Abstract
Given labeled instances on a source domain and unlabeled ones on a target domain, unsupervised domain adaptation aims to learn a task classifier that can well classify target instances. Recent advances rely on domain-adversarial training of deep networks to learn domain-invariant features. However, due to an issue of mode collapse induced by the separate design of task and domain classifiers, these methods are limited in aligning the joint distributions of feature and category across domains. To overcome it, we propose a novel adversarial learning method termed Discriminative Adversarial Domain Adaptation (DADA). Based on an integrated category and domain classifier, DADA has a novel adversarial objective that encourages a mutually inhibitory relation between category and domain predictions for any input instance. We show that under practical conditions, it defines a minimax game that can promote the joint distribution alignment. Except for the traditional closed set domain adaptation, we also extend DADA for extremely challenging problem settings of partial and open set domain adaptation. Experiments show the efficacy of our proposed methods and we achieve the new state of the art for all the three settings on benchmark datasets.

Introduction
Many machine learning tasks are advanced by large-scale learning of deep models, with image classification (Russakovsky et al. 2015) as one of the prominent examples. A key factor to achieve such advancements is the availability of massive labeled data on the domains of the tasks of interest. For many other tasks, however, training instances on the corresponding domains are either difficult to collect, or their labeling costs prohibitively. To address the scarcity of labeled data for these target tasks/domains, a general strategy is to leverage the massively available labeled data on related source ones via domain adaptation (Pan and Yang 2010). Even though the source and target tasks share the same label space (i.e. closed set domain adaptation), domain adaptation still suffers from the shift in data distributions. The main objective of domain adaptation is thus to learn domain-invariant features, so that task classifiers learned from the source data can be readily applied to the target domain. In this work, we focus on the unsupervised setting where training instances on the target domain are completely unlabeled.

Recent domain adaptation methods are largely built on modern deep architectures. They rely on great model capacities of these networks to learn hierarchical features that are empirically shown to be more transferable across domains (Yosinski et al. 2014; Zhang, Tang, and Jia 2018). Among them, those based on domain-adversarial training (Ganin et al. 2016; Wang et al. 2019) achieve the current state of the art. Based on the seminal work of DANN (Ganin et al. 2016), they typically augment a classification network with an additional domain classifier. The domain classifier takes features from the feature extractor of the classification network as inputs, which is trained to differentiate between instances from the two domains. By playing a minimax game (Goodfellow et al. 2014), adversarial training aims to learn domain-invariant features.

Such domain-adversarial networks can largely reduce the domain discrepancy. However, the separate design of task and domain classifiers has the following shortcomings. Firstly, feature distributions can only be aligned to a certain level, since model capacity of the feature extractor could be large enough to compensate for the less aligned feature distributions. More importantly, given practical difficulties of aligning the source and target distributions with high granularity to the category level (especially for complex distributions with multi-mode structures), the task classifier obtained by minimizing the empirical source risk cannot well generalize to the target data due to an issue of mode collapse (Kurmi and Namboodiri 2019; Tran et al. 2019), i.e., the joint distributions of feature and category are not well aligned across the source and target domains.

Recent methods (Kurmi and Namboodiri 2019; Tran et al. 2019) take the first step to address the above shortcomings by jointly parameterizing the task and domain classifiers into an integrated one. To further push this line, based on such a classifier, we propose a novel adversarial learning method termed Discriminative Adversarial Domain Adaptation (DADA), which encourages a mutually inhibitory relation between its domain prediction and category prediction for any input instance, as illustrated in Figure 1. This dis-
Closed Set Domain Adaptation

After the seminal work of DANN (Ganin et al. 2016), ADDA (Tzeng et al. 2017) proposes an untied weight sharing strategy to align the target feature distribution to a fixed source one. SimNet (Pinheiro 2018) replaces the standard FC-based cross-entropy classifier by a similarity-based one. MADA (Pei et al. 2018) and CDAN (Long et al. 2018b) integrate the discriminative category information into domain-adversarial training. VADA (Shu et al. 2018) reduces the cluster assumption violation to constrain domain-adversarial training. Some methods (Wang et al. 2019; Wen et al. 2019) focus on transferable regions to learn domain-invariant features and task classifier. TAT (Liu et al. 2019) enhances the discriminability of features to guarantee the adaptability. Some methods (Saito et al. 2018b; 2018a; Lee et al. 2019) utilize category predictions from two task classifiers to measure the domain discrepancy. The most related works (Kurmi and Namboodiri 2019; Tran et al. 2019) to us propose joint parameterization of the task and domain classifiers, which implicitly align the joint distributions. Differently, our proposed DADA makes the joint distribution alignment more explicit, thus promoting classification on the target domain.

Partial Domain Adaptation

The work (Zhang et al. 2018a) weights each source instance by its importance to the target domain based on one domain classifier, and then trains another domain classifier on target and weighted source instances. The works (Cao et al. 2018a; 2018b) reduce the contribution of outlier source instances to the task or domain classifiers by utilizing category predictions. Differently, DADA-P weights the proposed source discriminative adversarial loss by a reliable category confidence.

Open Set Domain Adaptation

Previous research (Jain, Scheirer, and Boult 2014) proposes to reject an instance as the unknown category by threshold filtering. The work (Saito et al. 2018c) proposes to utilize adversarial training for both domain adaptation and unknown outlier detection. Differently, DADA-O balances the joint distribution alignment in the shared label space with the outlier rejection.

Method

Related Works
Denote $p(x) \in [0, 1]^{K+1}$ as the output vector of class probabilities of $F(G(x))$ for an instance $x$, and $p_k(x), k \in \{1, \ldots, K+1\}$, as its $k^{th}$ element. The $k^{th}$ element of the conditional probability vector $\hat{p}(x)$ is written as follows:

$$\hat{p}_k(x) = \begin{cases} p_k(x) \left/ \left(1 - p_{K+1}(x) \right) \right., & k = 1, 2, \ldots, K, \\ 0, & k = K+1 \end{cases}.$$

For ease of subsequent notations, we also write $p^*_s = p_k(x^s)$ and $p^*_t = p_k(x^t)$. Then, such a network is trained by the classification-aware adversarial learning objective:

$$\min_F \frac{1}{n_s} \sum_{i=1}^{n_s} \log p_{y^i_s}(x^s_i) - \frac{1}{n_t} \sum_{j=1}^{n_t} \log p_{K+1}(x^t_j),$$

$$\max_G \frac{1}{n_s} \sum_{i=1}^{n_s} \log \hat{p}_{y^i_s}(x^s_i) + \frac{1}{n_t} \sum_{j=1}^{n_t} \log (1 - p_{K+1}(x^t_j)),$$

where $\lambda$ balances category classification and domain adversarial losses. The mechanism of this objective to align the joint distributions across domains is rather implicit.

To make it more explicit, based on the integrated classifier $F(\cdot)$, we propose a novel adversarial learning method termed Discriminative Adversarial Domain Adaptation (DADA), which explicitly enables a discriminative interplay of predictions among the domain and $K$ categories for any input instance, as illustrated in Figure 1. This discriminative interaction underlies the ability of DADA to promote the joint distribution alignment, as explained shortly.

