Since January 2020 Elsevier has created a COVID-19 resource centre with free information in English and Mandarin on the novel coronavirus COVID-19. The COVID-19 resource centre is hosted on Elsevier Connect, the company's public news and information website.

Elsevier hereby grants permission to make all its COVID-19-related research that is available on the COVID-19 resource centre - including this research content - immediately available in PubMed Central and other publicly funded repositories, such as the WHO COVID database with rights for unrestricted research re-use and analyses in any form or by any means with acknowledgement of the original source. These permissions are granted for free by Elsevier for as long as the COVID-19 resource centre remains active.
A systematic review and meta-analysis of published research data on COVID-19 infection fatality rates

Infection-fatality rate  
Global health  
Death rate

\section*{A B S T R A C T}

An important unknown during the coronavirus disease-2019 (COVID-19) pandemic has been the infection fatality rate (IFR). This differs from the case fatality rate (CFR) as an estimate of the number of deaths and as a proportion of the total number of cases, including those who are mild and asymptomatic. While the CFR is extremely valuable for experts, IFR is increasingly being called for by policy makers and the lay public as an estimate of the overall mortality from COVID-19.

\textbf{Methods:} PubMed, Medline, SSRN, and Medrxiv were searched using a set of terms and Boolean operators on 25/04/2020 and re-searched on 14/05/2020, 21/05/2020 and 16/06/2020. Articles were screened for inclusion by both authors. Meta-analysis was performed in Stata 15.1 by using the metan command, based on IFR and confidence intervals extracted from each study. Google/Google Scholar was used to assess the grey literature relating to government reports.

\textbf{Results:} After exclusions, there were 24 estimates of IFR included in the final meta-analysis, from a wide range of countries, published between February and June 2020. The meta-analysis demonstrated a point estimate of IFR of 0.68\% (0.53\%–0.82\%) with high heterogeneity (p < 0.001).

\textbf{Conclusion:} Based on a systematic review and meta-analysis of published evidence on COVID-19 until July 2020, the IFR of the disease across populations is 0.68\% (0.53\%–0.82\%). However, due to very high heterogeneity in the meta-analysis, it is difficult to know if this represents a completely unbiased point estimate. It is likely that, due to age and perhaps underlying comorbidities in the population, different places will experience different IFRs due to the disease. Given issues with mortality recording, it is also likely that this represents an underestimate of the true IFR figure. More research looking at age-stratified IFR is urgently needed to inform policymaking on this front.

\section*{Introduction}

The year 2020 saw the emergence of a global pandemic, coronavirus disease-2019 (COVID-19), caused by the SARS-CoV-2 virus, which began in China and has since spread across the world. One of the most challenging questions to answer during the COVID-19 pandemic has been regarding the true infection fatality rate (IFR) of the disease. While case fatality rates (CFR) are eminently calculable from various published data sources (Kahathuduwa et al., 2020) – CFR being the number of deaths divided by the number of confirmed cases – it is far more difficult to extrapolate to the proportion of all infected individuals who have died due to the infection because those who have very mild, atypical or asymptomatic disease are frequently left undetected and therefore omitted from fatality rate calculations (Rinaldi and Paradisi, 2020). Given the issues with obtaining accurate estimates, it is not unexpected that there are wide disparities in the published estimates of case numbers. This is an issue for several reasons, most importantly that policy is dependent on modelling, and modelling is dependent on assumptions. If we do not have a robust estimate of IFR, it is challenging to make predictions about the true impact of COVID-19 in any given susceptible population, which may stymie policy development and may have serious consequences for decision-making in the future. While CFR is a more commonly used statistic, and is very widely understood among experts, IFR provides important context for policymakers that is hard to convey, particularly given the wide variation in CFR estimates. While CFR is naturally a function of the denominator – i.e. how many people have been tested for the disease – policymakers are often most...
interested in the total burden in the population rather than the biased estimates given from testing only the acutely unwell patients.

