Abstract

One of the remarkable properties of cluster algebras is that any cluster, obtained from a sequence of mutations from an initial cluster, can be written as a Laurent polynomial in the initial cluster (known as the ‘Laurent phenomenon’). There are many nonlinear recurrences which exhibit the Laurent phenomenon and thus unexpectedly generate integer sequences. The mutation of a typical quiver will not generate a recurrence, but rather an erratic sequence of exchange relations. How do we ‘design’ a quiver which gives rise to a given recurrence? A key role is played by the concept of ‘periodic cluster mutation’, introduced in 2009. Each recurrence corresponds to a finite dimensional map. In the context of cluster mutations, these are called ‘cluster maps’. What properties do cluster maps have? Are they integrable in some standard sense? In this review I describe how integrable maps arise in the context of cluster mutations. I first explain the concept of ‘periodic cluster mutation’, giving some classification results. I then give a review of what is meant by an integrable map and apply this to cluster maps. Two classes of integrable maps are related to interesting monodromy problems, which generate interesting Poisson algebras of functions, used to prove complete integrability and a linearization. A connection to the Hirota–Miwa equation is explained.

This article is part of a special issue of Journal of Physics A: Mathematical and Theoretical devoted to ‘Cluster algebras in mathematical physics’.

Keywords: Poisson algebra, bi-Hamiltonian, integrable maps, super-integrability, Laurent property, cluster algebra

1. Introduction

The main purpose of this review is to explain how integrable maps arise in the context of cluster mutations. These maps will be derived from recurrences, so we must first ask how recurrences arise in the context of cluster mutations. To be specific, consider an $N$th order recurrence in a single variable $x_n$, of the form
where $F$ is a polynomial in $N-1$ variables. How can we represent such a recurrence as a sequence of cluster mutations?

Recall that cluster exchange relations (satisfied by the generators of a cluster algebra) are derived by looking at the nodes of an associated quiver (see section 2). Each quiver mutation leads to a specific exchange relation, but also to a change of the quiver. If we randomly choose even a fairly simple quiver, a little experimentation (using Keller’s Java Applet [23], for example) shows that mutation typically generates a series of completely different quivers with a wild growth of the number of arrows connecting nodes. Therefore, each successive exchange relation will involve a different formula for $x_k \mapsto \tilde{x}_k$, so cannot possibly lead to a regular formula such as (1.1). We need to construct a quiver with a special property that after mutation at node $k$ (say), at least one node of the new quiver should have the same configuration of arrows as at node $k$ of the original quiver. After playing with Keller’s Java Applet, this seems like a tall order! Nevertheless, in [13] we introduced the concept of ‘periodic cluster mutation’, which gives a way of building quivers for which a specific sequence of mutations leads to a recurrence. One of the purposes of this paper is to explain this construction.

Now, supposing we have a way of generating a recurrence from a sequence of cluster mutations, what properties can we expect this recurrence to have? One of the remarkable properties of cluster algebras [8] is that any cluster, obtained from a sequence of mutations from an initial cluster, can be written as a Laurent polynomial in the initial cluster (known as the ‘Laurent phenomenon’). In particular, if $\{x_n\}_{n=1}^\infty$ is a sequence generated by cluster mutations, we expect it to possess the Laurent property: i.e. that the general term $x_n$ can be written as a Laurent polynomial in the initial conditions, meaning a polynomial in $\{x_{n-1}\}_{n=1}^N$. This property cannot be expected to hold for a sequence generated by (1.1) for arbitrary $F$ since, for example, the calculation of $x_{2n+1}$ requires division by the polynomial $F(x_1, ..., x_N)$. Hence we generally expect $x_n$ to be rational, with non-trivial polynomials in the denominators. This means that miraculous cancellations must take place, rendering the denominator a monomial! An immediate consequence of the Laurent property is that if we take initial conditions $x_1 = \cdots = x_N = 1$, then the recurrence generates a sequence of integers.

The archetypal example is the Somos-4 recurrence

$$x_n x_{n+4} = x_{n+1} x_{n+3} + x_n^2 + 2,$$

which (with initial conditions $x_1 = x_2 = x_3 = x_4 = 1$) generates the integer sequence:

1, 1, 1, 1, 2, 3, 7, 23, 59, 314, 1529, 8209, ...

(see ‘The On-Line Encyclopedia of Integer Sequences’ [33] and [14]). Other examples are the Somos-5 and 6 recurrences

$$x_n x_{n+5} = x_{n+1} x_{n+4} + x_{n+2} x_{n+3},$$

$$x_n x_{n+6} = x_{n+1} x_{n+5} + x_{n+2} x_{n+4} + x_n^2 + 3.$$

In fact we can write a ‘Somos-$N$ recurrence’ for all $N$, but from Somos-8 onwards, they no longer possess the Laurent property. One might be tempted to think that any recurrence with the Laurent property should be derivable through cluster mutation, but the general cluster exchange relation (see (2.2)) has only two terms on the ‘right hand side’, so (1.4) cannot be so obtained. Nevertheless, Fomin and Zelevinsky did introduce other cluster-related techniques in [9], with which they could prove the Laurent property for this more general class of recurrence. Since both (1.2) and (1.3) have the correct two-term form, we may hope that they
are connected to some cluster mutations. Indeed, quivers corresponding to these were derived in [13] (see section 2).

Given the recurrence (1.1), we can consider a corresponding cluster map \( \varphi: \mathbb{C}^N \to \mathbb{C}^N \) of the form

\[
\varphi: (x_1, \ldots, x_N) \mapsto (x_2, \ldots, x_N, x_{N+1}), \quad \text{where} \quad x_{N+1} = \frac{F(x_2, \ldots, x_N)}{x_1},
\]

which defines a discrete dynamical system on \( \mathbb{C}^N \).

What properties (other than being Laurent) can we expect this map to possess? It is known [19] that both (1.2) and (1.3) are related to special cases of the QRT map [32], a well known 18 parameter family of integrable maps of the plane. Again, we might be tempted to think that all maps that are derived through cluster mutation are integrable. However, numerical experimentation, or applying one of the ‘tests for integrability’ (see section 5.1) soon shows that most cluster maps are non-integrable. We must, therefore, address the question of isolating integrable cases and possibly giving some sort of classification. Such ‘tests for integrability’ are, in fact, only an indication, usually just supplying necessary conditions.

When we say a map is integrable, we mean integrable in the Liouville sense. This means that we have a usual completely integrable Hamiltonian system, whose commuting Hamiltonian flows are continuous symmetries of our discrete dynamical system. Our maps (perhaps after reduction to a lower dimensional manifold) will be Poisson maps (generalizations of canonical transformations), subject to some additional invariance properties. To keep this review self-contained, section 3 gives a brief introduction to these concepts.

Given a map, it is a non-trivial task to find an appropriate symplectic or Poisson structure which is invariant under its action. Remarkably, in the case of cluster maps derived from periodic quiver mutation, this problem can be solved algorithmically. An invariant (pre-)symplectic structure is built out of the matrix \( B \) which defines the quiver. This in turn defines an invariant Poisson bracket on a (possibly lower dimensional) symplectic manifold (see section 4). However, there is no algorithm for finding the appropriate number of invariant, Poisson commuting functions. Nevertheless, for some classes of cluster maps it is possible to find these.

In section 6 we consider a special class of recurrence related to the simplest period 1 quivers (the ‘primitives’). For an even number of nodes, it was shown in [10] that these are bi-Hamiltonian and this can be used to algorithmically build the commuting integrals. Later, it was shown in [12] that for any number of nodes it is possible to build a \( 2 \times 2 \) matrix monodromy problem, from which we can derive the commuting integrals. It is also possible to show that the sequence \( \{x_n\}_{n=1}^{\infty} \) generated by a nonlinear ‘primitive’ recurrence, satisfies a higher order linear recurrence. Similar results can be derived for another recurrence, described in section 7, only this time the monodromy matrix is \( 3 \times 3 \). For this class it is sometimes (but not always!) possible to find the appropriate number of invariant, commuting integrals to prove complete integrability.

The Somos-4 and Somos-5 recurrences cannot be linearised, but their corresponding maps do have a Lax representation. This follows from the fact that these recurrences (and a larger class, containing them) are reductions of the Hirota–Miwa (discrete KP) equation. This is briefly described in section 8.

This paper is mainly a review of [10–13], but in the conclusions I mention some recent developments and discuss open problems.
2. Quiver mutation

A quiver is a directed graph, consisting of \( N \) nodes with directed edges between them. There may be several arrows between a given pair of vertices, but for cluster algebras there should be no one-cycles (an arrow which starts and ends at the same node) or two-cycles (an arrow from node \( a \) to node \( b \), followed by one from node \( b \) to node \( a \)). A quiver \( Q \), with \( N \) nodes, can be identified with the unique skew-symmetric \( N \times N \) matrix \( B_Q \) given by the number of arrows from \( i \) to \( j \) (with the obvious sign convention).

**Definition 2.1** (Quiver mutation). Given a quiver \( Q \) we can mutate at any of its nodes. The mutation of \( Q \) at node \( k \), denoted by \( \mu_k Q \), is constructed (from \( Q \)) as follows:

1. Reverse all arrows which either originate or terminate at node \( k \).
2. Suppose that there are \( p \) arrows from node \( i \) to node \( k \) and \( q \) arrows from node \( k \) to node \( j \) (in \( Q \)). Add \( pq \) arrows going from node \( i \) to node \( j \) to any arrows already there.
3. Remove (both arrows of) any two-cycles created in the previous steps.

Note that in step 2, \( pq \) is just the number of paths of length 2 between nodes \( i \) and \( j \) which pass through node \( k \).

Quiver mutation is very visual and easy to understand, but for computations we use the following:

**Definition 2.2** (Matrix mutation). Let \( B \) and \( \tilde{B} = \mu_k B \) be the skew-symmetric matrices corresponding to the quivers \( Q \) and \( Q_\mu = \mu_k Q \). Let \( b_{ij} \) and \( \tilde{b}_{ij} \) be the corresponding matrix entries. Then quiver mutation amounts to the following formula

\[
\tilde{b}_{ij} = \begin{cases} 
-b_{ij} & \text{if } i = k \text{ or } j = k, \\
 b_{ij} + \frac{1}{2} \left( |b_{ik}| b_{kj} + |b_{jk}| b_{ik} \right) & \text{otherwise.} 
\end{cases} \tag{2.1}
\]

### 2.1. Cluster exchange relations

Given a quiver (with \( N \) nodes), we attach a variable at each node, labelled \((x_1, \ldots, x_N)\) (the initial cluster). When we mutate the quiver we change the associated matrix according to formula (2.1) and, in addition, we transform the cluster variables \((x_1, \ldots, x_N) \mapsto (\tilde{x}_1, \ldots, \tilde{x}_N, x_k)\), where

\[
x_{ik} \tilde{x}_i = \prod_{k \cdot r > 0} x_i^{b_{ik}^+} + \prod_{k \cdot r < 0} x_i^{-b_{ik}^-}, \quad \tilde{x}_i = x_i \text{ for } i \neq k. \tag{2.2}
\]

If one of these products is empty (which occurs when all \( b_{ik} \) have the same sign) then it is replaced by the number 1. This formula is called the (cluster) exchange relation. Notice that it just depends upon the \( k \)th column of the matrix. Since the matrix is skew-symmetric, the variable \( x_k \) does not occur on the right side of (2.2).

After this process we have a new quiver \( \mu_k Q \), with a new matrix \( \mu_k B \). This new quiver has cluster variables \((\tilde{x}_1, \ldots, \tilde{x}_N)\). However, since the exchange relation (2.2) acts as the identity on all except one variable, we write these new cluster variables as \((x_1, \ldots, \tilde{x}_i, \ldots, x_N)\). We can
now repeat this process and mutate $\mu Q_k$ at node $p$ and produce a third quiver $\mu Q_{pk}$, with cluster variables $\tilde{x}_1, \ldots, \tilde{x}_p, \ldots, \tilde{x}_N$ with $\tilde{x}_p$ being given by an analogous formula (2.2).

**Remark 2.3** (Involutive property). If $p = k$, then $\mu Q_k = Q_k^2$, so we insist that $p \neq k$.

### 2.2. Periodicity

Before introducing the general concept of periodicity [13], I give a motivating example, which also illustrates the above definitions of mutation. This is the quiver which generates the Somos-4 recurrence.