**Discriminative Adversarial Learning**

To establish a direct interaction between category and domain predictions, we propose a novel source discriminative adversarial loss that is tailored to the design of the integrated classifier $F(\cdot)$. The proposed loss is inspired by the principle of binary cross-entropy loss. It is written as:

$$\mathcal{L}^* (G, F) = \frac{1}{n_s} \sum_{i=1}^{n_s} [ (1 - p_{K+1}(x^s_i)) \log p_{y^i_s}(x^s_i) + p_{K+1}(x^s_i) \log (1 - p_{y^i_s}(x^s_i))].$$

Intuitively, the proposed loss (3) establishes a mutually inhibitory relation between $p_{y^i_s}(x^s_i)$ of the prediction on the true category of $x^s_i$, and $p_{K+1}(x^s_i)$ of the prediction on the domain of $x^s_i$. We first discuss how the proposed loss (3) works during adversarial training, and we show that under practical conditions, minimizing (3) over the classifier $F(\cdot)$ has the effects of discriminating among task categories while distinguishing the source domain from the target one, and maximizing (3) over the feature extractor $G(\cdot)$ can discriminatively align the source domain to the target one.

**Discussion** We first write the gradient formulas of $\mathcal{L}^*$ on any source instance $x^s$ w.r.t. $p^*_s$ and $p^*_t$ as:

$$\nabla p^*_s = \frac{\partial \mathcal{L}^*}{\partial p_{y^i_s}} = p^*_s - p_{K+1} - (1 - p^*_s)(1 - p_{K+1}),$$

$$\nabla p^*_t = \frac{\partial \mathcal{L}^*}{\partial p_{K+1}} = \log \frac{p^*_t}{1 - p^*_t}.$$

Since both $p^*_s$ and $p^*_t$ are among the $K + 1$ output probabilities of the classifier $F(G(x^s))$, we always have $p^*_s \leq 1 - p^*_{K+1}$ and $p^*_t \leq 1 - p^*_s$, suggesting $\nabla p^*_s \leq 0$. When the loss (3) is minimized over $F(\cdot)$ via stochastic gradient descent (SGD), we have the update $p^*_s \leftarrow p^*_s - \eta \nabla p^*_s$, where $\eta$ is the learning rate, and since $\nabla p^*_s \leq 0$, $p^*_s$ increases; when it is maximized over $G(\cdot)$ via stochastic gradient ascent (SGA), we have the update $p^*_s \leftarrow p^*_s + \eta \nabla p^*_s$, and since $\nabla p^*_s \leq 0$, $p^*_s$ decreases. Then, we discuss the change of $p^*_K$ in two cases: (1) in case of $p^*_s > 0.5$ that guarantees $\nabla p^*_K > 0$, when minimizing the loss (3) over $F(\cdot)$ by SGD update $p^*_K \leftarrow p^*_K - \eta \nabla p^*_K$, we have decreased $p^*_K$; and when maximizing it over $G(\cdot)$ by SGA update $p^*_K \leftarrow p^*_K + \eta \nabla p^*_K$, we have increased $p^*_K$; (2) in case of $p^*_s < 0.5$ that guarantees $\nabla p^*_K < 0$, when minimizing the loss (3) over $F(\cdot)$ by SGD update, we have increased $p^*_K$, and when maximizing it over $G(\cdot)$ by SGA update, we have decreased $p^*_K$, as shown in Figure 2.

For discriminative adversarial domain adaptation, we expect that (1) when minimizing the proposed loss (3) over $F(\cdot)$, task categories of the source domain is discriminative and the source domain is distinctive from the target one, which can be achieved when $p^*_s$ increases and $p^*_K$ decreases; (2) when maximizing it over $G(\cdot)$, the source domain is aligned to the target one while retains discriminability, which can be achieved when $p^*_s$ decreases and $p^*_K$ increases.
increases in the case of $p_{ys}^s > 0.5$. To meet the expectations, the condition of $p_{ys}^s > 0.5$ for all source instances should be always satisfied. This is practically achieved by pre-training DADA on the labeled source data using a $K$-way cross-entropy loss, and maintaining in the adversarial training of DADA the same supervision signal. We present in the supplemental material empirical evidence on benchmark datasets that shows the efficacy of our used scheme.

To achieve the joint distribution alignment, the explicit interplay between category and domain predictions for any target instance should also be created. Motivated by recent works (Pei et al. 2018; Long et al. 2018b) which alleviate the issue of mode collapse by aligning each instance to several most related categories, we propose a target discriminative adversarial loss based on the design of the integrated classifier $F(\cdot)$, by using the conditional category probabilities to weight the domain predictions. It is written as

$$
\mathcal{L}_F(G,F) = -\frac{1}{n_t} \sum_{j=1}^{n_t} \sum_{k=1}^{K} \hat{p}_k(x'_j) \log \hat{p}_{k+1}(x'_j)
$$

(4)

$$
\mathcal{L}_G(G,F) = \frac{1}{n_t} \sum_{j=1}^{n_t} \sum_{k=1}^{K} \hat{p}_k(x'_j) \log (1 - \hat{p}_{k+1}(x'_j)),
$$

where the $k^{th}$ element of the domain prediction vector $\hat{p}^k$ for the $k^{th}$ category is written as follows

$$
\hat{p}_{k}(x'_j) = \begin{cases} 
\frac{p_k(x'_j)}{p_k(x'_j) + p_{k+1}(x'_j)}, & k = k', k + 1 \\
0, & \text{otherwise}
\end{cases}
$$

(5)

An intuitive explanation for our proposed (4) is provided in the supplemental material.

Established knowledge from cluster analysis (Nalewajski 2012) indicates that we can estimate clusters with a low probability of error only if the conditional entropy is small. To this end, we adopt the entropy minimization principle (Grandvalet and Bengio 2005), which is written as

$$
\mathcal{L}_{em}(G,F) = \frac{1}{n_t} \sum_{j=1}^{n_t} \mathcal{H}(\hat{p}(x'_j)),
$$

(6)

where $\mathcal{H}(\cdot)$ computes the entropy of a probability vector. Combining (3), (4), and (6) gives the following minimax problem of our proposed DADA

$$
\begin{align*}
\min_{F} \mathcal{L}_F &= \lambda(\mathcal{L}^s + \mathcal{L}^t_F) - \mathcal{L}_{em} \\
\max_{G} \mathcal{L}_G &= \lambda(\mathcal{L}^s + \mathcal{L}^t_G) - \mathcal{L}_{em},
\end{align*}
$$

(7)

where $\lambda$ is a hyper-parameter that trade-offs the adversarial domain adaptation objective with the entropy minimization one in the unified optimization problem. Note that in the minimization problem of (7), $\mathcal{L}_{em}$ serves as a regularizer for learning $F(\cdot)$ to avoid the trivial solution (i.e. all instances are assigned to the same category), and in the maximization problem of (7), it helps learn more target-discriminative features, which can alleviate the negative effect of adversarial feature adaptation on the adaptability (Liu et al. 2019).

By optimizing (7), the joint distribution alignment can be enhanced. This ability comes from the better use of discriminative information from both the source and target domains. Concretely, DADA constrains the domain classifier so that it clearly/explicitly knows the classification boundary, thus reducing false alignment between different categories. By deceiving such a strong domain classifier, DADA can learn a feature extractor that better aligns the two domains. We also theoretically prove in the supplemental material that DADA can better bound the expected target error.

**Extension for Partial Domain Adaptation**

Partial domain adaptation is a more realistic setting, where the target label space is subsumed by the source one. The false alignment between the outlier source categories and the target domain is unavoidable. To address it, existing methods (Cao et al. 2018a; Zhang et al. 2018a; Cao et al. 2018b) utilize the category or domain predictions, to decrease the contribution of source outliers to the training of task or domain classifiers. Inspired by these ideas, we extend DADA for partial domain adaptation by using a reliable category-level weighting mechanism, which is termed DADA-P.