This is particularly important when considering the reopening of countries post ‘lockdown’. Depending on the severity of the disease, it may be reasonable to reopen services such as schools, bars, and clubs, at different timings. Another salient point is the expected burden of disease in younger age groups — while there are likely long-term impacts other than death, it will be important for future planning to know how many people in various age groups are likely to die if the infection becomes widespread across societies. Age-stratified estimates are also important as it may give countries some way to predict the number of deaths expected given their demographic breakdown.

There are a number of methods for investigating the IFR in a population. Retrospective modelling studies of influenza, as a common cause of global pandemics, have successfully predicted the true number of cases and deaths from influenza-like illness records and excess mortality estimates (Wong et al., 2013; Thompson et al., 2009). However, these may not be accurate, in part due to the general difficulty in attributing influenza cases to subsequent mortality, meaning that CFRs may both overestimate and equally underestimate the true number of deaths due to the disease in a population (Spychalski et al., 2020).

The standard test for COVID-19 involves polymerase chain reaction (PCR) testing of nasopharyngeal swabs from patients suspected of having contracted the virus. This can produce some false negatives (Anon, 2020a), with one study demonstrating almost a quarter of patients experiencing a positive result following up to two previous false negatives (Xiao et al., 2020). The sensitivity of PCR is believed to be around 70%, which may lead to the underdiagnosis of COVID-19 (Fernández-Barat et al., 2020). PCR is also limited in that it cannot test for previous infection. Serology testing is more invasive, requiring a blood sample. However, it can determine whether there has been previous infection and can be performed rapidly at the point of care (PoC). Serology PoC testing cannot determine if a person is infectious or if infection is recent and there is a risk of misinterpretation of results (Winter and Hegde, 2020). Generally, serology testing is more sensitive and specific than PCR, but will still likely overestimate prevalence when few people have been infected with COVID-19 and underestimate in populations with more infections (Lisboa Bastos et al., 2020). Additionally, there has been great variation noted in the sensitivity, the ability of the test to detect truly positive cases, of COVID-19 serology tests (Ghaffari et al., 2020). Serological tests are reliant on seroconversion, which in COVID-19 occurs several days after the viral load has peaked, meaning serology is less effective in the earlier stages of the disease (Ghaffari et al., 2020). Some studies suggest that there are those who do not seroconvert at all (Staines et al., 2020). The lack of reliable testing may be problematic for estimating CFRs and IFRs.

Given the emergence of COVID-19 as a global pandemic, it is somewhat unlikely that these issues are entirely the same for the newer disease, but there are likely similarities between the two. Some analysis in mainstream media publications and pre-prints has implied that there is a large burden of deaths that remains unattributed to COVID-19. Similarly, serological surveys have demonstrated that there is a large proportion of cases that have not been captured in the case numbers reported in the US, Europe and potentially worldwide (Bendavid et al., 2020; Erikstrup et al., 2020; Simon, 2020).

This paper presents a systematic effort to collate and aggregate these disparate estimates of IFR using an easily replicable method. While any meta-analysis is only as reliable as the quality of included studies, this will at least put a realistic estimate to the IFR given current published evidence.

Methods

This study used a simple systematic review protocol. PubMed, MedLine, and MedRxiv were searched on the 25/04/2020 using the terms and Boolean operators: (infection fatality rate OR ifr OR seroprevalence) AND (COVID-19 OR SARS-CoV-2). This search was repeated on 14/05/2020, 25/05/2020 and 16/06/2020. The pre-print server SSRN was also searched on 25/05/2020; however, as it does not allow this format, the Boolean operators and brackets were removed. While MedRxiv and SSRN would usually be excluded from systematic review, given that the papers included
Table 1
Results of the systematic review of published research data on COVID-19 infection fatality rates.