**Example 2.4** (The Somos-4 quiver $S_4$). Consider the quiver (and its associated matrix) of figure 1. The mutation at node 1 leads to the quiver (and associated matrix) of figure 2. Placing $x_1, x_2, x_3, x_4$ respectively at nodes 1 to 4 of quiver $S_4$ gives the initial cluster. Along with the quiver mutation, we also have the exchange relation

$$x_1 \tilde{x}_1 = x_2 x_4 + x_4^2.$$ (2.3)

This corresponds to one arrow coming into node 1 from each of nodes 2 and 4 with 2 arrows going out to node 3. Figure 1. The Somos-4 $S_4$ and its matrix.

Figure 2. Mutation $\tilde{S}_4 = \mu S_4$ of the quiver $S_4$ at 1 and its matrix.

We can now consider mutations of quiver $\tilde{S}_4 = \mu S_4$. To avoid too many ‘tildes’, let us write $\tilde{x}_i = x_i$, so quiver $\tilde{S}_4$ has $x_1, x_2, x_3, x_4$ respectively at nodes 1 to 4. Mutation at node 1 would just take us back to quiver $S_4$ (as noted in the above remark). We compare the exchange relations we would obtain by mutating at nodes 2 or 3.

Mutation at node 2 would lead to exchange relation

$$x_2 \tilde{x}_2 = x_3 x_5 + x_5^2,$$ (2.4)
whilst that at node 3 would lead to
\[ x_3 \bar{x}_3 = x_2 \bar{x}_2^2 + x_4 \bar{x}_4^3. \] (2.5)

We see that the right hand sides of formula (2.3) and (2.4) are related by a shift, whilst formula (2.5) is entirely different. In fact, it can be seen in figures 1 and 2 that the configuration of arrows at node 2 of quiver \( \tilde{S}_4 \) is exactly the same as that at node 1 of quiver \( S_4 \), thus giving the same exchange relation. In fact, we have more. The whole quiver \( \tilde{S}_4 \) is obtained from \( S_4 \) by just rotating the arrows, whilst keeping the nodes fixed. It follows that mutation of quiver \( \tilde{S}_4 \) at node 2 just leads to a further rotation, with node 3 inheriting this same configuration of arrows. If at each step we relabel \( \tilde{x}_n \) as \( \bar{x}_{n+4} \), the \( n \)th exchange relation can be written
\[ x_n x_{n+4} = x_{n+1} x_{n+3} + x_n^2 + x_{n+2}^2. \] (2.6)

This rotational property of the quiver has lead to a recurrence, which in this case is just Somos-4.

The essential property of the quiver \( S_4 \) was that mutation at node 1 just gave us a copy of \( S_4 \) up to a permutation of the indices. If we insist (for an \( N \)-node quiver) that this permutation has order \( N \), then (by a change of labelling) we can represent it by the \( N \times N \) matrix
\[ \rho = \begin{pmatrix} 0 & \cdots & \cdots & 1 \\ 1 & 0 & \cdots & \vdots \\ \vdots & \ddots & \ddots & \vdots \\ 1 & 0 \end{pmatrix}. \]

which acts on the matrix \( B \) by
\[ B \mapsto \rho B \rho^{-1}. \]

In terms of the quiver we write this as \( Q \mapsto \rho Q \).

Consider a quiver \( Q = Q(1) \), with \( N \) nodes, and a sequence of mutations, starting at node 1, followed by node 2, and so on. Mutation at node 1 of a quiver \( Q(1) \) will produce a second quiver \( Q(2) \). The mutation at node 2 will therefore be of quiver \( Q(2) \), giving rise to quiver \( Q(3) \) and so on. In [13] we defined a period \( m \) quiver as follows.

**Definition 2.5.** A quiver \( Q \) has period \( m \) if it satisfies \( Q(m + 1) = \rho^n Q(1) \) (with \( m \) the minimum such integer). The mutation sequence is depicted by
\[ Q = Q(1) \xrightarrow{\mu_1} Q(2) \xrightarrow{\mu_2} \cdots \xrightarrow{\mu_{n-1}} Q(m) \xrightarrow{\mu_n} Q(m + 1) = \rho^n Q(1),\] (2.7)

and called the periodic chain associated to \( Q \).

The corresponding matrices would then satisfy \( B(m + 1) = \rho^n B(1) \rho^{-m} \).

**Remark 2.6** (The sequence of mutations). We must perform the correct sequence of mutations. For instance, if we mutate \( \mu_4 S_4 \) at node 3, we obtain a quiver which has 5 arrows from node 4 to node 1, which cannot be permutation equivalent to \( Q(1) = S_4 \). As we previously saw, the corresponding exchange relation (see (2.5)) was also different.

**Remark 2.7** (Other definitions of periodicity). Apparently, examples of periodicity were known in the context of T- and Y-systems, so this concept was formalised in [27]. Indeed, in this paper Nakanishi also defines and develops the theory of periodic cluster mutation, but his motivation is rather different from ours.
2.3. Period 1 quivers

Period 1 quivers can be completely classified in terms of a special class of quivers, called primitives. In our classification, the primitives are the atoms out of which we build the general period 1 quiver for each $N$.

**Definition 2.8** (Period 1 sink-type quivers). A quiver $Q$ is said to be a period 1 sink-type quiver if it is of period 1 and node 1 of $Q$ is a sink.

**Definition 2.9** (Skew-rotation). We shall refer to the matrix

$$
\tau = \begin{pmatrix}
0 & \cdots & \cdots & -1 \\
1 & 0 & \ddots & \vdots \\
& \ddots & \ddots & \ddots \\
1 & 0 & & \\
\end{pmatrix}
$$

as a skew-rotation.

If node 1 of $Q$ is a sink, there are no paths of length 2 through it, and the second part of definition 2.1 is void. Period 1 mutation then reduces to a simple conjugation.

**Lemma 2.10** (Period 1 sink-type equation). A quiver $Q$ with a sink at 1 is period 1 if and only if $\tau B_0 \tau^{-1} = B_0$.

The map $M \mapsto \tau M \tau^{-1}$ simultaneously cyclically permutes the rows and columns of $M$ (up to a sign), while $\tau^N = -I_N$, hence $\tau$ has order $N$. This gives us a method for building period 1 matrices: we sum over $\tau$-orbits.

The **period 1 primitive** $P_N^{(1)}$. We consider a quiver with just a single arrow from node $N - k + 1$ to node 1, represented by the skew-symmetric matrix $R_N^{(1)}$ with

$$(R_N^{(1)})_{N-k+1,1} = 1, \quad (R_N^{(1)})_{N,k} = -1 \text{ and } (R_N^{(1)})_0 = 0 \text{ otherwise.}$$

We remark that the geometric action of $\tau$ in the above sum is to rotate the arrow clockwise without change of orientation, except that when the tail of the arrow ends up at node 1 it is reversed. It follows that 1 is a sink in the resulting quiver. Since it is a sum over a $\tau$-orbit, we have $\tau B_N^{(1)} \tau^{-1} = B_N^{(1)}$, and thus that $P_N^{(1)}$ is a period 1 sink-type quiver. In fact, we have the simple description:

![Figure 3. The period 1 primitives for 4 and 5 nodes.](image-url)
\[ B_N^{(k)} = \begin{cases} \tau^t - (\tau^t)^t, & \text{if } N = 2r + 1 \text{ and } 1 \leq k \leq r, \text{ or } N = 2r \text{ and } 1 \leq k \leq r - 1, \\ \tau^r, & \text{if } N = 2r \text{ and } k = r, \end{cases} \quad (2.8) \]

where \( \tau^t \) denotes the transpose of \( \tau \). The choice \( \leq \) is because \( R_N \) and \( -R_N \) are in the same orbit.

Figure 3 shows these primitives for \( N = 4, 5 \).

2.3.1. The general period 1 quiver. We start with a skew-symmetric matrix whose first column is of the form \((0, m_1, \ldots, m_{N-1})^t\) and construct the remaining elements \( b_{ij} \). For \( 1 \leq i, j \leq N - 1 \), let

\[ \epsilon_{ij} = \frac{1}{2} \left( m_i | m_j \right) - m_j | m_i \right). \]

Then if \( m_i \) and \( m_j \) have the same sign, \( \epsilon_{ij} = 0 \). Otherwise \( \epsilon_{ij} = \pm |m_i m_j| \), where the sign is that of \( m_i \). The general formula (2.1) for matrix mutation then gives

\[ \tilde{B} = \mu B \Rightarrow \tilde{b}_{ij} = b_{ij} + \epsilon_{i,j,i,j}. \]

We also have that the effect of the rotation \( \rho \mapsto \rho B \rho^{-1} \) is to move the entries of \( B \) down and right one step, so that \((\rho B \rho^{-1})_{ij} = b_{i-1,i-1+1}, \) remembering that indices are labelled modulo \( N \), so \( N + 1 \equiv 1 \).

Therefore, \( \mu, B = \rho B \rho^{-1} \) implies

\[ b_{ij} = b_{i,j+1} + \epsilon_{i-j+1,i+j} \] and \( (b_{N,1}, b_{N,2}, \ldots, b_{N,N-1}) = (m_1, \ldots, m_{N-1}) \).

The first of these is a difference equation, building the lower triangular elements of \( B \), with initial conditions on the left column. The second of these is a boundary condition. Together, they imply that \( m_{n,\mu} = m_\mu \) (the \( \text{palindromic property} \)) and that

\[ b_{N,1} = b_{N,2} + \epsilon_{N-2,i-2} + \ldots + \epsilon_{j,j+i-1}. \quad (2.9) \]

A description in terms of primitives. Recall that for an even (or odd) number of nodes, \( N = 2r \) (or \( N = 2r + 1 \)), there are \( r \) primitives, labelled \( B_N^{(k)} \) (or \( B_N^{(k)} \)), \( k = 1, \ldots, r \). We denote the general linear combination of these by

\[ \tilde{B}_N^{(k)}(\mu_1, \ldots, \mu_r) = \sum_{j=1}^{r} \mu_j B_N^{(j)} \] and \( \tilde{B}_N^{(k+1)}(\mu_1, \ldots, \mu_r) = \sum_{j=1}^{r} \mu_j B_N^{(j+1)} \).

for integers \( \mu_j \). The quivers corresponding to \( \tilde{B}_N^{(k)}(\mu_1, \ldots, \mu_r) \) and \( \tilde{B}_N^{(k+1)}(\mu_1, \ldots, \mu_r) \) do not have periodicity properties (unless all \( \mu_j \) have the same sign).

Theorem 2.11 (The general period 1 quiver). Let \( B_N \) (respectively \( B_N^{(k)} \)) denote the matrix corresponding to the general even (respectively odd) node quiver of mutation periodicity 1. Then

\[ B_N = \tilde{B}_N(m_1, \ldots, m_r) + \sum_{k=1}^{r-1} \tilde{B}_{2r-2k}(\epsilon_{1,k+1}, \ldots, \epsilon_{r,k}), \]

where \( \tilde{B}_{2r-2k}(\epsilon_{1,k+1}, \ldots, \epsilon_{r,k}) \) is embedded in a \( 2r \times 2r \) matrix in rows and columns \( k + 1, \ldots, 2r - k \).
2.

\[ B_{2r+1} = \tilde{B}_{2r+1}(m_1, \ldots, m_r) + \sum_{k=1}^{r-1} \tilde{B}_{2(r-k)+1}(\varepsilon_{k+k+1}, \ldots, \varepsilon_{k+k}), \]

where \( \tilde{B}_{2(r-k)+1}(\varepsilon_{k+k+1}, \ldots, \varepsilon_{k+k}) \) is embedded in a \((2r+1) \times (2r+1)\) matrix in rows and columns \( k+1, \ldots, 2r+1-k \).

**Remark 2.12.** From these formulae, together with (2.8), we see that the first column of \( B_N \), corresponding to a period 1 quiver, is palindromic, with \( b_{11} = m_{r-1} \) and \( m_{N-r} = m_r \). These are the only matrix elements which enter the formula of the cluster exchange relation, and thus the recurrence formula. The matrix \( B \) has the following symmetry: \( b_{N-j+1,N-j+1} = b_{ij} \).

### 2.3.2. Recurrences from period 1 solutions.

Corresponding to each period 1 quiver, we have

\[ x_{n+N} = \prod_{m_j \geq 0} x_{n+m_j}^{m_j} + \prod_{m_j < 0} x_{n+m_j}^{-m_j}, \tag{2.10} \]

where the indices in each product lie in the range \( 1 \leq j \leq N-1 \), with the exponents \((m_1, \ldots, m_{N-1})\) forming an integer \((N-1)\)-tuple which is palindromic, so that \( m_j = m_{N-j} \).

**Example 2.13** (The Somos-4 quiver). For the Somos-4 quiver, we have \( m_1 = 1, m_2 = -2 \) and our formula requires the addition of a further two arrows between nodes 3 and 2 (see figure 4).