Concretely, we average the conditional probability vectors $\hat{p}(x'_j) \in [0,1]^K$ over all target data and then normalize the averaged vector $\bar{c} \in [0,1]^K$ by dividing its largest element. The category weight vector $c \in [0,1]^K$ with $c_k$ as its $k^{th}$ element is derived by a convex combination of the normalized vector and an all-ones vector $\mathbf{1}$, as follows

$$
c = \frac{\bar{c}}{\max(\bar{c})} + (1 - \lambda)\mathbf{1},
$$

(8)

where $\lambda \in [0,1]$ is to suppress the detection noise of outlier source categories in the early stage of training. Then, we apply the category weight vector $c$ to the proposed discriminative adversarial loss for any source instance, leading to

$$
\mathcal{L}^s(G,F) = -\frac{1}{n_s} \sum_{i=1}^{n_s} c_k \left[ (1 - p_{k+1}(x'_i)) \log p_{k}(x'_i) + p_{k+1}(x'_i) \log (1 - p_{k}(x'_i)) \right].
$$

(9)

Since predicted probabilities on the outlier source categories are more likely to increase when minimizing $-\mathcal{L}_{em}^t$ over $F(\cdot)$, which incurs negative transfer. To avoid it, we minimize $\mathcal{L}_{em}^t$ over $F(\cdot)$ and the objective of DADA-P is

$$
\begin{align*}
\min_{F} \mathcal{L}_F &= \lambda(\mathcal{L}^s + \mathcal{L}^t_F) + \mathcal{L}_{em}^t \\
\max_{G} \mathcal{L}_G &= \lambda(\mathcal{L}^s + \mathcal{L}^t_G) - \mathcal{L}_{em}^t.
\end{align*}
$$

(10)
By optimizing it, DADA-P can simultaneously alleviate negative transfer and promote the joint distribution alignment across domains in the shared label space.

Extension for Open Set Domain Adaptation

Open set domain adaptation is a very challenging setting, where the source label space is subsumed by the target one. We denominate the shared category and all unshared categories between the two domains as the “known category” and “unknown category” respectively. The goal of open set domain adaptation is to correctly classify any target instance as the known or unknown category. The false alignment between the known and unknown categories is inevitable. To this end, the work (Saito et al. 2018c) proposes to make a pseudo decision boundary for the unknown category, which enables the feature extractor to reject some target instances as outliers. Inspired by this work, we extend DADA for open set domain adaptation by training the classifier to classify all target instances as the unknown category with a small probability $q$, which is termed DADA-O. Assuming the predicted probability on the unknown category as the $K^{th}$ element of $p(x')$, i.e., $p_K(x')$, the modified target adversarial loss when minimized over the integrated classifier $F(\cdot)$ is

$$L_K^p(G,F) = - \frac{1}{n_t} \sum_{j=1}^{n_t} q \log p_K(x'_j) - (1-q) \log p_{K+1}(x'_j), \quad (11)$$

where $0 < q < 0.5$. When maximized over the feature extractor $G(\cdot)$, we still use the discriminative loss $L_C^d$ in (4). Replacing $L_K^p$ in (7) with (11) gives the overall adversarial objective of DADA-O, which can achieve a balance between domain adaptation and outlier rejection.

We utilize all target instances to obtain the concept of “unknown”, which is very helpful for the classification of unknown target instances as the unknown category but can cause the misclassification of known target instances as the unknown category. This issue can be alleviated by selecting an appropriate $q$. If $q$ is too small, the unknown target instances cannot be correctly classified; if $q$ is too large, the known target instances can be misclassified. By choosing an appropriate $q$, the feature extractor can separate the unknown target instances from the known ones while aligning the joint distributions in the shared label space.

Experiments

Datasets and Implementation Details

Office-31 (Saenko et al. 2010) is a popular benchmark domain adaptation dataset consisting of 4,110 images of 31 categories collected from three domains: Amazon (A), Webcam (W), and DSLR (D). We evaluate on six settings.

Syn2Real (Peng et al. 2018) is the largest benchmark. Syn2Real-C has over 280K images of 12 shared categories in the combined training, validation, and testing domains. The 152,397 images on the training domain are synthetic ones by rendering 3D models. The validation and test domains comprise real images, and the validation one has 55,388 images. We use the training domain as the source domain and validation one as the target domain. For partial domain adaptation, we choose images of the first 6 categories (in alphabetical order) in the validation domain as the target domain and form the setting: Synthetic 12 → Real 6. For open set domain adaptation, we evaluate on Syn2Real-O, which includes two domains. The training/synthetic domain uses synthetic images from the 12 categories of Syn2Real-C as “known”. The validation/real domain uses images of the 12 categories from the validation domain of Syn2Real-C as “known”, and 50k images from 69 other categories as “unknown”. We use the training and validation domains of Syn2Real-O as the source and target domains respectively.

Implementation Details

We follow standard evaluation protocols for unsupervised domain adaptation (Ganin et al. 2016; Wang et al. 2019): we use all labeled source and all unlabeled target instances as the training data. For all tasks of Office-31 and Synthetic 12 → Real 6, based on ResNet-50 (He et al. 2016), we report the classification result on the target domain of mean(±standard deviation) over three random trials. For other tasks of Syn2Real, we evaluate the accuracy of each category based on ResNet-101 and ResNet-152 (for closed and open set domain adaptation respectively). For each base network, we use all its layers up to the second last one as the feature extractor $G(\cdot)$, and set the neuron number of its last FC layer as $K + 1$ to have the integrated classifier $F(\cdot)$. Exceptionally, we follow the work (Ganin et al. 2016). We first fine-tune the trained source model on both the labeled source data and then fine-tune them on the labeled source data and unlabeled target data via adversarial training, where we maintain the same supervision signal as the pre-training.

We follow DANN (Ganin et al. 2016) to use the SGD training schedule: the learning rate is adjusted by $\eta = \frac{\eta_0}{(1+\alpha p)^{\beta}}$, where $p$ denotes the process of training iterations that is normalized to be in $[0, 1]$, and we set $\eta_0 = 0.0001, \alpha = 10$, and $\beta = 0.75$; the hyper-parameter $\beta$ is initialized at 0 and is gradually increased to 1 by $\lambda_p = \left(1 + \frac{p}{1+\exp(-\gamma p)}\right)^{-1}$, where we set $\gamma = 10$. We empirically set $q = 0.1$. We implement all our methods by PyTorch. The code will be available at https://github.com/huitangtang/DADA-AAAI2020.

Analysis

Ablation Study

We conduct ablation studies on Office-31 to investigate the effects of key components of our proposed DADA based on ResNet-50. Our ablation studies start with the very baseline termed “No Adaptation” that simply fine-tunes a ResNet-50 on the source data. To validate the mutually inhibitory relation enabled by DADA, we use DANN (Ganin et al. 2016) and DANN-CA (Tran et al. 2019) respectively as the second and third baselines. To investigate how the entropy minimization principle helps learn more target-discriminative features, we remove the entropy minimization loss (6) from our main minimax problem (7), denoted as “DADA (w/o em)”. To know effects of the proposed source and target discriminative adversarial losses (3) and (4), we

Results

Closed Set Domain Adaptation We compare in Tables 2 and 3 our proposed method with existing ones on Office-31 and Syn2Real-C based on ResNet-50 and ResNet-101 respectively. Whenever available, results of existing methods are quoted from their respective papers or the recent works (Pei et al. 2018; Long et al. 2018b; Liu et al. 2019; Saito et al. 2018b). Our proposed DADA outperforms existing methods, testifying the efficacy of DADA in aligning the joint distributions of feature and category across domains. Partial Domain Adaptation We compare in Table 5 our proposed method to existing ones on Syn2Real-C based on
discriminative interaction between category and domain predictions. Except for closed set domain adaptation, we also extend DADA for more challenging problem settings of partial and open set domain adaptation. Experiments on benchmark datasets testify the efficacy of our proposed methods for all the three settings.

