J/k_B T_c) - (J/k_B T_c)]^{-1} = 1.322 t^{-1}$ and Eq. (30) shows that $\xi_0 = 0.549 (2)$.

Figure 1 now shows the log-log plot of $(t \chi)^{-1}$ versus the scaling variable $t L^{d/2}$, using data for $T > T_c$ only (in view of the very accurate estimates of the critical coupling, the errors due to the inaccuracy of $T_c$ are not of major concern here). Available data for smaller system sizes have been omitted from this graph, because the rather strong deviations from scaling noted already in Ref. [2] would obscure its main purpose, namely to illustrate the use of the limits (30), (31) to extract $\xi_0$ and $\ell_0$. Of course, due to the corrections to scaling included in Eq. (32) the Monte Carlo data for $L = 12$ should not converge to the finite-size asymptote for $L \to \infty$, but to a slightly shifted straight line. However, on the scale of Fig. 1 the finite-size asymptotes for $L = 12$ and $L \to \infty$ are indistinguishable. Because of their central interest we repeat our estimates

$$\ell_0 = 0.603 (13), \quad \xi_0 = 0.549 (2). \tag{33}$$

The amplitude $\xi_0^2 \sqrt{\ell_0}$ which normalizes the scaling variable $t L^{d/2}$ [cf. Eq. (26)] becomes $0.234 (4)$.

In the following graphs, also Monte Carlo data from Ref. [2] ($L = 4$) and Ref. [3] ($L = 8, 12$) are included and it was found that all the Monte Carlo data are, within their statistical errors, nicely compatible with each other. We have omitted the data of Ref. [3] for $L \geq 13$ here, since the rather irregular behavior found for the specific heat and the cumulant intersections for these system sizes indicates that these data suffer from statistical inaccuracies due to critical slowing down. Note that Ref. [3] used a single-spin-flip Metropolis algorithm, whereas in Refs. [8, 41, 42] a single-cluster algorithm was applied. Available data from Refs. [4, 5] are restricted to temperatures very close to $T = T_c$ and hence are unsuitable for our purposes.

We now focus on the quantity $Q$, Eq. (4), since the scaling behavior of this quantity has been so controversial. Figure 2 gives a plot of the CD function (22), keeping both $x$ and $y$ as separate variables. One can see that for $x$ large and negative $Q = 1$ as it must be and for $x$ large and positive $Q = 1/3$, irrespective of $y$. This simply reflects the trivial properties of the low- and high-temperature phases, respectively. For $|t(L/\xi_0)^2| < 1$, however, a clear $y$ dependence is seen.

In Fig. 3 we compare the various Monte Carlo data to the CD function for $Q$ as a function of $t L^2$ (i.e., the variable proportional to $x$). Note that in these plots there are no adjustable parameters whatsoever, so the agreement is at first sight very remarkable. At second sight, however, one does observe that there are slight but systematic deviations between theory and simulation, which have consequences for the intersection of the amplitude ratios for different system sizes. Figure 4 demonstrates that both the CD function and the Monte Carlo data behave qualitatively similar: for a range of sizes ($4 \leq L \leq 12$) there is almost a common intersection point, but it occurs at a negative value of $t L^2$ and consequently the corresponding ordinate value $Q_{\text{int}}$ is significantly larger than the predicted asymptotic value (12). While this spurious value of the CD function, for the range of system sizes considered...
Fig. 3. Plot of $Q$ versus $tL^2$ for (a) $L = 4$, (b) $L = 8$ and (c) $L = 12$. The full curves denote the predictions of Ref. [31]. Monte Carlo data generated at specific temperatures, taken from Refs. [2] and [8,41,42] are shown as open or full squares, respectively, while the histogram extrapolation data of Ref. [3] are shown as a broken curve.

Fig. 4. Magnified plot of $Q$ versus $tL^2$ near $tL^2 = 0$, cf. Fig. 3, to demonstrate the occurrence of spurious cumulant intersections.

Fig. 5. Plot of $Q$ as a function of $tL^{5/2}$, including both Monte Carlo data for $L = 4, 8, 12$ and the CD functions. Note that the zero-mode curve, resulting from setting $Y = x^{1/2}$ in Eqs. (20), (22) and (23), practically coincides with the CD curve for $L = 12$ already, since $\ell_0$ [Eq. (33)] is so small.

here, is about $Q_{\text{int}} \approx 0.48$, it lies around $Q_{\text{int}} \approx 0.52$ for the Monte Carlo data; Rickwardt et al. [3] quoted $Q_{\text{int}} \approx 0.49 (1)$, including data up to $L = 17$. The lesson to be learned from this graph is threefold: (i) One must not pay too much attention to the value of such a cumulant intersection if one does not have a sufficiently large range of linear dimensions at one’s disposal. (ii) The CD function is a nice analytical example of a function that does produce a spurious “intersection”, as pointed out already in Ref. [31]: Although it looks so convincing on the graph, one knows that in the asymptotic limit the intersection occurs at $t = 0$ and yields $Q \approx 0.457$ [Eq. (12)]. (iii) The CD function produces the same trend as the Monte Carlo data only qualitatively, but not quantitatively.