**Example 2.14** (The Somos-5 quiver). For the Somos-5 quiver, we have \( m_1 = 1, m_2 = -1 \), giving

\[ x_n x_{n+5} = x_{n+1} x_{n+4} + x_{n+2} x_{n+3}. \tag{2.11} \]

The full quiver is given by \( P_4^{(1)} - P_4^{(2)} + P_3^{(1)} \) (see figure 5).
Example 2.15  (Period 1 quiver with 6 nodes). Here the matrix has the form

\[
B = \begin{pmatrix}
0 & -m_1 & -m_2 & -m_3 & -m_2 & -m_1 \\
m_1 & 0 & -m_1 & -m_2 & -m_3 & -m_2 \\
m_2 & m_1 & 0 & -m_1 & -m_2 & -m_3 \\
m_3 & m_2 & m_1 & 0 & -m_1 & -m_2 \\
m_4 & m_3 & m_2 & m_1 & 0 & -m_1 \\
m_5 & m_4 & m_3 & m_2 & m_1 & 0
\end{pmatrix}
\]

which can be written as

\[
B = \sum_{j=1}^6 m_j B_6^{(j)} + \sum_{k=1}^{5} \epsilon_{k,k+1} B_4^{(k)} + \epsilon_{23} B_2^{(1)},
\]

where the periodic solutions with fewer rows and columns are embedded symmetrically within a $6 \times 6$ matrix.

Some specific examples of this can be found in the next example.

Example 2.16  (Gale–Robinson sequence ($N$ nodes)). The 2-term Gale–Robinson recurrence is given by

\[
x_n x_{n+N} = x_{n+N-r} x_{n+r} + x_{n+N-s} x_{n+s},
\]

for $0 < r < s \leq N/2$, and is one of the examples discussed in [9]. This corresponds to the period 1 quiver with $m_r = 1$ and $m_s = -1$ (unless $N = 2s$, in which case we take $m_r = -2$).
Subcases of Somos-6 when $N = 6$: if we choose $m_1 = 1$, $m_2 = -1$, $m_3 = 0$, the full quiver is $P_6^{(1)} - P_6^{(2)} + P_4^{(1)}$ (see figure 6(a)) and corresponds to the recurrence

$$x_n x_{n+6} = x_{n+1} x_{n+5} + x_{n+2} x_{n+4}.$$  \tag{2.12}

If we choose $m_1 = 1$, $m_2 = 0$, $m_3 = -2$, the full quiver is $P_6^{(1)} - 2P_6^{(3)} + 2P_2^{(2)}$ (see figure 6(b)) and corresponds to the recurrence

$$x_n x_{n+6} = x_{n+1} x_{n+5} + x_{n+3}^2.$$  \tag{2.13}

If we choose $m_1 = 0$, $m_2 = 1$, $m_3 = -2$, the full quiver is $P_6^{(2)} - 2P_6^{(3)} + 2P_2^{(1)}$ (see figure 6(c)) and corresponds to the recurrence

$$x_n x_{n+6} = x_{n+2} x_{n+4} + x_{n+3}^2.$$  \tag{2.14}

2.4. Period 2 quivers

Already at period 2, we cannot give a full classification of the possible quivers. However, we can give the full list for low values of $N$, the number of nodes. We can also give a class of period 2 quivers which exists for all $N$.

Whereas period 1 quivers gave rise to recurrences in a single variable $x_n$, period 2 quivers give us two components $(x_n, y_n)$.

2.4.1. A family of period 2 solutions. It is possible to modify the derivation of the general period 1 quiver, to incorporate an involution so as to give a corresponding family of period 2 quivers.

We start with a skew-symmetric matrix whose first column is of the form $(0, m_1, \ldots, m_{N-1})^T$ and impose the condition $m_{N-r} = m_r$, $r \neq 1$ and $m_{N-1} = m_1 \neq m_0$. We require $c_{11} = 0$, so assume both $m_1 \geq 0$ and $m_0 \geq 0$. We write $B = B(m) = B(m_1, m_2, \ldots, m_{N-2}, m_1)$ and define $\sigma(m) = \sigma(m_1, m_2, \ldots, m_{N-2}, m_1) = (m_N, m_{N-1}, \ldots, m_2, m_1)$. 

Figure 6. Quivers giving subcases of Somos-6.
We construct a matrix $B = B(m)$ which satisfies the equation

$$\mu_1(B) = \rho B(\sigma(m))\rho^{-1}. \quad (2.15)$$

Since $\sigma$ is an involution, we obtain period 2 solutions in this way. This condition leads to the formula

$$b_{ij} = \sigma(b_{i-1,j-1}) + \varepsilon_{j-1,i-1}, \quad (2.16)$$

with which we iteratively build the matrix $B$ from the left column. Condition (2.15) also implies that $(b_1, b_{N,1}, \ldots, b_{N,N-1}) = \sigma(m)$, which acts as a boundary condition for the difference equation (2.16). This puts constraints on the possible values of $m_i$. We require $m_i \geq 0$ for $r$ odd, $r \geq 3$ and, in addition, $m_2 = -1$ for $N$ odd. To achieve non-trivial mutation, we must choose at least one of the $m_i < 0$, for $r$ even.

**Example 2.17** (The 4 node case). We take $m_1 = r > 0, m_2 = -s < 0, m_3 = m_1 = t > 0$, with $t \neq r$ and easily construct

$$B(1) = \begin{pmatrix} 0 & -r & s & -t \\ r & 0 & -t - rs & s \\ -s & t + rs & 0 & -r \\ t & -s & r & 0 \end{pmatrix}, \quad B(2) = \begin{pmatrix} 0 & r & -s & t \\ -r & 0 & -t & s \\ s & t & 0 & -r - st \\ -t & -s & r + st & 0 \end{pmatrix},$$

satisfying (2.15).

**Example 2.18** (The 5 node case). We take $m_1 = r > 0, m_2 = -1, m_3 = m_1 = t > 0$, with $t \neq r$ and easily construct

$$B(1) = \begin{pmatrix} 0 & -r & 1 & 1 & -t \\ r & 0 & -r - t & 1 - r & 1 \\ -1 & r + t & 0 & -r - t & 1 \\ -1 & r - 1 & r + t & 0 & -r \\ t & -1 & -1 & r & 0 \end{pmatrix}, \quad B(2) = \begin{pmatrix} 0 & r & -1 & -1 & t \\ -r & 0 & -t & 1 & 1 \\ 1 & t & 0 & -r - t & 1 - t \\ 1 & -1 & r + t & 0 & -r - t \\ -t & -1 & t - 1 & r + t & 0 \end{pmatrix}, \quad (2.17)$$

satisfying (2.15).

2.4.2. ‘Exceptional’ period 2 solutions. For low values of $N$ it is possible to determine all period 2 quivers. For $N \geq 5$ there exist quivers that are not in the ‘regular’ class, described in section 2.4.1. We call these ‘exceptional solutions’. I give one example here.

$$\rho^{-1}Q(2) \xrightarrow{\mu_1} \rho Q(1) \xrightarrow{\mu_2} \rho\rho^{-1}Q(2) \xrightarrow{\mu_3} \rho^{-1}Q(2) \xrightarrow{\mu_4} \rho^2 Q(2) \xrightarrow{\mu_5} \rho^2 Q(1) \xrightarrow{\mu_6} \rho^2 Q(2) \xrightarrow{\mu_7} \rho^2 Q(2) \xrightarrow{\mu_8} \rho^3 Q(2) \xrightarrow{\mu_9} \rho^3 Q(2).$$

**Figure 7.** Period 2 quivers and mutations.
Example 2.19  (An exceptional, period 2, 5 node quiver). Here we have

\[
B(1) = \begin{pmatrix}
0 & -m_1 & -1 & -m_1 - 1 & 1 \\
m_1 & 0 & 1 & -m_1 - 1 & -m_1 - 1 \\
1 & -1 & 0 & 0 & -1 \\
m_1 + 1 & m_1 + 1 & -1 & 0 & -m_1 \\
-1 & m_1 + 1 & m_1 & 0 & 
\end{pmatrix},
\]

\[
B(2) = \begin{pmatrix}
0 & m_1 & 1 & m_1 + 1 & -1 \\
-m_1 & 0 & 1 & -m_1 - 1 & -1 \\
-1 & -1 & 0 & 1 & 0 \\
-m_1 - 1 & m_1 + 1 & -1 & 0 & 1 \\
1 & 1 & 0 & -1 & 0 
\end{pmatrix}. \tag{2.18}
\]

2.4.3. Recurrences from period 2 solutions. Consider (2.7), with \( m = 2 \). The configuration of arrows at node 2 of \( Q(2) \) will be different from that at node 1 of \( Q(1) \), so the cluster exchange relation will be different. However, node 3 of \( Q(3) = \rho^3Q(1) \) will have the same configuration of arrows as node 1 of \( Q(1) \). Hence, after two mutations we obtain the same formula, but with the index shifted. The result is that we have a pair of formulae which alternate as we go around the nodes. It is thus natural to relabel the cluster variables accordingly.

Labelling the odd and even nodes by \( x \) and \( y \), we start with an initial cluster \((x_1, y_1, x_2, y_2, \ldots)\) at nodes 1, 2, 3, 4, .... We see immediately that there is a ‘mismatch’ if \( N \) is odd. This has a consequence for the initial value problem. When \( N = 2m \), the recurrence is of order \( m \). When \( N = 2m - 1 \), the recurrence is again of order \( m \), but the first exchange relation plays the role of a boundary condition.

Example 2.20  (The 4 node case). For example 2.17, we combine the two formulae to give a recurrence \((x_n, y_n) \mapsto (x_{n+2}, y_{n+2})\), given by

\[
x_n x_{n+2} = y_n^r y_{n+1}^s + x_n^s, \quad y_n y_{n+2} = x_n^r + 2x_n^s + y_n^s = \left(\frac{y_n^r y_{n+1}^s + x_n^s}{x_n^r}\right) x_{n+1}^r + y_{n+1}^r. \tag{2.19}
\]

Remark 2.21. We can construct a different recurrence by first rotating \( B(2) \), with \( B(2) \mapsto \rho^{-1} B(2) \rho \) (so node 2 becomes node 1). Mutation at this new node 1 then gives a rotated version of the old quiver \( Q(1) \), so we just cycle through the same pair of quivers (see figure 7). The rotation \( \rho^{-1} Q(2) \) is just \( Q(1) \) with \( r \leftrightarrow t \), so the second form of the recurrence is just (2.19), with \( r \leftrightarrow t \).

Example 2.22  (A 5 node case). Consider the case with matrices (2.17). The same procedure leads first to the relation

\[
x_1 y_1 = y_1^r x_3^s + x_3 y_2,
\]
after which the variables satisfy a third order (two-component) recurrence

\[ y_n x_{n+3} = y_{n+1} x_{n+1} + x_{n+2} y_{n+1}, \quad x_{n+1} y_{n+3} = x_{n+1} y_{n+1} + x_{n+2} y_{n+1}, \]  

(2.20)

where \( n = 1, 2, \ldots \). We start with initial conditions \( (x_1, y_1, x_2, y_2, x_3) = (c_1, c_2, c_3, c_4, c_5) \). The first relation gives \( y_3 \), which is the sixth initial condition required for the recurrence (2.20).

As above, it is possible to construct a companion recurrence, corresponding to the choice

\[ \tilde{B}(1) = \rho^{-1} B(2) \rho, \quad \tilde{B}(2) = \rho B(1) \rho^{-1}. \]

3. Symmetries and complete integrability

The main purpose of this section is to arrive at a general definition of complete integrability for a discrete dynamical system defined by a map. This definition requires the notion of a continuous symmetry, so we first discuss the Lie bracket and commutativity of vector fields. The culmination of this part of the discussion is Lie’s Theorem, which states that in \( n \) dimensions, \( n \) commuting vector fields form a completely integrable system, and can be simultaneously straightened.

When applied to a Hamiltonian system, this leads to Liouville’s Theorem of complete integrability. For this part of the discussion we first give the general definition of a Poisson bracket and Poisson manifold. Poisson commutativity of two functions gives the commutativity of the corresponding Hamiltonian vector fields. For complete integrability of a map we require some additional invariance properties.

In the case of cluster maps, the matrix \( B \) defines a pre-symplectic structure, which is invariant under the action of the map when \( B \) is mutation periodic. This then enables the construction of an invariant Poisson bracket, possibly after the reduction to a lower dimensional space.