| Study                              | Location                  | Study period                  | Method and sample size                                      | Results                                                                 |
|------------------------------------|---------------------------|-------------------------------|-------------------------------------------------------------|-------------------------------------------------------------------------|
| Bassett (2020)                     | New York (NYC), Madrid, Lombardy | Until 22nd April 2020 (commence date not provided) | Utilised R₀ of 2.4 to calculate a predicted infection rate of 81% (UK and USA). | Over the 3 regions, the IFR (using predicted total infection rate of 81%) was calculated at 0.17%, for each region specifically, using the same predicted infection rate: NYC 0.22%, Lombardy 0.15% and Madrid 0.14%. |
| Bendavid et al. (2020)             | Santa-Clara Country       | 2 days                        | Serological testing of 3100 local adults and children. Volunteer sampling. Bootstrap procedure used for weighted and unweighted prevalence estimates. | Crude prevalence rate 1.5% (95% CI 1.1%–2.0%), unweighted population prevalence 1.2% (bootstrap 95% CI 0.7%–1.8%), weighted population prevalence 2.8% (95% CI 1.3%–4.7%). Number of infections estimated to be greater than the number of recorded cases. IFR 0.17%. |
| Government of the Czech Republic   | Czech Republic             | Unspecified start date, concluded 1st May 2020 | Tested 26,549 people for antibodies (serology). | Uncovered 107 new cases. |
| Government of Denmark              | Denmark                   | Reported on 20th May 2020     | Serology samples randomly gathered from 885 people up until 24/05/2020 | An estimated 3.1% seroconversion, with a confidence interval ranging from 0.5% to 1.8%. 6.78% (5.21%–8.64%) tested positive on serological testing regimen. |
| Government of England (Office for National Statistics) | England, UK                | As of 24th May 2020          | Tested 1,071 people out of a total sample of 2600 for antibodies. | |
| Government (State) of Indiana, USA | Indiana, USA              | 7 days                        | Tested >4600 using viral PCR and serum for antibodies; 3500 randomly selected individuals and 900 volunteers. | 1.7% tested positive for COVID-19 on PCR plus an additional 1.1% who tested positive for antibodies. Estimated IFR 0.1%. 45% of positive cases report no symptoms. |
| Government of Finland              | Finland                   | Week 22                       | Random weekly sampling of the Finnish population, week 22 included 178 samples 1367 swabs and 1367 blood samples collected from a representative sample of the population. 60,983 participants invited, of which so far 37,992 (62.3%) have responded 1200 weekly samples. Initial analysis was reported from 1104 samples. | 5 positives from 178 lead to a 2.81% positive rate, ranging from 1.21% to 6.41%. 41 people (3.1%) tested positive for COVID-19 antibodies. |
| Government of Slovenia             | Slovenia                  | Not specified                 | All provinces of Spain                                        | 5% positive on serology, with death rates varying by region. Calculated IFR between 1%–1.3% 7.3% tested positive on serology in Stockholm county. Official government report estimates IFR at 0.6% (0.4%–1.1%) based on modelling and serological testing. |
| Government of Sweden               | Stockholm county          | 27/04/2020–3/05/2020 (week 18) | Tested 7216 using viral PCR and serum for antibodies; 3500 randomly selected individuals and 900 volunteers. | An overall seroconversion of 1.39%, with the authors reporting a calculated IFR of 1%, although it was impossible to ascertain whether this accounted for right censoring. |
| Hallal et al. (2020)               | Brazil                    | From 14th May to 21st May 2020 | 46,011 attempts lead to a total of 25,025 samples across every region of Brazil. | |
| Herzog et al. (2020)               | Belgium                   | Two time periods in April, with the estimate used in this paper from the 20–26 of April 2020 | Total of 7307 samples from locations around Belgium | Combined with death estimates, this produced an IFR of 1.1% overall |
| Jung et al. (2020)                 | Cases exported from China and diagnosed outside China | 16 days                       | A total of 51 cases diagnosed between 24/09/2020 and 09/02/2020. Data collected from government websites or media quoting government announcements. | Mean time from illness onset to death was 20.2 days. Estimated incidence in China on 24/01/2020 was 4718 (95% CI 3328–6278) and CFR 5.3% (95% CI 3.5%–7.6%). IFR 0.5%–0.8%. Clear increase in deaths was noted for early 2020. IFR increases with age. Range 0.02% (40–49 years old) to 15.1% (>90 years old). |
| Modi et al. (2020a, 2020b)         | Italy (1688 towns)        | Used data from 01/01/2015–28/03/2020 | Utilised data from the Italian Institute of Statistics. Compared death rates during the COVID-19 pandemic to previous death rates by age and region. | An overall seroconversion of 1.39%, with the authors reporting a calculated IFR of 1%, although it was impossible to ascertain whether this accounted for right censoring. |
| Nishiu et al. (2020)               | Japanese ‘evacuees’ returning to Japan from Wuhan | 3 days                        | A total of 565 individuals screened for symptoms and tested for COVID-19 (PCR). | A total of 8 passengers tested PCR positive for COVID-19 (1.4%). Estimated ascertainment rate of 9.2%. Estimated IFR 0.3%–0.6%. |
| Rinaldi and Paradisi (2020)        | Northern Italy (10 municipalities in Lombardy) | Utilised 5-year death data until April 2020 | Collected data from the Italian Institute of Statistics. The total population of the included municipalities was 50563. Bayesian model used to estimate IFR. | Deaths between February and April 2020 were 5-fold the 2015–2019 average (341 versus 70). IFR 1.29% (95% CI 0.89–2.01), increasing to 4.25% for those >60 years old (95%CI 3.0%–6.39%). Calculated IFR 0.5% (95% CI 0.3–0.8), when nursing home residents were adjusted for estimated IFR 0.8% (95% CI 0.45–1.25). Estimated ratio between those actually infected and those observed was 8 (95% CI 5–12). |
| Roques et al. (2020)               | France                    | 54 days                       | Obtained data on positive cases and deaths from Johns Hopkins University Centre for Systems Science and Engineering and data on tests performed from Santé Publique France, deaths from nursing homes were added to the official count. | 12.5% of specimens were reactive. Cumulative incidence was noted to be higher in Hispanic people, African-American people and non-Hispanic Asian people. There were 619 confirmed cases (17%), 318 of whom were asymptomatic (51%). Corrected CFR was 2.6% (95% CI 0.8%–6.7%). Corrected IFR was 1.3% (95% CI 0.38%–3.6%), CFR increased with age (3.6% for those aged 60–69 years, 95% CI 3.2–4.0) and 14.8% for those >80 years, 95% CI 13.0–16.7). |
| Rosenberg et al. (2020)            | New York State, USA       | 9 days                        | Cross-sectional Seroprevalence study of 15,101 adults. Used IgG immunoassay approved for COVID-19 | |
are not peer-reviewed, during the pandemic it has been an important source of information and contains many of the most recent estimates for epidemiological information about COVID-19. Inclusion criteria for the studies were:

- Regarding COVID-19/SARS-CoV-2 (i.e. not SARS-CoV-1 extrapolations).
- Presented an estimated population IFR (or allowed the calculation of such from publicly available data).

Titles and abstracts were screened for eligibility and discarded if they did not meet the inclusion criteria. GMK then conducted a simple Google and Google Scholar search using the same terms to assess the grey literature, in particular published estimates from government agencies that may not appear on formal academic databases. LM assessed the articles to ensure congruence. If these met the inclusion criteria, they were included in the systematic review and meta-analysis. Similarly, Twitter searches were performed using similar search terms to assess the evidence available on social media. Estimates for IFR and the confidence interval were extracted for each study.

All analysis and data transformation were performed in Stata 15.1. The meta-analysis was performed using the metan command for continuous estimates, with IFR and the lower/upper bounds of the confidence interval as the variables entered. This model used the DerSimonian and Laird random-effects method. The metan command in Stata automatically generates an I² statistic that was used to investigate heterogeneity. Histograms were visually inspected to ensure that there was no significant positive or negative skew to the results that would invalidate this methodology. For the studies where no confidence interval was provided, one was calculated.

A PRISMA flow diagram of the search methods.

Sensitivity analyses were performed stratifying the results into the type of study – serological vs non - by country, and by the month of calculation.

The metabias and metafunnel commands were used to examine publication bias in the included research, with Egger’s test used for the metabias estimation. It was challenging to formally rate the risk of bias of the included modelling studies, as there was very significant heterogeneity in methodology and implementation, with the result that the risk of bias in these studies was considered to be high across all included research. Serological surveys were rated using the risk of bias in the prevalence tool with a resulting estimate in line with Cochrane GRADE criteria of low, moderate or high (Hoy et al., 2012). This tool asks a series of 10 questions about the sampling and data collection of prevalence studies, with a final rating based on the previous questions. Each question is answered yes/no, with a lack of information presumed to be no/unclear. A separate sensitivity analysis was conducted using only serological survey results stratified by the risk of bias.