We provide an intuitive explanation for our proposed loss (4) in Section A. We theoretically prove that our proposed method can better bound the expected target error than existing ones in Section B. We provide more results and analysis on benchmark datasets of Digits, Office-31, Office-Home, and ImageNet-Caltech for closed set, partial, and open set domain adaptation in Section C. We present empirical evidence on benchmark datasets of digits that shows the efficacy of our used training scheme in Section D. We will release the code soon.

A Intuitive Explanation for Our Proposed Loss (4)

We denote the output vector of class scores of $F(G(x))$ before the final soft-max operation for an instance $x$ as $o(x) \in \mathbb{R}^{K+1}$ and its $k^{th}$ element as $o_k(x)$, $k \in \{1, \ldots, K+1\}$. We denote the output vector of class probabilities of $F(G(x))$ after the final soft-max operation for an instance $x$ as $p(x) \in [0,1]^{K+1}$, and its $k^{th}$ element as $p_k(x)$, $k \in \{1, \ldots, K+1\}$. We write $p_k(x)$, $k \in \{1, \ldots, K+1\}$ as

$$p_k(x) = \frac{\exp(o_k(x))}{\sum_{k'=1}^{K+1} \exp(o_{k'}(x))}.$$  

We always have $\sum_{k=1}^{K+1} p_k(x) = 1$ for any instance $x$. When maximized over the feature extractor $G(\cdot)$, the adversarial loss on an unlabeled target instance $x'$ (cf. objective (2) in Section Discriminative Adversarial Domain Adaptation) in the paper is written as

$$l'(G,F) = \log(1 - p_{K+1}(x'))$$

$$= \log \left( \sum_{k=1}^{K} p_k(x') \right)$$

$$= \log \left( \sum_{k=1}^{K} \frac{\exp(o_k(x'))}{\sum_{k'=1}^{K+1} \exp(o_{k'}(x'))} \right).$$

We write the gradient formulas of $l'$ w.r.t. $o_k(x)$, $k \in \{1, \ldots, K\}$ as

$$\nabla o_k(x') = \frac{\partial l'}{\partial o_k(x')}$$

$$= \frac{\sum_{k'=1}^{K+1} \exp(o_{k'}(x')) - \exp(o_k(x')) \cdot \exp(o_{K+1}(x'))}{\left( \sum_{k'=1}^{K+1} \exp(o_{k'}(x')) \right)^2}.$$  

where $\nabla o_k(x')$, $k \in \{1, \ldots, K\}$ differ in the term of $\exp(o_k(x'))$, meaning that they are proportional to the class scores of $o_k(x')$. In other words, the higher the class score is (i.e., the higher the class probability is), the stronger the gradient the corresponding category neuron back-propagates, suggesting that the target instance is aligned to several most confident/related categories on the source domain. Such a mechanism to align the joint distributions of feature and category across domains is rather implicit. To make it more explicit, our proposed target discriminative adversarial loss (cf. loss (4) in Section Discriminative Adversarial Learning in the paper) uses the conditional probabilities to weight the category-wise domain predictions. By such a design, the discriminative adversarial training on the target data explicitly conducts the competition between the domain neuron (output) and the most confident category neuron (output) as the discriminative adversarial training on the source data does, thus promoting the category-level domain alignment. This is what we mean by the mutually inhibitory relation between the category and domain predictions for any input instance.

This intuitive explanation manifests that the adversarial training of DADA clearly and explicitly utilizes the discriminative information of the target domain, thus improving the alignment of joint distributions of feature and category across domains.

B Generalization Error Analysis for Our Proposed DADA

We prove that our proposed DADA can better bound the expected target error than existing domain adaptation methods (Ganin et al. 2016; Tzeng et al. 2017; Pei et al. 2018; Pinheiro 2018; Zhang et al. 2018b; Shu et al. 2018; Long et al. 2018b; Wang et al. 2019; Wen et al. 2019; Tran et al. 2019), taking the similar formalism of theoretical results of domain adaptation (Ben-David et al. 2007; 2010).

For all hypothesis spaces introduced below, we assume them of finite effective size, i.e., finite VC dimension, so that the following distance measures defined over these spaces can be estimated from finite instances (Ben-David et al. 2010). We consider a fixed representation function $G(\cdot)$ from the instance set $X$ to the feature space $Z$, i.e., $z = G(x)$, and a hypothesis space $H$ for the $K$-category task classifier $C(\cdot)$ from the feature space $Z$ to the label space $Y$, i.e., $C \in H$ (Ganin et al. 2016). Note that $y \in Y$ is the $K$-dimensional one-hot vector for any label $y$. Denote the marginal feature distribution and the joint distribution of feature and category by $P_Z$ and $P_{Z,Y}$ for the source domain $D_s$ and similarly $P_Z$ and $P_{Z,Y}$ for the target domain $D_t$, respectively. Let $\epsilon_s(C) = I_{(a,y) \sim P_{Z,Y}^s}[C(z) \neq y]$ be the expected source error of a hypothesis $C \in H$ w.r.t. the joint distribution $P_{Z,Y}^s$, where $I[a]$ is the indicator function which is $1$ if predicate $a$ is true, and $0$ otherwise. Similarly, $\epsilon_t(C) = I_{(a,y) \sim P_{Z,Y}^t}[C(z) \neq y]$ denotes the expected target error of $C$ w.r.t. the joint distribution $P_{Z,Y}^t$. Let $C^* = \arg\min_{C \in H} \{\epsilon_s(C) + \epsilon_t(C)\}$ be the ideal joint hypothesis that explicitly embodies the notion of adaptability (Ben-David et al. 2010). Let $\epsilon_s(C,C^*) = I_{(a,y) \sim P_{Z,Y}^s}[C(z) \neq C^*(z)]$ and $\epsilon_t(C,C^*) = I_{(a,y) \sim P_{Z,Y}^t}[C(z) \neq C^*(z)]$ be the disagreement between hypotheses $C$ and $C^*$ w.r.t. the joint distributions $P_{Z,Y}^s$ and $P_{Z,Y}^t$, respectively. Specified by the two works (Ben-David et al. 2007; 2010), the probabilistic bound of the expected target error $\epsilon_t(C)$ of the hypothesis $C$ is given by the sum of the expected source error $\epsilon_s(C)$, the combined error $[\epsilon_s(C^*) + \epsilon_t(C^*)]$ of the ideal joint hypothesis $C^*$, and the distribution discrepancy across data domains, as the follow

$$\epsilon_t(C) \leq \epsilon_s(C) + [\epsilon_s(C^*) + \epsilon_t(C^*)] + |\epsilon_s(C,C^*) - \epsilon_t(C,C^*)|.$$  