3.1. The Lie bracket and commuting vector fields

Let \( M \) be an \( n \)-dimensional manifold, and suppose \( (x_1, \ldots, x_n) \) is a local coordinate system at point \( p \in M \). Any collection of smooth functions \( \{X_i(x)\}_{i=1}^n \) in some neighbourhood of \( M \) defines a smooth vector field, which we can associate with a first order partial differential operator (acting on smooth functions \( f: M \to \mathbb{R} \))

\[ X_i = \sum_{j=1}^n \frac{\partial}{\partial x_j} \frac{d}{dx_i} \]  

(3.1)

Integral curves are any trajectories \( x_i(t) \), satisfying \( \frac{dx_i}{dt} = X_i \).

Definition 3.1 (The commutator). The commutator \( [X, Y] = X \circ Y - Y \circ X \) of two vector fields, \( X = \sum_{i=1}^n X_i \frac{\partial}{\partial x_i} \) and \( Y = \sum_{i=1}^n Y_i \frac{\partial}{\partial x_i} \), is the vector field with components:

\[ [X, Y]_i = \sum_{j=1}^n \left( X_j \frac{\partial Y_j}{\partial x_i} - Y_j \frac{\partial X_j}{\partial x_i} \right) = X(Y_i) - Y(X_i). \]  

(3.2)
The commutator is also called the Lie bracket. It is bilinear, skew-symmetric and satisfies the Jacobi identities, so defines a Lie algebraic structure on vector fields.

Clearly, the coordinate vector fields \( e_i = \frac{\partial}{\partial x_i} \) commute: \( [e_i, e_j] = 0 \). This means that their respective integral curves can be used as coordinate curves, since, from a given initial point, we unambiguously arrive at the same point, by following first one and then the other, regardless of the order we choose. Furthermore, if two vector fields commute \( \{X, Y\} = 0 \), then this property still holds, which means that we can simultaneously straighten the vector fields. This means that there exist coordinates \( y_\mu \), such that \( X = \frac{\partial}{\partial y_1} \) and \( Y = \frac{\partial}{\partial y_2} \). Generally, we have:

**Theorem 3.2** (Complete integrability (Lie’s theorem)). Let \( X_1, \ldots, X_n \) be \( n \) independent vector fields on \( \mathbb{R}^n \):

\[
X_i = \sum_{j=1}^{n} a_{ij} \frac{\partial}{\partial x_j}.
\]

If \( [X_i, X_j] = 0 \), for all \( i, j \), then we can **simultaneously straighten** these \( n \) vector fields.

**Proof.** Our task is to solve the linear equations

\[
X_i Y_j = \delta_{ij} \Rightarrow \sum_{i=1}^{n} a_{ik} \frac{\partial y_j}{\partial x_k} = \delta_{ij},
\]

which reduce to

\[
\frac{\partial y_j}{\partial x_i} = b_{ij}, \quad \text{where} \quad B = A^{-1}.
\]

The integrability conditions:

\[
\frac{\partial b_{ij}}{\partial x_k} = \frac{\partial b_{ik}}{\partial x_j}
\]

are guaranteed by the commutativity of the vector fields. Since \( b_{ij} \) are just functions of \( x \), this reduces to quadratures, which can be explicitly integrated for simple vector fields. \( \square \)

### 3.2. Poisson manifolds

We now suppose there exists an algebraic operation \( \{f, g\} \) between functions on \( M \), possessing the following properties, thus defining a Poisson bracket on \( M \).

**Definition 3.3** (A Poisson bracket). Let \( f, g \) and \( h \) be functions, \( \alpha \) and \( \beta \) constants. Then the operation \( \{f, g\} \) is said to be a Poisson bracket if the following properties hold:

1. **Bilinearity:** \( \{\alpha f + \beta g, h\} = \alpha \{f, h\} + \beta \{g, h\} \)
2. **Skew symmetry:** \( \{f, g\} = -\{g, f\} \)
3. **Jacobi identity:** \( \{\{f, g\}, h\} + \{\{g, h\}, f\} + \{\{h, f\}, g\} = 0 \)
4. **Leibnitz rule:** \( \{fg, h\} = \{f, h\} g + f \{g, h\} \)

The first three define a Lie algebra on the functions on \( M \). The fourth guarantees the existence of a Hamiltonian vector field.
\[ X_{sf} = \{ f, h \} \implies X_{s(fg)} = (X_{sf})g + f(X_{sg}). \]

**Definition 3.4** (Poisson tensor). The Poisson tensor \( P(x) \), is defined by its matrix of coefficients:
\[ P = \begin{pmatrix} x_i, x_j \end{pmatrix}, \]
which is skew-symmetric: \( P_{ij} = -P_{ji} \).

**Remark 3.5** The Poisson tensor is a bivector so in standard tensor notation would have upper indices (as should \( x_k \)), but we have avoided this notation here. This accounts for the formula for the Lie derivative, given below.

The Jacobi identity implies:
\[ \{ \{ x_i, x_j \}, x_k \} + \{ \{ x_j, x_k \}, x_i \} + \{ \{ x_k, x_i \}, x_j \} = 0, \quad \text{for } i < j < k, \]
which then imply
\[ \sum_{\ell=1}^{n} \left( \frac{\partial P_{\ell i}}{\partial x_{\ell}} + \frac{\partial P_{\ell j}}{\partial x_{\ell}} + \frac{\partial P_{\ell k}}{\partial x_{\ell}} \right) = 0, \quad \text{for } i < j < k. \quad (3.5) \]

These conditions are implied by the properties given in the definition of an abstract Poisson bracket. In applications, we define a (specific) Poisson bracket by presenting a skew-symmetric matrix \( P_{ij} \), satisfying conditions (3.5).

The \( \ell \)th component of \( X_h \) is just \( X_{h x_i} = \{ x_i, h \} = P_{ij} \frac{\partial h}{\partial x_j} \), so the Hamiltonian vector field and Poisson bracket formulae are given by
\[ X_h = \sum_{i,j=1}^{n} P_{ij} \frac{\partial h}{\partial x_j} \frac{\partial}{\partial x_i}, \quad \text{and} \quad \{ f, h \} = \sum_{i,j} \frac{\partial f}{\partial x_i} P_{ij} \frac{\partial h}{\partial x_j}. \quad (3.6) \]

**Definition 3.6** (Casimirs and rank of a Poisson tensor). Suppose the rank of the Poisson tensor \( P \) is \( 2r \), so \( n = 2r + m \). When \( m = 0 \), the Poisson bracket is non-degenerate and its inverse defines a symplectic form. If \( m > 0 \) and the \( m \) null vectors can be written as gradients of some functions \( \varphi_k, k = 1, \ldots, m \), then these functions are said to be Casimirs. The Casimir functions satisfy
\[ \{ f, \varphi_k \} = 0 \quad \text{for arbitrary function } f. \]

**The Lie derivative of a Poisson tensor along** \( X \) **is defined by the formula**
\[ (L_X P)_{ij} = \sum_k \left( X_i \frac{\partial P_{kj}}{\partial x_k} - P_{ik} \frac{\partial X_j}{\partial x_k} - P_{jk} \frac{\partial X_i}{\partial x_k} \right). \]

In the particular case of \( X_h \), we have
\[ (L_{X_h} P)_{ij} = -\sum_{\ell} \left( P_{i\ell} \frac{\partial P_{\ell j}}{\partial x_k} + P_{j\ell} \frac{\partial P_{\ell i}}{\partial x_k} + P_{\ell \ell} \frac{\partial h}{\partial x_k} \right) \frac{\partial h}{\partial x_{\ell}}. \]

We can interpret this formula in two ways:
1. If $P$ is a Poisson tensor, then for any Hamiltonian vector field $X_h$, $L_{X_h}P = 0$.

2. If for any function $h$, $L_{X_h}P = 0$, where $X_h$ is defined by formula (3.6), for some skew-symmetric (contravariant) tensor $P$, then $P$ satisfies the Jacobi identities, so defines a Poisson bracket.

3.2.1. The commutator of two Hamiltonian vector fields. To each function $f(x)$ there corresponds a Hamiltonian vector field (3.6). The commutator of two such vector fields is defined by (3.2). The Jacobi identities give us an important relation between two Lie algebras.

**Theorem 3.7.** If $f$ and $g$ are any 2 functions on phase space, then:

$$\left[ X_f, X_g \right] = -X_{\{ f, g \}}.$$  \hspace{1cm} (3.7)

We thus have that the commutator of 2 Hamiltonian vector fields is not just a vector field, but also Hamiltonian. The formula (3.7) is perhaps the most important consequence of the Jacobi identities, giving us that the flows generated by Poisson commuting functions commute:

$$\{ f, g \} = 0 \implies \left[ X_f, X_g \right] = 0.$$ \hspace{1cm} (3.8)

3.2.2. Complete integrability of a Hamiltonian system. We now describe Liouville integrability, which is a corollary to Lie’s theorem 3.2. See [3, 5] for more details.

We start with a Poisson tensor $P$ of rank $2r$ $(n = 2r + m)$, with $m$ Casimir functions $C_i, i = 1, \ldots$ satisfying $[C_i, f] = 0$, for all functions $f(x)$. This last statement means that all Hamiltonian flows generated by $P$ are tangent to the level surfaces of $C_i$, of dimension $2r$:

$$M_i = \{ x \in M: C_i = s_i \}, \quad s_i \text{ constants},$$

determined by the initial conditions. The matrix $\frac{\partial^2 P_{ij}}{\partial x^i \partial x^j}$, $i = 1, \ldots, n, j = 1, \ldots, m$ will have maximum rank $m$ almost everywhere. This condition will fail at most on some lower dimensional surfaces within $M$. The regular open regions of maximal rank are foliated by the surfaces $M_i$, called symplectic leaves. If we use $C_i$ as local coordinates in such a region, then the matrix $P$ will have a $2r \times 2r$ non-degenerate block, with the remainder of the matrix being an array of zeros.

Now consider such a symplectic leaf, with local coordinates $x_1, \ldots, x_{2r}$. Suppose we now have $r$ independent functions $h_i, i = 1, \ldots, r$ (again the matrix $\frac{\partial h_i}{\partial x^j}$, $i = 1, \ldots, 2r, j = 1, \ldots, r$ must be of maximal rank $r$), which are in involution:

$$\{ h_i, h_j \} = 0, \quad \text{for all } i, j = 1, \ldots, r.$$ \hspace{1cm} (3.9)

If this is written

$$X_{h_i} h_j = 0, \quad \text{for } i = 1, \ldots, r,$$

we see that, for each $j = 1, \ldots, r$, $X_{h_j}$ is tangent to the level surface

$$M_i = \{ x \in M_i: h_j(x) = c_j \}, \quad c_j \text{ constants},$$

determined by initial conditions. Furthermore, by (3.7), the $r$ vector fields $X_{h_j}$ commute on this $r$ dimensional surface $M_i$. By Lie’s theorem 3.2 these vector fields form a completely integrable system, so can be ‘simultaneously straightened’, forming coordinate curves within $M_i$. 

18
Theorem 3.8 (Liouville integrability). Let $h_1, \ldots, h_r$ be $r$ independent functions, satisfying (3.9) on the $2r$ dimensional manifold $M_r$. Then each of the Hamiltonian systems defined by the vector fields $X_{h_i}$ is completely integrable.

Remark 3.9. This discussion has been ‘formal’ in the sense that I have not considered global conditions, such as the completeness of the trajectories of $X_{h_i}$ within the surface $M_r$. When $M_r$ is compact, then it is topologically a torus and it is possible to build action-angle variables. See [5] for a careful analysis of this.

3.2.3. Bi-Hamiltonian systems. Within the context of soliton theory and the ‘Lenard scheme’ the notion of bi-Hamiltonian systems was introduced in [17, 26] (see also [2, 7, 29]). Here we just present some basic facts, which find use in the discussion of section 6.4.

Let $P_1$ and $P_2$ define Poisson tensors (see definition 3.4) on a given Poisson manifold.

Definition 3.10 (Compatible Poisson brackets). The matrices $P_1$ and $P_2$ are said to be compatible Poisson tensors if $P_1$, $P_2$ and $P = P_1 + P_2$ satisfy the Jacobi identities (3.5). We can then define the following Poisson brackets:

$$\{f, g\}_1 = \nabla f P_1 \nabla g, \quad \text{and} \quad \{f, g\}_2 = \nabla f (P_1 + P_2) \nabla g.$$  

Typically, both Poisson brackets will be degenerate, allowing us to define a bi-Hamiltonian ladder, starting with a Casimir function of $P_1$ and ending with one of $P_2$:

$$P_i V h_i = 0, \quad P_i V h_i = P_i V h_{i-1}, \quad \text{for} \quad 2 \leq k \leq M, \quad \text{and} \quad P_i V h_M = 0, \quad (3.10)$$

for some $M$. It is possible to start with the Casimir $h_1$ of $P_i$ and use the ladder relations to successively construct $h_k$ for $k > 1$. When we reach $h_M$ the ladder relations stop, with $P_2 V h_M = 0$.