Because of a recent surge in the number of serological surveys being published, these were included in the infection fatality estimate despite not formally calculating an IFR in the study text itself. Regional death rates were taken from the Johns Hopkins University CSSE dashboard (Dong et al., 2020) 10 days after the serosurvey completion where no IFR was calculated to account for right-censoring of these estimates (Giorgi Rossi et al., 2020), and used to estimate the IFR given the population.

All code and data files are available (in. do and. csv format) upon request.

Results

Initial searches identified 252 studies across all databases. Later searches on Google and social media, as well as resampling the
included databases revealed a further 17 estimates to include in the study. These came from a variety of sources, with some appearing from blog posts, others posted on Twitter, and some government documents being found through Google. There were no duplicates specifically, however, two pre-prints had been published and so appeared in slightly different forms in both databases. In this case, the published study was used rather than the pre-print. Results are collated in Table 1.

Studies were excluded for a variety of reasons. Some studies only looked at COVID-19 incidence, rather than the prevalence of antibodies, and were thus considered potentially unreliable as population estimates (Gudbjartsson et al., 2020). The most common reason for exclusion was selection bias — many studies only looked at targeted populations in their seroprevalence data, and thus could not be used as population estimators of IFR (Erikstrup et al., 2020; Doi et al., 2020; Takita et al., 2020; Jerkovic et al., 2020; Valenti et al., 2020; Garcia-Basteiro et al., 2020; Fontanet et al., 2020; Thompson et al., 2020; Ed Slot and Reusken, 2020). For some data, it was difficult to determine the numerator (i.e. number of deaths) associated with the seroprevalence estimate or the denominator (i.e. population) was not well defined and thus we did not calculate an IFR (Silveira et al., 2020; Bryan et al., 2020). One study explicitly warned against using its data to obtain an IFR (Sood et al., 2020). Another study calculated an IFR, but did not allow for an estimate of confidence bounds and thus could not be included in the quantitative synthesis (Wilson, 2020).

After screening titles and abstracts, 227 studies were removed. Many of these looked at case fatality rates or discussed IFR as a concept and/or a model input, rather than estimate the figure themselves. Forty papers were assessed for eligibility for inclusion in the study, which resulted in a final 25 to be included in the qualitative synthesis.

Studies varied widely in design, with 3 entirely modelled estimates (Nishiura et al., 2020; Jung et al., 2020; Salje et al., 2020), 4 observational studies (Bendavid et al., 2020; Verity et al., 2020; Tian et al., 2020; Russell et al., 2020), 5 pre-prints that were challenging to otherwise classify (Rinaldi and Paradisi, 2020; Roques et al., 2020; Villa et al., 2020; Modi et al., 2020a; Streeck et al., 2020), and a number of serological surveys of varying types reported by government agencies (Bassett, 2020; Anon, 2020b; IU, 2020; Snoeck et al., 2020; Slovenia RO, 2020; Anon, 2020c; Shakiba et al., 2020; Statistics OFN, 2020; Hallal et al., 2020; Institut SS, 2020; Folkhalsomyndigheten, 2020a; Anon, 2020e; Stringhini et al., 2020b). For the purposes of this research, an estimate for New York City was calculated from official statistics and the serosurvey; however, this was correlated with a published estimate (Wilson, 2020) to ensure validity.
The main result from the random effects meta-analysis is presented in Figure 1. Overall, the aggregated estimate across all 24 studies indicated an IFR of 0.68% (95% CI 0.53%–0.82%), or 68 deaths per 10,000 infections. Heterogeneity was extremely high, with the overall I² exceeding 99% (p < 0.0001) (Figure 2).

The monthly sensitivity analysis from Figure 3 showed that earlier estimates of IFR were lower, with later estimates showing a higher figure, although this appears to have stabilised in May.