For domain adaptation to be possible, a natural assumption is that there exists the ideal joint hypothesis $C^* \in H$ so that the combined error $[\epsilon_s(C^*) + \epsilon_t(C^*)]$ is small. The ideal joint hypothesis $C^*$ may not be unique, since in practice we always have the same error obtained by two different machine learning models. Denote a set of ideal joint hypotheses by $H^*$, which is a subset of $H$, i.e., $H^* \subset H$. Based on this assumption, domain adaptation aims to reduce the domain discrepancy $|\epsilon_s(C,C^*) - \epsilon_t(C,C^*)|$. Let $c = C(z)$ be the proxy of the label vector $y$ of $z$, for every pair of $(z,y) \sim P_{Z,Y}^s \cup P_{Z,Y}^t$. Denote the thus obtained proxies of the joint distributions $P_{Z,Y}^s$ and $P_{Z,Y}^t$ by $P_{Z,C}^s = (z, C(z))_{a \sim P_{Z,Y}^s}$ and $P_{Z,C}^t = (z, C(z))_{a \sim P_{Z,Y}^t}$, respectively (Courty et al. 2017). Then, by definition, $\epsilon_s(C,C^*) = \epsilon_s(C,C^*) \leq \epsilon_s(C) + [\epsilon_s(C^*) + \epsilon_t(C^*)] + |\epsilon_s(C,C^*) - \epsilon_t(C,C^*)|.$
proxies, we have the domain discrepancy

\[ |e_s(C, C^*) - e_t(C, C^*)| = |E_{(x, y) \sim P_{x,y}^Z} I(C(z) \neq C^*(z))| \]
and similarly \( e_t(C, C^*) = E_{(x, y) \sim P_{x,y}^Z} I(C(z) \neq C^*(z)) = E_{(x, z) \sim P_{x-z}^C} I[c \neq C^*(z)] \). Based on the two joint distribution proxies, we have the domain discrepancy

\[ |e_s(C, C^*) - e_t(C, C^*)| = |E_{(x, z) \sim P_{x-z}^C} I[c \neq C^*(z)]| \]

**Definition 2.** Let \( F_{H^*} = \{ F(C^*(z), c) = I[c \neq C^*(z)] | C^* \in H^* \} \) be a (loss) difference hypothesis space over the joint variable \( (C^*(z), c) \), where \( F : (C^*(z), c) \rightarrow [0, 1] \) computes the empirical 0-1 classification loss of the task classifier \( C^* \in H^* \) for any input pair of \( (z, c) \sim P_{z, c}^Z \cup P_{z, c}^C \). Then, the \( F \)-distance between two distributions \( P_{z, c}^Z \) and \( P_{z, c}^C \), is defined as

\[ d_{F_{H^*}}(P_{z, c}^Z, P_{z, c}^C) \triangleq \sup_{F \in F_{H^*}} |E_{(z, c) \sim P_{z, c}^Z} F(C^*(z), c) - E_{(z, c) \sim P_{z, c}^C} F(C^*(z), c)| \]

**Theorem 1.** The distribution discrepancy between the source and target domains \( |e_s(C, C^*) - e_t(C, C^*)| \) can be upper bounded by the \( F_{H^*} \)-distance, the \( F_{H^*} \)-distance, the \( F \)-distance, and the \( D \)-distance as follows

\[ |e_s(C, C^*) - e_t(C, C^*)| \leq d_{F_{H*}}(P_{z, c}^Z, P_{z, c}^C) \]
\[ |e_s(C, C^*) - e_t(C, C^*)| \leq d_{F_{H*}}(P_{z, c}^C, P_{z, c}^C) \]
\[ |e_s(C, C^*) - e_t(C, C^*)| \leq d_{F}(P_{z, c}^Z, P_{z, c}^C) \]
\[ |e_s(C, C^*) - e_t(C, C^*)| \leq d_{D}(P_{z, c}^Z, P_{z, c}^C) \]

**Proof.** Comparing (2.2) and (3.3), since \( |E_{(z, c) \sim P_{z, c}^Z} I[c \neq C^*(z)]| \)

Inspired by the two works (Long et al. 2018b; Mansour, Mohri, and Rostamizadeh 2009), we next introduce four definitions of the distance measure that can upper bound the domain discrepancy.

**Definition 1.** Let \( F_{H^*} = \{ F(C^*(z), c) = I[c \neq C^*(z)] | C^* \in H^* \} \) be a (loss) difference hypothesis space over the joint variable \( (C^*(z), c) \), where \( F : (C^*(z), c) \rightarrow [0, 1] \) computes the empirical 0-1 classification loss of the task classifier \( C^* \in H^* \) for any input pair of \( (z, c) \sim P_{z, c}^Z \cup P_{z, c}^C \). Then, the \( F \)-distance between two distributions \( P_{z, c}^Z \) and \( P_{z, c}^C \), is defined as

\[ d_{F_{H^*}}(P_{z, c}^Z, P_{z, c}^C) \triangleq \sup_{F \in F_{H^*}} |E_{(z, c) \sim P_{z, c}^Z} F(C^*(z), c) - E_{(z, c) \sim P_{z, c}^C} F(C^*(z), c)| \]

**Definition 2.** Let \( F \) be a (loss) difference hypothesis space, which contains a class of functions \( F : (z, c) \rightarrow [0, 1] \) over the joint variable \( (z, c) \sim P_{z, c}^Z \cup P_{z, c}^C \). Then, the \( F \)-distance between two distributions \( P_{z, c}^Z \) and \( P_{z, c}^C \), is defined as

\[ d_F(P_{z, c}^Z, P_{z, c}^C) \triangleq \sup_{F \in F} |E_{(z, c) \sim P_{z, c}^Z} F(z, c) - E_{(z, c) \sim P_{z, c}^C} F(z, c)| \]

**Definition 3.** Let \( F_{H} = \{ F : (C^*(z), c) \rightarrow [0, 1] | C^* \in H \} \) be a (loss) difference hypothesis space over the joint variable \( (C^*(z), c) \), where \( F : (C^*(z), c) \rightarrow [0, 1] \) computes the empirical 0-1 classification loss of the task classifier \( C^* \in H \) for any input pair of \( (z, c) \sim P_{z, c}^Z \cup P_{z, c}^C \). Then, the \( F \)-distance between two distributions \( P_{z, c}^Z \) and \( P_{z, c}^C \), is defined as

\[ d_{F_{H}}(P_{z, c}^Z, P_{z, c}^C) \triangleq \sup_{F \in F_{H}, C^* \in H} |E_{(z, c) \sim P_{z, c}^Z} F(C^*(z), c) - E_{(z, c) \sim P_{z, c}^C} F(C^*(z), c)| \]

**Definition 4.** Let \( D \) be a (loss) difference hypothesis space, which contains a class of functions \( D : z \rightarrow [0, 1] \) over \( z \sim P_{z}^Z \cup P_{z}^C \). Then, the \( D \)-distance between two distributions \( P_{z, c}^Z \) and \( P_{z, c}^C \), is defined as

\[ d_D(P_{z, c}^Z, P_{z, c}^C) \triangleq \sup_{D \in D} |E_{z \sim P_{z}^Z} D(z) - E_{z \sim P_{z}^C} D(z)| \]

We are now ready to give an upper bound on the domain discrepancy in terms of the distance measures we have defined.
Wen et al. 2019) are based on one or several conditional domain classifiers that take as input both the feature representation and the category prediction, they aim to measure and minimize the $\mathcal{F}$-distance. Since the recent work (Tran et al. 2019) and the proposed DADA unify the task and domain classifiers into an integrated one, i.e., conditioning the domain classifier on the task classifier, they aim to measure and minimize the $\mathcal{F}_H$-distance. The $\mathcal{F}_H$-distance can be upper bounded by the optimal solution of the integrated domain and task classifier $\hat{F}(\cdot)$. In the meanwhile, the upper bound of $\mathcal{F}_H$-distance is minimized by learning a domain-invariant feature extractor $G(\cdot)$.

Furthermore, our proposed DADA can be intuitively formalized as category-regularized domain-adversarial training, since our proposed discriminative adversarial training can learn an integrated classifier $F(\cdot)$ that has explicit intra-domain discrimination and inter-domain indistinguishability, which may enable a better performed ideal joint hypothesis $C^*$. Consequently, the expected target error $\epsilon_s(C)$ can be better approximated by the expected source error $\epsilon_s(C)$. As verified above, our proposed DADA can formally better bound the expected target error than existing domain adaptation methods.