To prove complete integrability, we use the following result.

Lemma 3.11 (Bi-Hamiltonian relations). With the Poisson brackets given by definition 3.10, the functions $h_1, \ldots, h_M$ satisfy

$$\{h_i, h_j\}_1 = \{h_i, h_{j-1}\}_2 \quad \text{and} \quad \{h_i, h_j\}_2 = \{h_{i+1}, h_j\}_1.$$  

Proof. The ladder relations (3.10) imply

$$\{h_i, h_j\}_1 = \nabla h_i P_1 \nabla h_j = \nabla h_i P_2 \nabla h_{j-1} = \{h_i, h_{j-1}\}_2,$$

and the second formula follows from this after writing $\{h_j, h_{i+1}\}_1 = \{h_j, h_i\}_1$. □

Theorem 3.12 (Complete integrability). The functions $h_1, \ldots, h_M$ are in involution with respect to both of the above Poisson brackets

$$\{h_i, h_j\}_1 = \{h_i, h_{j-1}\}_2 = 0, \quad \text{and hence} \quad \{h_i, h_j\}_2 = 0.$$  

It then follows from Liouville’s theorem 3.8 that the functions $h_1, \ldots, h_M$ define a completely integrable Hamiltonian system.
**Proof.** Without loss of generality, choose $i < j$. Then
\[
\{ h_i, h_j \}_1 = \{ h_i, h_{j-1} \}_2 = \{ h_{i+1}, h_{j-1} \}_1 = \cdots = \{ h_i, h_k \}_\ell = 0,
\]
for some $k, \ell$. Similarly
\[
\{ h_i, h_j \}_2 = \{ h_{i+1}, h_j \}_1 = \{ h_{i+1}, h_{j-1} \}_2 = \cdots = \{ h_k, h_1 \}_1 = 0,
\]
for some $k, \ell$.

We can arrange the ladder relations to form
\[
(P_1 + P)(V h_{M-1} + V h_{M-2} - \cdots + (-1)^{M+1} V h_1) = 0,
\]
so
\[
C = h_M - h_{M-1} + h_{M-2} - \cdots + (-1)^{M+1} h_1
\]
is the Casimir function of the Poisson matrix $P$. Such a formula arises in our discussion of section 6.

### 3.2.4. Super-integrability of a Hamiltonian system
On the symplectic leaves of dimension $2r$ we can have at most $r$ Poisson commuting functions (in which case we have complete integrability). However, we can have up to $2r - 1$ independent functions Poisson commuting with a single function $H$. When we have $s$ independent functions $\{ f_k, k = 1, \ldots, s \}$, with $r < s \leq 2r - 1$, then the system is said to be super-integrable. When $s = 2r - 1$, $H$ is said to be maximally super-integrable. In this case, the trajectories of $X_H$ must lie in the common level set of $2r - 1$ functions. Since the latter is itself 1-dimensional, this common level set (determined by initial conditions) is just the trajectory itself and (in principle) is determined algebraically by solving the
\[
f_k = c_k, \quad k = 1, \ldots, 2r - 1.
\]
Well-known examples of super-integrable systems are the isotropic harmonic oscillator, the Kepler system (additional integrals coming from the Runge–Lenz vector) and the Calogero-Moser system with inverse square potential. The additional integrals are often called ‘hidden symmetries’.

### 3.3. Liouville integrability of a map
We now consider a map $\varphi: M \to M$ in the context of Poisson manifolds. We generalize the idea of a ‘canonical transformation’. We write
\[
(x_1, \ldots, x_n) \mapsto (\tilde{x}_1, \ldots, \tilde{x}_n), \quad \text{with} \quad \tilde{x}_i = \varphi_i(x_1, \ldots, x_n).
\]
Now suppose $P$ defines a Poisson bracket, with $\{ x_i, x_j \} = P_{ij}$. Then
\[
\{ \tilde{x}_i, \tilde{x}_j \} = \{ \varphi_i(x_1, \ldots, x_n), \varphi_j(x_1, \ldots, x_n) \}.
\]
The right-hand side of this is a function of $(x_1, \ldots, x_n)$.
If it can be written explicitly in terms of the variables $(\tilde{x}_1, \ldots, \tilde{x}_n)$, then we can define
\[
\tilde{P}_{ij} = \{ \tilde{x}_i, \tilde{x}_j \}.
\]
This means

\[ \dot{P} = \frac{\partial \xi}{\partial x} \left( \frac{\partial P}{\partial x} \right)^T. \]

**Definition 3.13** (Invariant Poisson bracket). If \( P_x = \{ x_i, x_j \} \) and \( \dot{P}_x = \{ \dot{x}_i, \dot{x}_j \} \) have the same functional form of their respective arguments, then the Poisson bracket defined by \( P \) is said to be invariant under the action of the map.

**Definition 3.14** (Invariant function). A function \( f: M \rightarrow R \) is said to be invariant under the map \( \phi: M \rightarrow M \), if \( f \circ \phi = f \).

The notion of complete integrability of a Poisson map was introduced in [25, 34].

**Definition 3.15** (Complete integrability of a Poisson map). Let \( M \) be a Poisson manifold with coordinates \( x_1, \ldots, x_n \) and Poisson matrix \( P \), rank \( 2r \). Suppose \( P \) is invariant under the map \( \phi: M \rightarrow M \) and that the Casimir functions \( C_k \), \( k = 1, \ldots, m \) are themselves invariant:

\[ C_k \circ \phi = C_k \quad \text{for each } k. \]

Suppose further that there exist \( r \) independent, invariant functions \( h_i \), \( i = 1, \ldots, r \), which are in involution with respect to the Poisson bracket defined by \( P \):

\[ \{ h_i, h_j \} = 0 \quad \text{for all } i, j. \]

Then the map \( \phi \) is said to be Liouville integrable.

Since the Casimir functions are invariant, each orbit of the map is on one particular symplectic leaf \( M_c \). Since the functions \( h_i \), \( i = 1, \ldots, r \), are invariant, the orbit is further restricted to lie on \( M_{c_i} \), for values of \( c_i \) determined by initial conditions. Since \( \{ h_i, h_j \} = 0 \), the vector fields \( X_{h_i} \) commute.

Since the Poisson bracket, its Casimir functions and the functions \( h_i \) are all invariant, the map commutes with the continuous flows of \( X_{h_i} \). These continuous flows are therefore continuous symmetries of the map.

**Remark 3.16** (Connected components). The manifolds \( M_c \) are often not connected. Whilst the above continuous flows must lie entirely within a single connected component, the commuting map can jump between components.

Unlike the continuous case, we cannot think of the map as some combination of ‘time-advance maps’ of the commuting flows.

**Remark 3.17** (Invariance of Casimir functions). If \( P_{\xi} = \{ x_i, x_j \} \) is degenerate, its Casimir functions are not guaranteed to be invariant, so the trajectory of the map may not lie within a symplectic leaf, in which case we cannot deduce Liouville integrability. See example 3.20 below.

**Remark 3.18** (Super-integrability). Each symplectic leaf \( M_c \) has dimension \( 2r \). We have seen that there exist super-integrable continuous systems with at most \( 2r - 1 \) first integrals,
since the common level set is already 1-dimen-
sional and hence just the (unparameterized) tra-
jectory of $X_{H}$. We can also have super-integrable discrete systems, but in this case it is even possible to have $2r$ first integrals, whose common set consists of a finite number of points. In such cases the map is periodic. Conversely, given a periodic map $\varphi$ (period $p$), any function $f(x)$ will generate a finite sequence of functions $f(x), f(\varphi(x)), \ldots, f(\varphi^{p-1}(x))$, any cyclically symmetric combination of which represents a first integral. In this way we can construct $2r$ independent first integrals.

### 3.4. Log-canonical brackets for cluster mutations

In [15] it was shown that very general cluster algebras admit a linear space of Poisson brackets of log-canonical type, compatible with the cluster maps generated by mutations, and having the form

$$\{x_j, x_k\} = c_{jk} x_j x_k,$$

(3.13)

for some skew-symmetric constant coefficient matrix $C = (c_{jk})$. Compatibility of the Poisson structure means that the cluster transformations $\mu_i$ given by (2.2) correspond to a change of coordinates, $x^i = \mu_i(x)$, with their bracket also being log-canonical,

$$\{\tilde{x}_j, \tilde{x}_k\} = \tilde{c}_{jk} \tilde{x}_j \tilde{x}_k,$$

for another skew-symmetric constant matrix $\tilde{C} = (\tilde{c}_{jk})$.

If we regard the cluster transformation as a birational map $x \mapsto \tilde{x} = \varphi(x)$ in $\mathbb{C}^N$, and require a Poisson structure that is invariant with respect to $\varphi$ (not just covariant), then we require $\tilde{C} = C$. However, there may not be a non-trivial log-canonical Poisson bracket that is covariant or invariant under cluster transformations.

#### Example 3.19

Corresponding to the 3 node period 1 primitive $P_3^{(1)}$, the matrix $B$ and birational map on $\mathbb{C}^3$ are given by

$$B = \begin{pmatrix} 0 & -1 & -1 \\ 1 & 0 & -1 \\ 1 & 1 & 0 \end{pmatrix}, \quad \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} \mapsto \begin{pmatrix} x_2 \\ x_3 \\ (x_2 x_3 + 1)/x_1 \end{pmatrix}.$$

(3.14)

It is easy to see that there is no invariant Poisson bracket of the form (3.13). However, we will see that it is possible to reduce (3.14) to a map acting on a 2-dimensional space on which there does exist a log-canonical bracket.

Even when it is possible to find such a Poisson bracket it may not be the ‘correct bracket’ for discussing complete integrability, since we require that any Casimir functions be invariant under the map.

#### Example 3.20

(Invariant Poisson bracket for the Somos-4 map). The Somos-4 map is

$$\varphi: \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} \mapsto \begin{pmatrix} x_2 \\ x_3 \\ x_4 \\ x_2 x_4 + x_3^2 \end{pmatrix}/x_1.$$

(3.15)
which preserves the log-canonical Poisson bracket (see [19])

\[
\{ x_j, x_k \} = c_{jk} x_j x_k, \quad \text{where} \quad C = \begin{pmatrix}
0 & 1 & 2 & 3 \\
-1 & 0 & 1 & 2 \\
-2 & -1 & 0 & 1 \\
-3 & -2 & -1 & 0
\end{pmatrix}.
\] (3.16)

This has rank 2, with two independent null vectors

\[
m_1 = (1, -2, 1, 0)^T, \quad m_2 = (0, 1, -2, 1)^T,
\]

providing two independent Casimir functions for the bracket:

\[
y_1 = \frac{x_1 x_3}{x_2^2}, \quad y_2 = \frac{x_2 x_4}{x_3^2}.
\]

The map (3.15) induces the following map on the 2-dimensional \(y\)-space, \(Q\):

\[
\tilde{\phi}: \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \mapsto \begin{pmatrix} y_2 \\ (y_1 + 1)/(y_1 y_2^2) \end{pmatrix},
\] (3.17)

which is of QRT type [32] (a well known class of integrable maps), and preserves the log-canonical bracket

\[
\{ y_1, y_2 \}_Q = y_1 y_2.
\] (3.18)

A similar result holds for the Somos-5 map (see [11]).

The finding of Poisson brackets such as (3.16) is ad hoc, by assuming a bracket of general form (3.13) and using the map to fix the values of \(c_{ij}\) (if possible!). This bracket can turn out to be unsuitable, with non-invariant symplectic leaves. In the case of Somos-4, the associated Liouville integrable map is not (3.15) at all, but the induced map on the Casimir functions, for which another Poisson bracket had to be found by ad hoc calculations.

In fact, it is possible to systematically construct all these Poisson brackets from a knowledge of the matrix \(B\), which defines the original periodic quiver. In the next section we consider an invariant two-form in the variables \(x_j\), which naturally exists for any cluster map.

### 4. Symplectic maps from cluster recurrences

Given a recurrence, a major problem is to find an appropriate symplectic or Poisson structure which is invariant under the action of the corresponding finite-dimensional map. Remarkably, in the case of cluster recurrences (from mutation periodic quivers) this problem can be solved algorithmically.