Analysing by the region of origin did not appear to have a substantial effect on the findings, although there was a slightly lower estimate seen in Asia. As the Middle East was only represented by one study, this region was excluded from the meta-synthesis by region. Two studies were also excluded as they did not present an IFR for a specific region (i.e. Diamond Princess).

Of note, there was some difference in the estimates of IFR between estimates based on serosurveys and those of modelled or PCR-based estimates. The overall estimates from serosurvey studies were 0.60% (0.42%–0.77%), although again with very high heterogeneity, as can be seen in Figure 4.

There were insufficient data in the included research to perform a meta-analysis of IFR by age. However, qualitatively synthesizing the data that were presented indicates that the expected IFR below the age of 60 years is likely to be reduced by a large factor. This is supported by studies examining the CFR, which were not included in the quantitative synthesis and studies examining IFR in selected populations younger than 70 years of age that demonstrate a strong age-related gradient to the death rate from COVID-19.

Plotting the studies using a funnel plot produced some visual indication of publication bias, with more high estimates than would be expected; however, the Egger’s regression was not significant (p = 0.74).

**Risk of bias**

As previously noted, all estimates obtained from modelling studies are considered to be at a high risk of bias due to the heterogeneity and difficulty in rating these studies for accuracy. After using the rating ‘risk of bias’ tool for prevalence studies, 6 studies were considered to be at a low risk of bias, 4 studies at a moderate risk of bias, and the remaining 5 estimates at a high risk of bias. This is summarized in the table below (full scoring in Supplementary materials) (Table 2).

In general, the primary reason for down-rating studies was non-response bias, the lack of representativeness of the population sample, and a lack of information across all fields. Some reports
were published with minimal information, which substantially increased the uncertainty and thus the risk of bias in these estimates.

The sensitivity analysis by study quality results are given below. Broadly, study quality was correlated with a higher inferred IFR, with lower-quality serosurveys reporting higher estimates of population prevalence than randomly sampled population-wide prevalence estimates. Restricting the analysis to only those studies at a low risk of bias resulted in modestly reduced heterogeneity and an increased IFR of 0.76% (0.37%–1.15%) (Figure 5).

Other estimates of IFR

Several estimates of IFR were identified but not included in the meta-analysis as they did not meet the inclusion criteria. The aggregated best estimate from the Centre for Evidence-Based Medicine at Oxford University of 0.1%–0.41% (Jason Oke, 2020), and the pre-print estimate reported by Grewelle and Leo of 1.04% (0.77%–1.38%) (Grewelle and De Leo, 2020) were both pertinent but could not be included because of collinearity.

Similarly, the estimate of symptomatic IFR produced by Basu of 1.3% (0.6%–2.1%) (Basu, 2020) was excluded because of the exclusion of asymptomatic cases. Using reported estimates of asymptomatic cases, this estimate would likely match the meta-analytic IFR; however, this correction could not be applied for the estimates in this study as it could easily introduce bias in the results.

Discussion

As pandemic COVID-19 progresses, it is useful to use the IFR when reporting figures, particularly as some countries begin to engage in enhanced screening and surveillance, and observe an increase in positive cases that are asymptomatic and/or mild enough that they have so far avoided testing (Sutton et al., 2020). It has been acknowledged that COVID-19 is often spread from asymptomatic and/or very mildly symptomatic cases – potentially up to 50% of all patients – and that asymptomatic transmission may also be possible with COVID-19 (Nishiura et al., 2020; Bai et al., 2020) and the use of IFR would aid the capture of these individuals in mortality figures. IFR modelling, calculation and figures, however, are inconsistent.

The main finding of this research is that there is very high heterogeneity among estimates of IFR for COVID-19 and therefore,
it is difficult to draw a single conclusion regarding the number. Aggregating the results together provides a point estimate of 0.68% (0.53%–0.82%), but there remains considerable uncertainty about whether this is a reasonable figure or simply a best guess. It appears likely, however, that the true population IFR in most places from COVID-19 will lie somewhere between the lower bound and upper bounds of this estimate.