C Additional Results and Analysis

C.1 Datasets

**Digits** datasets of MNIST (Lecun et al. 1998), Street View House Numbers (SVHN) (Netzer et al. 2011), and USPS (Hull 1994) are popular. we follow ADR (Saito et al. 2018a) and evaluate on three adaptation settings of SVHN$\rightarrow$MNIST, MNIST$\rightarrow$USPS, and USPS$\rightarrow$MNIST. For all adaptation settings, we adopt the same network architecture and experimental setting as ADR.

**Office-31** (Saenko et al. 2010) is a benchmark domain adaptation dataset as introduced in Section Datasets and Implementation Details in the paper. For partial domain adaptation, we select images of 10 categories shared by Office-31 and Caltech-256 (Griffin, Holub, and Perona 2007) in each domain of Office-31 as the target domain. Note that the source domain here contains 31 categories and the target domain here contains 10 categories. For open set domain adaptation, we use the selected 10 categories as the known categories. In alphabetical order, 11 $\rightarrow$ 20 categories and 21 $\rightarrow$ 31 categories are used as the unknown categories in the source and target domains respectively. In this setting, an 11-category classification is performed.

**Office-Home** (Venkateswara et al. 2017) is a much more challenging benchmark dataset for domain adaptation, which includes 15, 500 images of 65 object categories in office and home scenes, shared by four extremely distinct domains: Artistic images (Ar), Clip Art (Cl), Product images (Pr), and Real-World images (Rw). We build 12 adaptation settings: Ar $\rightarrow$ Cl, Ar $\rightarrow$ Pr, Ar $\rightarrow$ Rw, Cl $\rightarrow$ Ar, Cl $\rightarrow$ Pr, Cl $\rightarrow$ Rw, Pr $\rightarrow$ Ar, Pr $\rightarrow$ Cl, Pr $\rightarrow$ Rw, Rw $\rightarrow$ Ar, Rw $\rightarrow$ Cl, Rw $\rightarrow$ Pr. For partial domain adaptation, we choose images of the first 25 categories (in alphabetical order) in each domain of this dataset as target domains. Note that each source domain here contains 31 categories and each target domain here contains 25 categories.

**ImageNet-Caltech** is built from ImageNet (Russakovsky et al. 2015) that contains 1000 categories, and Caltech-256 (Griffin, Holub, and Perona 2007) that contains 256 categories. They share 84 common categories, thus we construct two adaptation settings: I (1000) $\rightarrow$ C (84), and C (256) $\rightarrow$ I (84). When ImageNet is used as the source domain, we use its training set; when it is used as the target domain, we use its validation set to prevent the model from the effect of pre-training on its training set.

Figure 4: An illustration for the effect of the $\lambda$ on the rate of source instances failing to satisfy the condition in the early stage (e.g., the first 100 iterations) of adversarial training on the two adaptation settings of (a) A$\rightarrow$D and (b) D$\rightarrow$A.

C.2 Closed Set Domain Adaptation.

**Effect of the $\lambda$** We provide the empirical evidence on Office-31 (Saenko et al. 2010) based on ResNet-50 (He et al. 2016) for the effect of the hyper-parameter $\lambda$ on keeping the source instances satisfying the condition of $p_{tr} > 0.5$ (cf. Section Discriminative Adversarial Learning in the paper for its derivation) in the early stage of adversarial training of DADA in Figure 4, which shows that the rate of source instances failing to satisfy the condition rises rapidly in the early stage of adversarial training when the $\lambda$ is not used.

**Alternative Choice of Adversarial Loss for Target Instances** For a target adversarial loss, when maximized over the feature extractor $G(\cdot)$, we have an alternative choice. In this section, we give further discussion and experiments to compare our used $\mathcal{L}_G^D$ in loss (4) in the paper with this alternative. Inspired by the works (Tzeng et al. 2015; Zhang et al. 2019), one may opt for a symmetric adversarial loss

\[
\mathcal{L}_G^D(G,F) = \frac{1}{n_t} \sum_{j=1}^{n_t} \sum_{k=1}^{K} \hat{p}_k(x_j^t) \left[ \frac{1}{2} \log p_{K+1}(x_j^t) + \frac{1}{2} \log (1 - p_{K+1}(x_j^t)) \right],
\]  

(C.1)
which when maximized over $G(\cdot)$, gives a confused prediction of $p_{K+1}(\mathbf{x}^t) = 0.5$. This result does not give category prediction $p_{y^t}(\mathbf{x}^t)$ on the unknown true category $y^t$ of a target instance $\mathbf{x}^t$ a chance to approach 1. Thus, this alternative choice is sub-optimal.

In contrast, our used $\mathcal{L}_G^\circ$ in loss (4) in the paper gives a prediction of $p_{K+1}(\mathbf{x}^t) = 0$ when maximized over $G(\cdot)$. This result gives $p_{y^t}(\mathbf{x}^t)$ a better chance to approach 1, i.e. $p_{y^t}(\mathbf{x}^t)$ is more likely to approach 1. In other words, the target data are more likely to be correctly classified, which is enabled by our proposed mutually inhibitory relation between the category and domain predictions.

To compare the effectiveness of our used $\mathcal{L}_G^\circ$ in loss (4) in the paper and this alternative choice, we conduct experiments on Office-31 (Saenko et al. 2010) based on ResNet-50 (He et al. 2016), by replacing $\mathcal{L}_G^\circ$ in loss (4) in the paper with the domain confusion loss (C.1) in our main minimax problem (7) in the paper. We denote these this alternative as “DADA-DC”. Results in Table 6 and convergence performances in Figure 5 show advantages of our used $\mathcal{L}_G^\circ$ in loss (4) in the paper.

### Feature Visualization

To visualize how different methods are effective at aligning learned features on the source and target domains, we use t-SNE embeddings (van der Maaten and Hinton 2008) to plot the output activations from the feature extractors of “No Adaptation”, DANN, DANN-CA, and DADA. Figure 6 gives the plotting, where samples are from the adaptation setting of $A \rightarrow W$ of Office-31 (Saenko et al. 2010) based on ResNet-50 (He et al. 2016). Figure 6 shows qualitative improvements of these meth-

C.3 Partial Domain Adaptation.

For each partial adaptation setting of Office-31, Office-Home, and ImageNet-Caltech, we follow the work (Cao et al. 2018b) to report the mean classification result on the target domain over three random trials.

Office-31

We compare in Table 8 our proposed method with existing ones on Office-31 based on ResNet-50 (He et al. 2016) pre-trained on ImageNet (Russakovsky et al. 2015). Results of existing methods are quoted from PADA (Cao et al. 2018b). Our proposed DADA-P outperforms all comparative methods by a large margin, showing the effectiveness of the adopted category-level weighting mechanism on reducing the negative influence of source outliers on adaptation settings with small source domain and small target domain, e.g., $A \rightarrow W$. Although PADA uses the same weighting mechanism, it performs much worse than our proposed DADA-P, suggesting the effectiveness of DADA-P on enhancing the positive influence of shared categories.