For the period \(m\) case, we need to combine the sequence of \(m\) mutations to form a map which preserves \(B(1)\). Most of the discussion below is concerned with the period 1 case, but some period 2 examples are presented.

#### 4.1. Maps from period 1 recurrences

Given a period 1 quiver, with matrix \(B\), the cluster recurrence (2.10) corresponds to the map \(\phi: \mathbb{C}^N \to \mathbb{C}^N\), given by
One can decompose the map (4.1) as \( \phi = \rho^{-1} \circ \mu_i \), where in terms of the cluster \( x = (x_j) \) the map \( \mu_i \) sends \( (x_1, x_2, \ldots, x_N) \) to \( (\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_N) \), with \( \tilde{x}_i \) defined according to the exchange relation (2.2) with \( k = 1 \), and \( \rho^{-1} \) sends \( (x_1, x_2, \ldots, x_N) \) to \( (x_2, \ldots, x_N, x_1) \). We have already seen examples of this in (3.14) and (3.15).

Given the same skew-symmetric matrix \( B \), one can define the log-canonical two-form

\[
\omega = \sum_{j<k} \frac{b_{jk}}{x_j x_k} \, dx_j \wedge dx_k,
\]

which is just the constant skew-form \( \omega = \sum_{j<k} b_{jk} \, dz_j \wedge dz_k \), written in the logarithmic coordinates \( z_j = \log x_j \), so it is evidently closed, but may be degenerate. Such a form is called pre-symplectic and is a genuine symplectic form when \( B \) is non-degenerate.

**Remark 4.1** (Covariance versus invariance). In [16] it was shown that for a cluster algebra defined by a skew-symmetric integer matrix \( B \), this two-form is compatible with cluster transformations, in the sense that under a mutation map \( \mu_i : x \mapsto \tilde{x} \), it transforms as \( \mu_i^* \omega = \sum_{j<k} b_{jk} \, d\log \tilde{x}_j \wedge d\log \tilde{x}_k \). It is important for us that for a period 1 quiver, \( \rho \rho^{-1} = -B \), so this 2–form is invariant.

**Lemma 4.2.** Let \( B \) be a skew-symmetric integer matrix, corresponding to a cluster mutation-periodic quiver with period 1.

Then the two-form \( \omega \) is preserved by the map \( \phi \), i.e. \( \phi^* \omega = \omega \).

When \( B \) is non-singular, we define \( C \) to be any convenient integer matrix proportional to \( B^{-1} \) and use this to define a log-canonical Poisson bracket (3.13). Otherwise we must first reduce \( \omega \) to a non-singular form (reduce to a symplectic submanifold).

**Example 4.3** (The 4 node period 1 quiver). For integer values of \( c \geq 0 \), the skew-symmetric matrix

\[
B = \begin{pmatrix}
0 & -1 & c & -1 \\
1 & 0 & -(c+1) & c \\
-c & (c+1) & 0 & -1 \\
1 & -c & 1 & 0
\end{pmatrix},
\]

defines a period 1 cluster mutation-periodic quiver \( Q \), giving rise to the recurrence \( x_{n+4} \equiv (x_n + x_{n+1} + x_{n+2})^2 \). Thus, by lemma 4.2, for each \( c \) the map \( \phi \), given by

\[
\phi : \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} \mapsto \begin{pmatrix} x_2 \\ x_3 \\ x_4 \\ x_3 x_4 + x_2^2 \end{pmatrix},
\]

... continues...
preserves the two-form
\[
\omega = \left( \frac{dx_1 \wedge dx_2}{x_1 x_2} + \frac{dx_1 \wedge dx_4}{x_1 x_4} + \frac{dx_3 \wedge dx_4}{x_3 x_4} \right) + c \left( \frac{dx_1 \wedge dx_3}{x_1 x_3} + \frac{dx_2 \wedge dx_4}{x_2 x_4} \right) - (c + 1) \frac{dx_2 \wedge dx_3}{x_2 x_3}. \tag{4.5}
\]
For \( c \neq 2 \) this is symplectic (\( B \) non-singular) and leads to the log-canonical bracket with
\[
C = \begin{pmatrix}
0 & 1 & c & 1 + c \\
-1 & 0 & 1 & c \\
-c & -1 & 0 & 1 \\
-1 - c & -c & -1 & 0
\end{pmatrix}.
\]
Even when \( c = 2 \) this matrix defines an invariant Poisson bracket for (4.4) and is identical to (3.16).

4.1.1. Reduction to symplectic manifolds. If \( B \) is singular (of rank \( 2r \), with \( N = 2r + m \)) we consider the null distribution of \( \omega \), which (away from the hyperplanes \( x_j = 0 \)) is generated by \( m \) independent commuting vector fields, each of which is of the form
\[
X_u = \sum_{j=1}^N u_j \frac{\partial}{\partial x_j} \quad \text{for} \quad u = (u_j) \in \ker B. \tag{4.6}
\]
Since this is an integrable distribution, Frobenius’ theorem gives local coordinates \( t_1, \ldots, t_m, y_1, \ldots, y_r \) such that the integral manifolds of the null distribution are given by \( y_j = \text{constant}, \ j = 1, \ldots, 2r \). The coordinates \( y_j \) must be common invariants for these commuting vector fields, and can be chosen as linear functions of the logarithmic coordinates \( z_j = \log x_j \), so each \( y \) is of the form
\[
y = x^y := \prod_j x_j^{y_j} \quad \iff \quad (u, v) = 0, \quad \forall \ u \in \ker B,
\]
where \((, ,)\) denotes the standard scalar product.

On the manifold with coordinates \( y_j \), \( \omega \) defines a log-canonical symplectic form
\[
\hat{\omega} = \sum_{j \in I} \hat{b}_j \ dy_j \wedge dy_k. \tag{4.7}
\]

**Example 4.4** (Somos-4). Returning to (4.3), with \( c = 2 \), \( \ker B \) is spanned by the integer column vectors \( u_1 = (1, 1, 1, 1)^T \), \( u_2 = (1, 2, 3, 4)^T \). Then \( B = (\ker B)^T = <v_1, v_2> \), with \( v_1 = (1, -2, 1, 0)^T \), \( v_2 = (0, 1, -2, 1)^T \), whose components provide the exponents for the monomial invariants
\[
y_1 = \frac{x_1 x_3}{x_2^2}, \quad y_2 = \frac{x_2 x_4}{x_3^2}. \tag{4.8}
\]
(These monomials are just two independent Casimirs for the degenerate Poisson bracket (3.16), which can, in fact, be written as the bivector \( u_1 \wedge u_2 \).)

As we already saw, the map (3.15) reduces to the map (3.17), which is of QRT type [32], and preserves the symplectic form
whose ‘inverse’ defines the Poisson bracket (3.18).

For a given example it is straightforward to calculate coordinates $y_i$, such that the $y$-map is birational. In [12] we proved the following theorem, which guarantees the existence of such a birational map.

**Theorem 4.5.** The map $\varphi$ is symplectic whenever $B$ is non-degenerate. For rank $B = 2r \leq N$, there is a rational map $\pi$ and a symplectic birational map $\hat{\varphi}$ such that the diagram

\[
\begin{array}{ccc}
\mathbb{C}^N & \xrightarrow{\varphi} & \mathbb{C}^N \\
\downarrow \pi & & \downarrow \pi \\
\mathbb{C}^{2r} & \xrightarrow{\hat{\varphi}} & \mathbb{C}^{2r}
\end{array}
\]

is commutative, with a log-canonical symplectic form $\omega$ on $\mathbb{C}^{2r}$ that satisfies $\pi^*\omega = \omega$.

### 4.2. Maps from period 2 recurrences

For the period 2 case, we need to combine the sequence of two mutations to form a map which preserves $B(1)$.

**Example 4.6** (The 4 node case). We take the quivers of example 2.17. Recall that we alternate the labels of the cluster variables, with $x_n$, $x_{n+1}$, $x_{n+2}$ at nodes $1$–$4$, respectively. After two mutations we have the recurrence (2.19), which leads to the map

\[
(x_1, x_2, y_1, y_2) \mapsto (x_2, y_2, \tilde{x}_2, \tilde{y}_2), \quad \text{where} \quad \tilde{x}_2 = \frac{y_1^2 + y_2^2 + x_2^2}{x_1}, \quad \tilde{y}_2 = \frac{x_2^2 + y_2^2}{y_2}.
\]

Hence this map has the invariant (pre-)symplectic form (4.2) with matrix $B(1)$, taking the explicit form

\[
\omega = r \frac{dx_1 \wedge dy_1}{x_1y_1} - s \frac{dx_1 \wedge dx_2}{x_1x_2} + t \frac{dx_1 \wedge dy_2}{x_1y_2} + t \frac{dx_2 \wedge dy_1}{x_2y_1} - (r + st) \frac{dx_2 \wedge dy_2}{x_2y_2} + s \frac{dy_1 \wedge dy_2}{y_1y_2},
\]

which is degenerate if and only if $r^2 - s^2 + t^2 + rst = 0$.

**Example 4.7** (The 5 node case). We take the quivers of example 2.18 (with $r = 1$, $t = 0$ for simplicity), with initial cluster variables $x_1$, $x_2$, $y_2$, $z_3$ at nodes $1$–$5$, respectively. After two mutations we obtain the 5-dimensional map

\[
(x_1, x_2, y_2, z_3) \mapsto (x_2, y_2, x_3, \tilde{y}_2, \tilde{x}_3), \quad \text{where} \quad \tilde{y}_2 = \frac{y_1 + x_2x_3}{x_1}, \quad \tilde{x}_3 = \frac{y_1 + x_2x_3 + x_3x_1y_2}{x_1y_1}.
\]

This map has the invariant (pre-)symplectic form (4.2) with matrix $B(1)$, taking the explicit form

\[
\omega = r \frac{dx_1 \wedge dy_1}{x_1y_1} - s \frac{dx_1 \wedge dx_2}{x_1x_2} + t \frac{dx_1 \wedge dy_2}{x_1y_2} + t \frac{dx_2 \wedge dy_1}{x_2y_1} - (r + st) \frac{dx_2 \wedge dy_2}{x_2y_2} + s \frac{dy_1 \wedge dy_2}{y_1y_2},
\]
\[ \omega = \frac{dx_1 \wedge dx_2}{x_1 x_2} + \frac{dx_1 \wedge dy_1}{x_1 y_1} - \frac{dx_2 \wedge dy_2}{x_2 y_2} + \frac{dx_2 \wedge dy_3}{x_2 y_3} + \frac{dx_3 \wedge dx_1}{x_3 x_1}, \]

which is degenerate with null vector \((0, y_1, 0, y_2, 0)\). For the reduced symplectic manifold, we may choose coordinates

\[ q_1 = x_1, \ q_2 = x_2, \ q_3 = x_3, \ q_4 = \frac{y_1}{y_2}, \]

giving

\[ (q_1, q_2, q_3, q_4) \mapsto \left( q_2, q_3, \frac{q_2 q_4 + q_1}{q_3}, \frac{q_3}{q_2 + q_1} \right), \]

and

\[ \omega = \frac{dq_1 \wedge dq_2}{q_1 q_2} - \frac{dq_1 \wedge dq_3}{q_1 q_3} + \frac{dq_2 \wedge dq_3}{q_2 q_3} - \frac{dq_2 \wedge dq_4}{q_2 q_4} - \frac{dq_3 \wedge dq_4}{q_3 q_4}. \]

5. Integrability of cluster maps from periodic quivers

We have seen that each periodic quiver gives rise to a recurrence with the Laurent property. Furthermore, we can write our recurrences as maps on finite dimensional spaces (a space of dimension \(N\) for a period 1 quiver with \(N\) nodes) and these maps possess an invariant pre-symplectic form, given purely in terms of the matrix \(B\) which defines the quiver. All of this is algorithmic.

The next question is much more difficult to answer. \textit{Which of these maps are completely integrable?} We need to first isolate those cases which have some chance of being integrable. We can use one of the ‘tests for integrability’, such as calculating the algebraic entropy. I give a brief description of this for period 1 recurrences.

We then need to analyse those maps which ‘pass’ this test. An important task is to construct the ‘correct number’ of Poisson commuting invariant functions on the (possibly reduced) symplectic manifold of \(\omega\).