One reason for the very high heterogeneity is likely that different countries and regions will experience different death rates due to the disease. One factor that may impact this is government response, with more prepared countries suffering lower death rates than those that have sufficient resources to combat a large outbreak (Scally et al., 2020). Moreover, it is very likely, given the evidence around age-related fatality, that a country with a significantly younger population would see fewer deaths on average than one with a far older population, given similar levels of healthcare provisions between the two. For example, Israel, with a median age of 30 years, would expect a lower IFR than Italy, with a much higher median age (45.4 years).

Some included studies (Rinaldi and Paradisi, 2020; Modi et al., 2020a) compared fatality during COVID-19 pandemic with previous years’ average fatality, determining that mortality has been higher during the pandemic and whilst correlation does not necessarily equate to causation, it is reasonable to link the events as causal given the high CFR observed across countries. It is highly likely from the data analysed that IFR increases with age group, with those aged over 60 years old experiencing the highest IFR, in
one case close to 15% (Modi et al., 2020a). Given the elderly are the most vulnerable in society to illness and likely to carry a higher disease burden owing to increased susceptibility and comorbidity (Liu et al., 2020; Rothan and Byrareddy, 2020), the lower IFRs observed in the younger populations may skew the figure somewhat. There are some reasonable estimates of fatality in younger age groups that were not included in the population estimates (Erikstrup et al., 2020; Valentí et al., 2020; Thompson et al., 2020), which imply a substantially lower rate of death in the population below 70 years of age. While these studies were not considered applicable for quantitative synthesis, they do imply a lower IFR for those aged 18–70 years. Indeed, a recently published estimate stratified infection fatality by age and found a very low risk for under 50 s that increased exponentially with age from 0.0016% <50 years to 0.14% for 50–64 year olds and up to 5.6% for those 65 years and older (Perez-Saez et al., 2020). This has also been demonstrated in a pre-print meta-analysis of age-stratified IFR that found an exponential increase in IFR by age, from 0.005% for children to 0.2% at age 50, 0.75% at age 60, and 27% for ages 85 and above (Levin et al., 2020).

While not included in the quantitative synthesis, one paper did examine the extreme lower bound of IFR of COVID-19 in situations where the healthcare system has been overwhelmed. This is likely to be higher than the IFR in a less problematic situation but demonstrates that the absolute minimum in such a situation cannot be lower than 0.2%, and is likely much higher than this figure in most scenarios involving overburdened hospitals.

Of note, there appears to be a divergence between estimates based on serosurveys and those that are modelled or inferred from other forms of testing, with the IFR based purely on serosurveillance being 0.60% (0.43–0.77%). Some have argued that serological surveys are the only proper way to estimate IFR, which would lead to the acceptance of this slightly lower IFR as the most likely estimate (Ioannidis, 2020). However, even these estimates are very heterogeneous in quality, with some extremely robust data such as that reported from the Spanish and Swedish health agencies (Anon, 2020b; Folkhälsoomsnyndigheten, 2020b), and some that have clear and worrying flaws such as a study from Iran where death estimates are reportedly substantially lower than the true figure (Shakiba et al., 2020). However, when taking quality into account, and only analysing those serosurveys that had a low risk of bias, it is interesting to note that the inferred IFR rises substantially to 0.76% (0.37–1.15%). This may be due to the bias in lower-quality serosurveys being towards a higher prevalence (Sood et al., 2020), which in turn lowers the IFR substantially.

Another key issue is accounting for deaths. While official death counts were used for all serosurvey estimates, and included in all modelled estimates, these counts are increasingly being recognized as undercounts of the true death figure (Modi et al., 2020a). Published research is already estimating that, even in many
wealthy countries with excellent death-reporting systems, more than 50% of COVID-19 deaths are likely being missed (Modi et al., 2020b; Modig and Ebeling, 2020). It is not unlikely that, after correcting for excess mortality not captured in official death-reporting systems, the IFR of COVID-19 in most populations would be substantially higher than our analysis suggests. It is also possible that the IFR of the disease will drop over time as treatments improve; however, our analysis at least does not demonstrate that this has been the case in the first half of 2020.