From the experimental results, several interesting observations can be derived. (1) Previous deep domain adaptation methods including those based on domain-adversarial training (e.g., DANN) and those based on MMD (e.g., DAN) perform much worse than the very baseline “No Adaptation”, showing the huge impact of negative transfer. Domain-adversarial training based methods aim to learn domain-invariant intermediate features to deceive the domain classifier, and MMD based methods aim to minimize the discrepancy between data distributions of the source and target domains. Both of them align the whole source domain to the whole target one. However, in partial domain adaptation, since the source domain contains categories that do not exist in the target domain, i.e., outlier source categories, they will suffer false alignment between the outlier source categories and the target domain. This explains their poor performance in partial domain adaptation. (2) Among previous deep domain adaptation methods, RTN is the only one that performs better than “No Adaptation”. RTN exploits the entropy minimization principle (Grandvalet and Bengio 2005) to encourage the low-density separation of target categories. Its target task classifier directly has access to the unlabeled target data and can amend itself to pass through the target low-density regions where the outlier source categories may exist, which alleviate the negative influence of source outliers. Nevertheless, PADA, which does not use the entropy minimization principle but a category-level weighting mechanism, performs much better than RTN, demonstrating that RTN still suffers negative transfer and may be not able to bridge such a large domain discrepancy caused by different label spaces. (3) Although our proposed DADA-P applies the same weighting mechanism as PADA, it performs much better than PADA. PADA has a separate design of task and domain classifiers and only aims to align marginal feature distributions, whereas our proposed DADA-P based on an integrated domain and task classifier, aims to promote the joint distribution alignment across domains. This explains the good performance of our proposed method in partial domain adaptation.

To investigate a wider spectrum of partial domain adaptation, we conduct experiments by varying the number of target categories. Figure 7 shows results for the baseline DANN (Ganin et al. 2016) and our proposed DADA-P on the partial adaptation setting $A \rightarrow W$ of Office-31 with a base network of ResNet-50. The source domain has always 31 categories, but the number of target categories varies from 30 to 10, i.e., $\{30, 28, 26, 24, 22, 20, 18, 16, 14, 12, 10\}$. As the number of target categories decreases, performances of the two methods have no evident decline in spite of the aggravation of negative transfer effect, since the difficulty of domain adaptation problem itself becomes smaller. We observe a sharp rise and a dramatic drop when the number of target categories decreases from 20 to 18 and from 14 to 12 respectively. One explanation is that the positive influence incurred by reducing the difficulty of domain adaptation problem itself is more (for the former observation) or less (for the latter one) than the negative influence caused by increasing the domain discrepancy. The results show that our proposed DADA-P performs much better than DANN in all settings. It is noteworthy...

Figure 7: The accuracy curve of varying the number of target categories for the baseline DANN (Ganin et al. 2016) and our proposed DADA-P on the partial adaptation setting A → W of Office-31 with a base network of ResNet-50.

Figure 8: The accuracy curve of varying the number of source categories for the baseline DANN (Ganin et al. 2016) and our proposed DADA-P on the partial adaptation setting A → W of Office-31 with a base network of AlexNet.

that the relative performance improvement becomes larger when the number of target categories decreases, testifying the superiority of our methods in reducing the influence of negative transfer. Thus, given a source domain, our methods can perform much better when applied to the target domain with unknown number of categories.

We compare in Table 9 our proposed method with existing ones on Office-31 based on AlexNet (Krizhevsky, Sutskever, and Hinton 2012) pre-trained on ImageNet. Results of existing methods are quoted from their respective papers or SAN (Cao et al. 2018a). Our proposed DADA-P achieves a much better result than all comparative methods, showing the efficacy of our methods with a shallower neuron network as the base network.

To investigate the influence of the number of outlier source categories on the performance, we conduct experiments by varying the number of source categories. Figure 8 shows results for the baseline DANN (Ganin et al. 2016) and our proposed DADA-P on the partial adaptation setting A → W of Office-31 with a base network of AlexNet. The target domain has always 10 categories, but the number of source categories varies from 12 to 31, i.e., {12, 14, 16, 18, 20, 22, 24, 26, 28, 30, 31}. As the number of source categories increases, performances of the two methods have evident decline but also some rises, e.g., when the number of source categories increases from 22 to 24 and from 28 to 30. One explanation is that the positive influence incurred by increasing dis-
We compare in Table 10 our proposed method Office-Home performance when utilizing different source tasks. Thus, for a given target task, our methods can have a much better relative performance improvement is larger when posed DADA-P significantly outperforms DANN in all settings. Particularly, the relative performance improvement is larger when increasing the domain discrepancy. The results show that our proposed DADA-P significantly outperforms all comparative methods by a large margin, showing the effectiveness of DADA-P and AODA can effectively reduce false alignment, since they have a good outlier rejection mechanism to recognize the unknown instances. (4) The results of all comparative methods on almost all adaptation settings are better in the evaluation metric OS than OS*, showing that many known target instances are classified as the unknown category. Since Open-set SVM is trained to detect outliers and the task classifier of AODA is trained to recognize all the target instances as the unknown category, they are inclined to classify the target instances as the unknown category. (5) For our proposed DADA-O, the results of all adaptation settings are better in the evaluation metric OS* than OS, since their classifiers are trained to classify all target instance as the unknown category with a small probability q, which can minimize the misclassification of the known target instances as the unknown category.

Table 11: Results for partial domain adaptation on ImageNet-Caltech based on ResNet-50.

| Methods                  | \(I \rightarrow C\) | \(C \rightarrow I\) | \(Avg\) |
|--------------------------|----------------------|----------------------|---------|
| No Adaptation (He et al. 2016) | 71.65                | 66.14                | 68.90   |
| DAN (Long et al. 2018a) | 71.57                | 66.48                | 69.03   |
| DANN (Ganin et al. 2016) | 68.67                | 52.97                | 60.82   |
| RTN (Long et al. 2016) | 72.24                | 68.33                | 70.29   |
| PADA (Cao et al. 2018b) | 75.03                | 70.48                | 72.76   |
| **DADA-P**              | **80.94**            | **76.91**            | **78.93** |

DADA-P target domain contains unknown instances, false alignment between the known source instances and unknown target ones will occur, resulting in a sharp drop of the classification performance. (2) DANN performs worse than DAN, since DANN is better at aligning marginal feature distributions across data domains, leading to more serious false alignment. (3) ATI-\(\lambda\) and AODA can effectively reduce false alignment, since they have a good outlier rejection mechanism to recognize the unknown instances. (4) The results of all comparative methods on almost all adaptation settings are better in the evaluation metric OS than OS*, showing that many known target instances are classified as the unknown category. Since Open-set SVM is trained to detect outliers and the task classifier of AODA is trained to recognize all the target instances as the unknown category, they are inclined to classify the target instances as the unknown category. (5) For our proposed DADA-O, the results of all adaptation settings are better in the evaluation metric OS* than OS, since their classifiers are trained to classify all target instance as the unknown category with a small probability \(q\), which can minimize the misclassification of the known target instances as the unknown category.

Office-Home We compare in Table 10 our proposed method with existing ones on Office-Home based on ResNet-50. Results of existing methods are quoted from PADA (Cao et al. 2018b). Our proposed DADA-P significantly outperforms all comparative methods, showing the efficacy of DADA-P on adaptation settings with more categories in both the source and target domains and larger domain discrepancy between the two domains, e.g., \(Cl \rightarrow Rw\).

ImageNet-Caltech We compare in Table 11 our proposed method with existing ones on ImageNet-Caltech based on ResNet-50. Results of existing methods are quoted from PADA (Cao et al. 2018b). Our proposed DADA-P outperforms all comparative methods by a large margin, showing the effectiveness of DADA-P on adaptation settings with large-scale source and target domains and a large number of categories in the two domains.

C.4 Open Set Domain Adaptation.

We compare in Table 12 our proposed method with existing ones on Office-31 based on AlexNet (Krizhevsky, Sutskever, and Hinton 2012) pre-trained on ImageNet (Russakovsky et al. 2015). Results of existing methods are quoted from AODA (Saito et al. 2018c).

Our proposed DADA-O outperforms all comparative methods in both evaluation metrics of OS* and OS, showing the efficacy of DADA-O in both aligning distributions of the known instances across domains and identifying the unknown target instances as the unknown category for open set domain adaptation.