5.1. Algebraic entropy and tropical recurrences

The connection between the integrability of maps and various weak growth properties of the iterates has been appreciated for some time (see [34] and references). In the case of rational maps, Bellon and Viallet [4] considered the growth of degrees of iterates, and used this to define a notion of algebraic entropy. Each component of a rational map \(\varphi\) in affine space is a rational function of the coordinates, and the degree of the map, \(d = \deg \varphi\), is the maximum of the degrees of the components. By iterating the map \(n\) times one gets a sequence of rational functions whose degrees grow generically like \(d^n\). At the \(n\)th step one can set \(d_n = \deg \varphi^n\), and then the algebraic entropy \(E\) of the map is defined to be \(E = \lim_{n \to \infty} \frac{1}{n} \log d_n\). Generically, for a map of degree \(d\), the entropy is \(\log d > 0\), but for special maps there can be cancellations in the rational functions that appear under iteration, which means that the entropy is smaller than expected.
It is conjectured that Liouville–Arnold integrability corresponds to zero algebraic entropy. In an algebro-geometric setting, there are plausible arguments which indicate that zero entropy should be a necessary condition for integrability in the Liouville–Arnold sense. In the latter setting, each iteration of the map corresponds to a translation on an Abelian variety (the level set of the first integrals), and the degree is a logarithmic height function, which necessarily grows like $d_n \sim Cn^2$.

Often the algebraic entropy of a map can only be guessed experimentally, by calculating the degree sequence $(d_n)$ up to some large $n$ and doing a numerical fit to a linear recurrence. This is increasingly impractical as the dimension increases, and provides no proof that the linear relation, with its corresponding entropy value, is correct.

The Laurent property for period 1 recurrences implies that the iterates have the factorized form

$$x_n = \frac{N_n(x)}{M_n(x)}, \quad \text{with} \quad N_n \in \mathbb{Z}[x] = \mathbb{Z}[x_1, \ldots, x_N] , \quad M_n = \prod_{j=1}^{N} x_j^{d(j)_n},$$

where the polynomials $N_n$ are not divisible by $x_j$ for $1 \leq j \leq N$, and $M_n$ are Laurent monomials, which leads to the dynamics of the $M_n$ being decoupled from the $N_n$.

This leads to a tropical (or ultradiscrete [28]) analogue of the original nonlinear recurrence (2.10), in terms of the max-plus algebra.

**Proposition 5.1.** For all $n$, the exponent $d_{n+1}^{(j)}$ of each variable in the Laurent monomial $M_n$ satisfies the recurrence

$$d_{n+2} + d_n = \max \left( \sum_{j=1}^{N-1} \left[ b_{j+1} \right] d_{n+j}, \sum_{j=1}^{N-1} \left[ -b_{j+1} \right] d_{n+j} \right),$$

with the initial conditions $d_1 = -1, d_2 = \cdots = d_N = 0$ (up to shifting the index).

**Example 5.2** (Tropical Somos-4). The tropical version of the Somos-4 recurrence is

$$d_{n+4} + d_n = \max \left( d_{n+3} + d_{n+1}, 2d_{n+2} \right).$$  

(5.2)

With initial conditions $d_1 = -1$ and $d_2 = d_3 = d_4 = 0$ this generates a sequence that begins $-1, 0, 0, 1, 1, 2, 3, 3, 5, 6, 7, 9, 10, 12, 14, 15, 18, 20, 22, 25, 27, 30, 33, \ldots$, which are the degrees (in each of the variables $x_1, x_2, x_3, x_4$) of the denominators of the Laurent polynomials generated by (2.6). The preceding sequence has quadratic growth, $d_n \sim Cn^2$ as $n \to \infty$ (consistent with the growth of logarithmic height on an elliptic curve), so that the algebraic entropy is zero.

Using (5.1), together with a number of conjectures from the cluster algebra literature (see [12] for details), we arrive at the following conjecture.

**Conjecture 5.3.** For a birational map given by (4.1), corresponding to a recurrence of the form (2.10), the algebraic entropy is positive if and only if

$$\max \left( \sum_{m_j > 0} m_j, \sum_{m_j < 0} (-m_j) \right) \geq 3.$$

(5.3)
Theorem 5.4. Suppose that conjecture 5.3 holds. Then there are only four distinct cases for which the algebraic entropy is zero, giving the following families of recurrences:

(i) For even $N = 2m$ only, we have the recurrence
\[ x_{n+2m} x_n = x_{n+m} + 1. \] (5.4)

(ii) For each $N \geq 2$ and $1 \leq q \leq \lfloor N/2 \rfloor$, we have the recurrence
\[ x_{n+N} x_n = x_{n+N-q} x_{n+q} + 1. \] (5.5)

(iii) For even $N = 2m$ only, and $1 \leq q \leq m - 1$, we have the recurrence
\[ x_{n+2m} x_n = x_{n+2m-q} x_{n+q} + x_{n+m}. \] (5.6)

(iv) For each $N \geq 2$ and $1 \leq p < q \leq \lfloor N/2 \rfloor$, we have the recurrence
\[ x_{n+N} x_n = x_{n+N-p} x_{n+p} + x_{n+N-q} x_{n+q}. \] (5.7)

The simplest is case (i), where the recurrence (5.4) decouples into $m$ independent copies of the Lyness map: all the orbits are periodic, and the overall period of the sequence of $x_n$ is $5m$.

The families (ii) and (iii) are linearizable and super-integrable and discussed in sections 6 and 7. The family (iv) includes the Somos-4 and 5 recurrences as well as the 3-term Gale–Robinson recurrences and will be discussed in section 8.

This Theorem only concerns period 1 recurrences. There is currently no classification of integrable cases of recurrences associated with higher periodicity.

6. Linearizable recurrences from period 1 primitives

We already saw in theorem 2.11 that the general period 1 quiver is built out of period 1 primitives. It turns out that the period 1 primitives themselves give rise to interesting recurrences. They correspond to case (ii) of theorem 5.4 and can be rewritten as
\[ x_{n+N} x_n = x_{n+p} x_{n+q} + 1, \quad p + q = N. \] (6.1)

When $p$ and $q$ are coprime, the associated quivers can be ‘unfolded’ to be mutation-equivalent to the affine Dynkin quivers $\tilde{A}_{q,p}$, corresponding to the $\tilde{A}_{q,p}^{(1)}$ Dynkin diagram with $q$ edges oriented clockwise and $p$ oriented anticlockwise, while if gcd$(p, q) = k > 1$ so that $p = k\tilde{p}$, $q = k\tilde{q}$, then the quiver is just the disjoint union of $k$ copies of $\tilde{A}_{\tilde{p},\tilde{q}}$. Whilst these quivers are of finite mutation type the corresponding cluster algebras are not finite and the recurrences generate infinite sequences.

Much of the general structure will be discussed for arbitrary $q$, but a detailed description of complete integrability of the associated maps (sections 6.4 and 6.5) is restricted to the case $q = 1$. The key to understanding the complete integrability is the structure of the Poisson algebras generated by some functions $J_n$ and $K_n$, defined by equations (6.4) and (6.5) below. The algebras for the case $q \neq 1$ can be shown to be isomorphic to others for $q = 1$, but the technical details are fairly complicated (see [12]).
6.1. Linear relations with periodic coefficients

We can write the nonlinear recurrence (6.1) in the form

\[
det \Psi_n = 1, \quad \text{where} \quad \Psi_n = \begin{pmatrix} x_n & x_{n+q} \\ x_{n+p} & x_{n+2p} \\ x_{n+q+N} & x_{n+2p+N} \end{pmatrix}.
\]  

Upon forming the matrix

\[
\hat{\Psi}_n = \begin{pmatrix} x_n & x_{n+q} & x_{n+2q} \\ x_{n+p} & x_{n+q+N} & x_{n+2p+N} \\ x_{n+2p} & x_{n+3p+N} & x_{n+2p+2N} \end{pmatrix},
\]  

one can use Dodgson condensation [6] to expand the 3 × 3 determinant in terms of its 2 × 2 minors, as

\[
det \hat{\Psi}_n = \frac{1}{x_{n+N}} \left( det \Psi_n det \Psi_{n+2p} - det \Psi_{n+q} det \Psi_{n+2p+N} \right) = 0,
\]

by (6.2). By considering the right and left kernels of \( \hat{\Psi}_n \), we are led to the following result.

**Lemma 6.1.** The iterates of the recurrence (6.1) satisfy the linear relations

\[
x_{n+2q} - J_0 x_{n+q} + x_n = 0,
\]

\[
x_{n+2p} - K_0 x_{n+p} + x_n = 0,
\]

whose coefficients are periodic functions of period \( p, q \) respectively, that is

\[
J_{n+p} = J_n, \quad K_{n+q} = K_n, \quad \text{for all } n.
\]

In particular, when \( q = 1 \) we have \( K_{n+1} = K_n = K \), constant for all \( n \), so \( x_n \) satisfies a constant coefficient, linear difference equation

\[
x_{n+2N-2} + x_n = K x_{n+N-1}.
\]

**Remark 6.2.** The key idea is that since \( \hat{\Psi}_n \) and \( \hat{\Psi}_{n+p} \) share two rows, they have the same right null vector. Similarly \( \hat{\Psi}_n \) and \( \hat{\Psi}_{n+q} \) share two columns.

We can use the recurrence (6.1) to write \( J_1, \ldots, J_p, K_1, \ldots, K_q \) in terms of initial values \( x_1, \ldots, x_N \) and then any cyclically symmetric combination of the \( J_i \) or of the \( K_i \) furnishes us with a first integral for the map \( \phi \) derived from (6.1). Alternatively, starting with

\[
J_1 = \frac{x_1 + x_{2q+1}}{x_{q+1}},
\]

written in terms of \( x_1, \ldots, x_N \), we can use the map \( \phi \) to generate independent functions \( J_1, \ldots, J_p \). Similarly, we can generate \( K_1, \ldots, K_q \) from \( K_1 \). Of course, we cannot have \( p + q = N \) independent integrals, since these maps are not periodic. From the monodromy relations derived from (6.4) and (6.5), we can derive a single polynomial relationship between the functions \( J_i \) and \( K_i \) (see (6.11)). The existence of \( N - 1 \) independent first integrals for \( \phi \) means that it is maximally super-integrable.
6.2. Monodromy matrices and linear relations with constant coefficients

The relation (6.4) implies that the matrix \( \Psi_n \) satisfies

\[
\Psi_{n+q} = \Psi_n L_n, \quad L_n = \begin{pmatrix} 0 & -1 \\ 1 & J_n \end{pmatrix}.
\] (6.7)

Upon taking the ordered product of the \( L_n \) over \( p \) steps, shifting by \( q \) each time, we have the monodromy matrix

\[
M_n := L_n L_{n+q} \cdots L_{n+(p-1)q} = \Psi_n^{-1} \Psi_{n+pq}.
\] (6.8)

On the other hand, the recurrence (6.5) yields

\[
\Psi_{n+p+1} = \hat{\Psi}_n, \quad \hat{L}_n = \begin{pmatrix} 0 & 1 \\ -1 & K_n \end{pmatrix},
\] (6.9)

which gives another monodromy matrix

\[
\hat{M}_n := \hat{L}_{n+(q-1)p} \cdots \hat{L}_{n+p} \hat{L}_n = \Psi_{n+pq} \Psi_n^{-1}.
\] (6.10)

The cyclic property of the trace implies that

\[
\text{tr}(M_n) = \text{tr}(\hat{M}_n) = \text{tr}(\hat{M}_n) = \cdots = \text{tr}(\Psi_n) = \text{tr}(\hat{M}_n) = \text{tr}(\Psi_n).
\] (6.11)

Also, since \( L_n \) has period \( p \), shifting \( n \to n + p \) in (6.8) and taking the trace implies that \( \text{tr}(M_n) = \text{tr}(\hat{M}_n) \), so \( \text{tr}(M_n) = \text{tr}(\Psi_n) = \text{tr}(\hat{M}_n) = \text{tr}(\Psi_n) \) is an invariant of \( \varphi \).

We can now generalize the result (6.6). This is theorem 9.5 of [13], but this particular proof is from [12].

**Theorem 6.3.** The iterates of the nonlinear recurrence (6.1) satisfy the linear relation

\[
\Psi_{n+2pq} = \mathcal{K} \Psi_{n+pq},
\] (6.12)

where \( \mathcal{K} \) is the first integral defined by (6.11), with \( \mathcal{K}_n = \mathcal{K} \) for all \( n \).