What is the consequence of these results for the asymptotic scaling, Eq. (10)? This question is addressed in Fig. 5, where the data from Fig. 3 are replotted as a function...
of the scaling variable \( tL^{d/2} \): It is seen that the data for \( L = 4 \) deviate from scaling in a systematic way, while for \( L = 8, 12 \) the data scale already rather nicely, although they are still a little bit set off in comparison to the theoretical scaling curves. Note that on these large scales one cannot distinguish the CD curve for \( L = 12 \) from the lowest-mode result! The general trend appears that in the neighborhood of \( T = T_c \) Eq. (22) yields a too small value for \( Q(L) \).

In order to highlight the differences, we now amend the plot of \( Q \) at \( T_c \) as a function of \( L \), which was shown in Ref. [8], by the prediction that would follow from CD (see Fig. 6): One indeed observes that the result of CD underestimates the differences between \( Q(T_c, L) \) and \( Q(T_c, \infty) \) distinctly—it basically yields a \( 1/\sqrt{L} \) correction, while the additional \( 1/L \) term resulting from CD is very small, unlike the rather pronounced \( 1/L \) correction that was found in the empirical fit of Ref. [8]. Another, more tentative, way to quantify the differences is by adjusting \( \ell_0 \) such that the CD curve yields a reasonable description of the numerical data. It turns out that a value as high as \( \ell_0 \approx 3.2 \) (instead of the estimated value 0.603±0.013) is required to find some agreement in the region \( 12 \leq L \leq 22 \). It clearly must be waited for a loop expansion to second order—which will yield additional \( 1/L \) corrections of so far unknown magnitude—before one can draw final conclusions about the agreement between theory and simulation (or lack thereof).

While in the comparison of the temperature dependence of \( Q \) as predicted by CD theory to the simulation results we have seen most of the disagreement for \( t > 0 \), Fig. 7 shows that much more drastic deviations between theory and simulation occur for \( \chi \) in the regime \( t < 0 \). The fact that for \( t > 0 \) there is perfect agreement for \( L = 12 \) is no surprise, of course, since these data have been of central relevance for the fit in Fig. 1 that yielded \( \xi_0 \) and \( \ell_0 \). It is clear that perhaps a better overall fit of the data
is reached if one would fit $\ell_0$ to describe the behavior of $\chi$ for $tL^2$ large and negative, but then the behavior for $t > 0$ would deteriorate. Let us note in passing that the term “susceptibility” is just used for convenience here: Below $T_c$ the real (reduced) susceptibility is of course given by $L^2\left\langle M^2 \right\rangle - \langle |M|^2 \rangle$.

Figure 8 shows then a plot of $\chi L^{-5/2}$ versus $tL^{5/2}$, comparing Monte Carlo data for $L = 4$ and $L = 12$ [8] with corresponding predictions of the CD theory and the “zero-mode” curve. Again systematic deviations between CD theory and simulations are apparent: while the theory [31] converges to the zero-mode result from above, the Monte Carlo results fall clearly below $T_c$ the real (reduced) susceptibility is of course given by $L^2\left\langle M^2 \right\rangle - \langle |M|^2 \rangle$).

Of course, discrepancies between finite-size data for very small linear dimensions (such as $L = 4$ and $L = 8$) and the CD theory [Eqs. (21)–(23)], which only fully captures the leading zero-mode result and the first correction terms (of order $L^{-1/2}$) to it, would not be an argument against the usefulness of the theory. However, Figs. 6 and 9 clearly reveal that even for $L = 22$ one is still far from the regime where the CD theory satisfactorily describes the MC data.

4 Concluding remarks

In this paper Monte Carlo results for five-dimensional Ising lattices have been reanalyzed and compared to recent theoretical predictions obtained by Chen and Dohm, in an attempt to clarify a somewhat controversial discussion. Our results can be summarized as follows:

(i) The CD theory reduces in the limit $t \to 0$, $L \to \infty$, $tL^{d/2}$ fixed, to the scaling structure proposed originally by Binder et al. [1] and explicitly illustrates the mechanism of multiplicative “renormalization” of variables by a dangerous irrelevant variable. In addition, it yields both the asymptotic scaling functions of various moments of the order parameter distribution as a function of the variable $tL^{d/2}$ and the leading corrections to it, which are of order $L^{(4-d)/2}$. However, the comparison with the Monte Carlo data indicates that strong subleading corrections (of order $1/L$ in $d = 5$) are present as well, which are not predicted by the CD theory, and one would need much larger $L$ than accessible here ($L_{\text{max}} = 22$) in order that these subleading corrections are visible. So a quantitative agreement between theory and simulation is still far out of reach!

(ii) The question must be asked to what extent the $\phi^4$ model on a lattice for $d > 4$ yields the same behavior as the Ising model. Of course, one can take the parameters $r_0 \to -\infty$, $\nu_0 \to \infty$ in Eq. (17) in such a proportion that the model precisely reduces to the Ising model (for a discussion see, e.g., Ref. [47]). At this point, we have not attempted to deal with this problem.

(iii) The CD theory yields a nice illustrative example how one can be misled by apparent cumulant intersections which converge to the exact result extremely slowly as $L \to \infty$. It is rather likely that this is the reason for the difficulties noted in the Monte Carlo studies in Refs. [1–3]. Both the CD theory and the simulations give clear
evidence that for a full understanding of the problem a variation of parameters over a broad range is desirable, including the behavior both above and below \( T_c \), as well as at \( T_c \). Corrections to the leading scaling behavior need careful consideration, which was already one of the central messages of Refs. [27,6,8].