From the experimental results, we have some interesting observations. (1) DAN and DANN perform much worse than “No Adaptation”. DAN and DANN aim to align the whole marginal feature distributions across the source and target domains. If the feature distributions across the source and target domains. If the unknown category for open set domain adaptation. Thus, for a given target task, our methods can have a much better performance when utilizing different source tasks.

Office-Home We compare in Table 10 our proposed method with existing ones on Office-Home based on ResNet-50. Results of existing methods are quoted from PADA (Cao et al. 2018b). Our proposed DADA-P significantly outperforms all comparative methods, showing the efficacy of DADA-P on adaptation settings with more categories in both the source and target domains and larger domain discrepancy between the two domains, e.g., \(Cl \rightarrow Rw\).

ImageNet-Caltech We compare in Table 11 our proposed method with existing ones on ImageNet-Caltech based on ResNet-50. Results of existing methods are quoted from PADA (Cao et al. 2018b). Our proposed DADA-P outperforms all comparative methods by a large margin, showing the effectiveness of DADA-P on adaptation settings with large-scale source and target domains and a large number of categories in the two domains.

C.4 Open Set Domain Adaptation.

We compare in Table 12 our proposed method with existing ones on Office-31 based on AlexNet (Krizhevsky, Sutskever, and Hinton 2012) pre-trained on ImageNet (Russakovsky et al. 2015). Results of existing methods are quoted from AODA (Saito et al. 2018c).

Our proposed DADA-O outperforms all comparative methods in both evaluation metrics of OS* and OS, showing the efficacy of DADA-O in both aligning distributions of the known instances across domains and identifying the unknown target instances as the unknown category for open set domain adaptation.

From the experimental results, we have some interesting observations. (1) DAN and DANN perform much worse than “No Adaptation”. DAN and DANN aim to align the whole marginal feature distributions across the source and target domains. If the target domain contains unknown instances, false alignment between the known source instances and unknown target ones will occur, resulting in a sharp drop of the classification performance. (2) DANN performs worse than DAN, since DANN is better at aligning marginal feature distributions across data domains, leading to more serious false alignment. (3) ATI-\(\lambda\) and AODA can effectively reduce false alignment, since they have a good outlier rejection mechanism to recognize the unknown instances. (4) The results of all comparative methods on almost all adaptation settings are better in the evaluation metric OS than OS*, showing that many known target instances are classified as the unknown category. Since Open-set SVM is trained to detect outliers and the task classifier of AODA is trained to recognize all the target instances as the unknown category, they are inclined to classify the target instances as the unknown category. (5) For our proposed DADA-O, the results of all adaptation settings are better in the evaluation metric OS* than OS, since their classifiers are trained to classify all target instance as the unknown category with a small probability \(q\), which can minimize the misclassification of the known target instances as the unknown category.
When \( q = 0 \), the objective of the feature extractor is to align the whole source domain and the whole target domain, resulting in the misclassification of all unknown target categories as known categories, as illustrated in Figure 9. This demonstrates that the model does not learn feature representations that can separate the unknown target instances from the known instances. To make a trade-off, we empirically set \( q = 0.1 \) for all open set adaptation settings.

### D Investigation for Our Used Training Scheme

In this section, we investigate our used training scheme of pre-training DADA on the labeled source data and maintaining the same supervision signal in the adversarial training of DADA, on benchmark datasets of MNIST (Lecun et al. 1998) and USPS (Hull 1994), where two adaptation settings of MNIST→USPS and USPS→MNIST are built.

To always satisfy the condition of \( p_{adv} > 0.5 \) discussed in Section Discriminative Adversarial Learning in the paper, we train DADA of \( F(G(j)) \) by a well-designed scheme, which can be formulated as alternating the classification training on the labeled source data and the adversarial training of DADA on the labeled source data and unlabeled target data. We denote the number of training epochs or training iterations for classification training in each alternation respectively as \( T_{cls} \) and \( T_{adv} \), the number of training epochs or training iterations for adversarial training in each alternation respectively as \( T_{adv-c} \) and \( T_{adv} \), and the number of alternating the classification and adversarial training as \( N_{alter} \). For the two adaptation settings of MNIST→USPS and USPS→MNIST, \( T_{cls}, T_{adv-c}, \) and \( N_{alter} \) are respectively set to 10, 2, and 16, according to the rate of source instances failing to satisfy the condition; the hyper-parameter \( \lambda \) (cf. Section Discriminative Adversarial Learning in the paper for its definition) is not used, since \( T_{adv-c} \) is a quite small number. We investigate the efficacy of our used training scheme on keeping the condition satisfied by visualizing training processes on the two adaptation settings in Figure 10.

From Figure 10, we can obtain several interesting observations.

1. The classification training makes “Rate of Source Instances Failing to Satisfy Condition” fall into a valley whereas the adversarial training of DADA makes it rise to a peak, showing that a part of source instances change from satisfying the condition to not satisfying it during adversarial training.
2. “Rate of Source Instances Failing to Satisfy Condition (No Target Data)” is much lower than “Rate of Source Instances Failing to Satisfy Condition” at epochs of adversarial training, showing that the training of target data affects the source data and results in that a part of them do not satisfy the condition.
3. “Rate of Source Instances Failing to Satisfy Condition” declines to a very low value in an oscillatory manner, showing the efficacy of this training scheme on keeping the condition satisfied.

### Table 12: Results for open set domain adaptation on Office-31 based on AlexNet.

| Methods                  | A → W | B → W | C → W | D → W | E → W | F → W | G → W | H → W | I → W | J → W | K → W | L → W | M → W | N → W | O → W | P → W | Q → W | R → W | S → W | T → W | U → W | V → W | W → W | Ave |
|--------------------------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| No Adaptation (Krizhevsky, Sutskever, and Hinton 2012) | 57.1 | 55.0 | 44.1 | 39.3 | 62.5 | 59.2 | 59.6 | 59.1 | 14.3 | 5.9  | 13.0 | 4.5  | 40.6 | 37.1 |      |      |      |      |      |      |      |      |      |
| DAN (Long et al. 2018a) | 41.5 | 36.2 | 34.4 | 28.4 | 62.0 | 58.5 | 47.8 | 44.3 | 9.9  | 0.9  | 11.5 | 2.7  | 34.5 | 28.5 |      |      |      |      |      |      |      |      |      |      |
| DANN (Ganin et al. 2016) | 31.0 | 24.3 | 33.6 | 27.3 | 49.7 | 44.8 | 40.8 | 35.6 | 10.4 | 1.5  | 11.5 | 2.7  | 29.5 | 22.7 |      |      |      |      |      |      |      |      |      |      |
| ATI-A (Busto, Iqbal, and Gall 2018) | 65.3 | 82.2 | 92.7 | 72.0 | 66.4 | 71.6 | 75.0 |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| AODA (Saito et al. 2018c) | 70.1 | 69.1 | 94.4 | 94.6 | 96.8 | 96.9 |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |      |
| DADA-O                   | 75.5 | 75.6 | 91.2 | 93.0 | 93.3 | 94.4 | 82.7 | 83.9 | 73.5 | 74.8 | 71.1 | 71.6 | 81.2 | 82.2 |      |      |      |      |      |      |      |      |      |      |

Note that all methods do not use unknown source instances. \( OS^* \) indicates the mean classification result over known categories whereas \( OS \) also includes the unknown category.
Figure 10: Training processes in terms of the test error of the target data for each epoch, the test error of the target data for each epoch of adversarial training, the training error of the source data for each epoch, the rate of source instances failing to satisfy the condition for each epoch, and the rate of source instances failing to satisfy the condition for each epoch when no target data is used in the adversarial training, on the two adaptation settings of (a) MNIST → USPS and (b) USPS → MNIST.