Conversely, there is evidence that the tests used in these serosurveys have drawbacks despite their high specificity and sensitivity. For example, in asymptomatic/mild cases, the tests may have reduced sensitivity, leading to a biased overestimation of the IFR (Takahashi et al., 2020). A recent systematic review and meta-analysis of serological tests for COVID-19 found that even the better serology tests would likely overestimate prevalence in an area with few cases and underestimate prevalence when many people had already been infected (Lisboa Bastos et al., 2020). In areas with a prevalence of 1%–2%, for example, the systematic review implies that a study employing an enzyme-linked immunosorbent assay to examine antibodies would produce an estimated infection rate almost double the true prevalence. This would then cause the IFR to be underestimated by the same fraction.

There are a number of limitations to this research. Importantly, the heterogeneity in the meta-analysis was very high. This may mean that the point estimates are less reliable than would be expected. It is also notable that any meta-analysis is only as reliable as the data contained within — this research included a very broad range of studies that address slightly different questions with a very wide range of methodological rigor, and thus cannot represent the certainty of any kind. While modelling studies were not formally graded, at least one has already been critiqued for simple mathematical errors, and given that many were pre-prints, it is hard to ascertain if they have provided accurate representations of the data. Serology studies were at a variable risk of bias, and analysing only the highest quality serosurveys produced a higher estimate than relying on lower quality studies.

Moreover, the quality of included serosurvey estimates was often questionable. Many countries have a clear political motivation to present lower estimates, making it challenging to ascertain whether these may have biased the reporting of results, particularly for those places that have only presented results as press releases thus far. Some have also been criticized for sampling issues that would likely lead to a biased overestimate of population infection rates (Bendavid et al., 2020).

Accounting for right-censoring in these estimates was also a challenge. Using a 10-day cut-off for deaths is far too crude a method to create a reliable estimate. In some cases, this could be an overestimate, due to the seroconversion process taking almost as much time as the median time until death. Conversely, there is a long tail for COVID-19 deaths (Giorgi Rossi et al., 2020), and therefore it is almost certain that some proportion of the ‘true’ number of deaths will be missed by using a 10-day cut-off, biasing the estimated IFRs down. This may be why serosurvey estimates at first appear to result in somewhat lower IFRs than modelled and observational data suggest.

It is also important to recognize that this is a living estimate. With new data being published every single day during this pandemic, in a wide variety of languages and in innumerable formats, it is impossible to collate every single piece of information into one document no matter how rigorous. Moreover, this aggregated estimate is only as correct as the most recent search — the point estimate has not shifted substantially because of the inclusion of new research, but the confidence interval has changed. It is almost certain that, over the course of coming months and years, the IFR will be revised a number of times. In particular, it is vital that future research stratifies this estimate by age, as this appears to be the most significant factor in the risk of death from COVID-19.

This research has a range of very important implications. Some countries have announced the aim of pursuing herd immunity with regard to COVID-19 in the absence of a vaccination. The aggregated IFR would suggest that, at a minimum, you would expect 0.45%–0.53% of a population to die before the herd immunity threshold of the disease (based on R0 of 2.5–3 (Russell et al., 2020)) was reached (Mahase, 2020). As an example, in the US this would imply more than 1 million deaths at the lower end of the scale. Even with a lower herd immunity threshold suggested by more recent modelling (Aguas et al., 2020), this would imply an unmanageable number of deaths to reach the threshold across a country.

This also has implications for future planning. Governments looking to exit lockdowns should be prepared to see a relatively high IFR within the population that is infected if COVID-19 re-emerges. This should inform the decision to relax restrictions, given that the IFR for people infected with COVID-19 appears to be not insignificant even in places with very robust healthcare systems.

Conclusions

Based on a systematic review and meta-analysis of published evidence on COVID-19 until July 2020, the IFR of the disease across populations is 0.68% (0.53%–0.82%). However, because of very high heterogeneity in the meta-analysis, it is difficult to know if this represents the ‘true’ point estimate. In particular, higher quality serosurveys with lower risk of bias appeared to generate higher IFRs. It is likely that, because of age and perhaps underlying comorbidities in the population, different places will experience different IFRs due to the disease. Given the issues with mortality recording, it is also likely that this represents an underestimate of the true IFR figure. More research looking at age-stratified IFR is urgently needed to inform policymaking on this front.