**Proof.** Using (6.8) we see that \( \Psi_{n+pq} = \Psi_n M_n \), so \( \Psi_{n+2pq} = \Psi_n M_n \Psi_{n+pq} = \Psi_n M_n^2 \) by periodicity. Noting that \( M_n \) is a 2 \( \times \) 2 matrix, with \( \det M_n = 1 \) and \( \text{tr} M_n = \mathcal{K} \), yields (by Cayley–Hamilton)

\[
\Psi_{n+2pq} = \mathcal{K} \Psi_{n+pq} + \Psi_n = \Psi_n \left( M_n^2 - \mathcal{K} M_n + I \right) = 0.
\]

The (1, 1) component of this equation is just (6.12). \( \square \)

6.3. The structure of monodromy matrices

Since the only non-trivial invariant of \( M_n \) (or indeed \( \hat{M}_n \)) is \( \mathcal{K} \), it is possible to write the whole matrix \( M_n \) in terms of \( \mathcal{K} \) and its derivatives. We just present the case of \( P_n^{(1)} \).

For the case \( q = 1 \), we denote the matrix \( M_n = L_n L_{n+1} \cdots L_{n+p-1} \) by \( M_n^{(2m)} \), when \( p = 2m - 1, m \geq 1 \), or \( M_n^{(2m+1)} \), when \( p = 2m, m \geq 1 \).

It is important to note that \( M_n^{(p+1)} \) depends only upon the variables \( J_{n}, \ldots, J_{n+p-1} \). For the moment, this is not really a monodromy matrix, if we do not assume any periodicity. We give a recursive procedure for building the matrices \( M_n^{(2m)} \) and \( M_n^{(2m+1)} \).

We use the recursion \( M_n^{(j+3)} = M_n^{(j+1)} L_{n+j+1} L_{n+j+2} \) to prove the following.
Lemma 6.4 (The structure of $M_n$). The components of $M_n^{(p+1)} = \begin{pmatrix} A_n^{(p+1)} & B_n^{(p+1)} \\ \text{C}_n^{(p+1)} & D_n^{(p+1)} \end{pmatrix}$ satisfy the relations

$$\frac{\partial A_n^{(p+1)}}{\partial J_n} = 0, \quad \frac{\partial B_n^{(p+1)}}{\partial J_n} = 0, \quad \frac{\partial \text{C}_n^{(p+1)}}{\partial J_n} = -\frac{\partial D_n^{(p+1)}}{\partial J_n}, \quad \frac{\partial D_n^{(p+1)}}{\partial J_n} = -\frac{\partial \text{C}_n^{(p+1)}}{\partial J_n}.$$ 

where $\text{K}^{(p+1)} = A_n^{(p+1)} + D_n^{(p+1)}$.

Furthermore, we can build the functions $\text{K}^{(p+1)}$ by use of a recursion operator. We have $\text{K}^{(p+3)} = \mathcal{R}^{(p)} \text{K}^{(p+1)}$, where the recursion operator is

$$\mathcal{R}^{(p)} = J_{n+p} J_{n+p+1} \frac{\partial^2}{\partial J_n \partial J_{n+p-1}} - J_{n+p} \frac{\partial}{\partial J_n} - J_{n+p+1} \frac{\partial}{\partial J_{n+p-1}} + (J_{n+p} J_{n+p+1} - 1).$$

We start with $\text{K}^{(2)} = J_n$ and $\text{K}^{(3)} = J_n J_{n+1} - 2$.

At each step this introduces a new pair of variables $J_{n+p}$ and $J_{n+p+1}$ into the formula. The next two functions are

$$\text{K}^{(4)} = J_n J_{n+1} J_{n+2} = (J_n + J_{n+1} + J_{n+2}), \quad \text{with} \quad J_{n+3} = J_n,$n
$$\text{K}^{(5)} = J_n J_{n+1} J_{n+2} J_{n+3} = (J_n J_{n+1} + J_{n+1} J_{n+2} + J_{n+2} J_{n+3} + J_{n+3} J_n) + 2, \quad \text{with} \quad J_{n+4} = J_n,$n

which are just $S_4$ and $S_5$, of the list in example 9.10 of [13].

### 6.3.1. Link with the poisson structure

Now consider the quiver $P^{(1)}_m$ for fixed $p = 2m - 1$, with periodicity $L_{n+p} = L_n$. The relation

$$M_n L_n = L_n M_{n+1}$$

leads to $C_{n+1} = -B_n$, so $C_n = -B_{n-1} = -B_{n+1}$, and

$$J_n B_n = A_n - D_{n+1}, \quad B_{n+p-1} - B_{n+1} = J_n (D_{n+1} - D_n).$$

Consider the scalar product

$$\langle 0, J_n, J_{n+1}, \ldots, J_{n+p-1}, J_{n+p-1} \rangle \cdot \begin{pmatrix} B_n, B_{n+1}, \ldots, B_{n+p-1} \end{pmatrix} = A_{n+1} - D_{n+2} - A_{n+2} + D_{n+1} + \cdots + A_{n+p-2} - D_{n+p-1} - A_{n+p-1} + D_{n+p} = A_{n+1} - \text{K} + D_n = D_n - D_{n+1}$$

where we have used $A_n + D_n = \text{K}$ and $D_{n+p} = D_n$. The alternating sign (and the fact that $p = 2m - 1$) means that only one of the $\text{K}$ survives the sum. Multiplying this scalar product by $J_n$ and using the second of (6.14), leads to

$$\langle 0, J_n J_{n+1}, J_{n+2}, \ldots, J_{n+p-1}, J_{n+p-1} \rangle \cdot \begin{pmatrix} B_n, B_{n+1}, \ldots, B_{n+p-1} \end{pmatrix} = B_{n+1} - B_{n+p-1},$$

together with similar expressions obtained by cyclic permutations. We can form a matrix equation

$$(P^{(2)} + P^{(0)}) b = 0, \quad \text{with} \quad b = \begin{pmatrix} B_n, B_{n+1}, \ldots, B_{n+p-1} \end{pmatrix}^T = -\nabla \text{K},$$

where

$$P^{(2)}_{ik} = c^{(2)}_{ik} J_{J_i}, \quad P^{(0)}_{ik} = c^{(0)}_{ik},$$

(6.15)

where $c^{(2)}_{ik}$ and $c^{(0)}_{ik}$ are the components of skew-symmetric Toeplitz matrices with top rows given by
\[
\begin{align*}
\left( c^{(2)}_{jk} \right) &= (0, 1, -1, \ldots, 1, -1), \\
\left( c^{(0)}_{jk} \right) &= (0, 1, 0, \ldots, 0, -1).
\end{align*}
\]

**Remark 6.5.** Remarkably, these are the Poisson tensors which appear in lemma 6.7 below, and which are derived from the Poisson bracket \{x_i, x_k\}, itself coming from the inversion of the matrix \(B\), defining the corresponding quiver. On the other hand, the quiver has played no role in the manipulations since equation (6.2).

We can summarize these results in:

**Theorem 6.6.** The function \(\mathcal{K}_t\), defined by (6.11) is the Casimir of the Poisson bracket of lemma 6.7:

\[
\left( P^{(2)} + P^{(0)} \right) \nabla \mathcal{K} = 0. \tag{6.16}
\]

### 6.4. Poisson brackets and Liouville integrability for \(P^{(1)}_{2m}\)

The matrix \(B\) in the case of \(P^{(1)}_{2m}\) is non-degenerate, having the form

\[
B = \tau_N - \tau_N^T, \quad \text{with} \quad \tau_N = \sum_{r=1}^{N-1} E_{r+1,r} - E_{r,N}, \tag{6.17}
\]

where \(E_{rs}\) denotes an element of the standard basis for \(gl(N)\). This ‘skew rotation’ matrix \(\tau_N\) already appeared in definition 2.9.

By theorem 4.5, the map is symplectic, and hence there is a non-degenerate Poisson bracket of the form (3.13), with \(C = B^{-1}\), up to scaling. We can take

\[
C = \tau_N^T + \left( \tau_N^T \right)^3 + \cdots + \left( \tau_N^T \right)^{N-1} = \sum_{r=1}^{N-1} \sum_{s=1}^{N-2r+1} \left( E_{r+s+2,s-1} - E_{r+s-1,s} \right),
\]

so that \(CB = 2I\), which gives

\[
\{ x_j, x_k \} = \begin{cases} 
\text{sgn} (k - j)x_j x_k, & \text{if } k - j \text{ odd}, \\
0 & \text{otherwise},
\end{cases} \tag{6.18}
\]

for \(j, k = 1, \ldots, N\), with \(\text{sgn}\) denoting the sign function. We can then directly calculate the Poisson brackets \{ \(J_n, J_k\) \}.

**Lemma 6.7.** For even \(N = p + 1\) and \(q = 1\), the functions \(J_n\) given by (6.4) define a Poisson subalgebra of codimension one in the algebra (6.18), with brackets

\[
\left\{ J_n, J_k \right\} = 2P_n, \quad \text{where matrix} \quad \left( P_n \right) = P^{(2)} + P^{(0)}, \tag{6.19}
\]

for \(i, k = 1, \ldots, p\), and \(P^{(0)}\) are the matrices defined by (6.15).

The bracket for the \(J_n\) is clearly a sum \{ \{ \cdot, \cdot \} \}, corresponding to the splitting of the Poisson tensor into homogeneous parts \(P^{(2)} + P^{(0)}\), each of which is itself a Poisson bracket. Hence we have a pair of compatible Poisson brackets \{ \{ \cdot, \cdot \} \}, to which we can apply the theory of section 3.2.3. Indeed, we have formula (6.16), in which \(\mathcal{K}\) is given by the repeated action of \(\mathcal{K}^{(0)}\) on \(\mathcal{K}^{(2)} = J_n\) (see (6.13) for \(p = 2m - 1\), so
\[ \mathcal{K} = \sum_{j=0}^{n-1} (-1)^{m+j+1} I_j, \quad (6.20) \]

where \( I_j \) is the term of degree \( 2j + 1 \) in the variables \( J_i \) (compare with (3.12)). The homogeneous parts of formula (6.16) can then be written \( P^{(0)} \nabla I_0 = 0, \ P^{(0)} \nabla I_k = P^{(2)} \nabla I_{k-1}, \) for \( 1 \leq k \leq m - 1, \) and \( P^{(2)} \nabla I_{m-1} = 0. \) (6.21)

It follows that \( \{ I_j, I_k \}_0 = 0 = \{ I_j, I_k \}_2, \) for all \( j, k. \)

In summary, we have:

**Theorem 6.8** (Complete integrability). For \( N = 2m \) and \( q = 1 \) the map \( \varphi \) defined by (6.1) has \( m \) functionally independent Poisson commuting integrals, given by the terms of each odd homogeneous degree in the quantity \( \mathcal{K} \), as given by equation (6.20). The map is also maximally super-integrable, having a total of \( N - 1 \) independent first integrals.

### 6.4.1. Examples.

I present here some low dimensional examples. Recall that, in terms of the variables \( x_k \), each of these integrals \( I_j \) is a rational function with complicated numerator, but with simple denominator, given by \( \prod_{k=1}^{2m} x_k. \)

**Example 6.9** (The case \( N = 4 \)). Here we have three basic functions \( J_1, J_2, J_3 \). With, \( m = 2 \), we have \( I_0 = J_1 + J_2 + J_3 \) and \( I_1 = J_1 J_2 J_3. \)

**Example 6.10** (The case \( N = 6 \)). Here we have five basic functions \( J_1, ..., J_5 \). With, \( m = 3 \) we have

\[
I_0 = \sum_{i=1}^{5} J_i, \quad I_1 = \sum_{i=1}^{5} J_i J_{i+1} J_{i+2}, \quad I_2 = \prod_{i=1}^{5} J_i,
\]

the indices here being taken modulo 5.

**Example 6.11** (The case \( N = 8 \)). Here we have seven basic functions \( J_1, ..., J_7 \). With, \( m = 4 \) we have

\[
I_0 = \sum_{i=1}^{7} J_i, \quad I_1 = \sum_{i=1}^{7} J_i J_{i+1} (J_{i+2} + J_{i+3}), \quad I_2 = \sum_{i=1}^{7} J_i J_{i+1} J_{i+2} J_{i+3} J_{i+4}, \quad I_3 = \prod_{i=1}^{7} J_i,
\]

the indices here being taken modulo 7.

### 6.5. Primitives of the form \( P^{(1)}_{2m+1} \)

The recurrences (6.1) for \( p = 2m \) and \( q = 1 \) are given by

\[ x_{n+2m+1} x_n = x_{n+2} x_{n+1} + 1. \quad (6.22) \]

The formula (6.17) still holds, but now the matrix \( B \) is singular with a one-dimensional kernel, spanned by the vector \( u = (1, -1, ..., 1, -1, 1)^T. \) In the coordinates

\[ y_j = x_j x_{j+1}, \quad j = 1, ..., 2m, \quad (6.23) \]
the degenerate form (4.2) gives rise to a symplectic form (4.7) in dimension \(2m\), whose coefficients \(\hat{b}_{jk}\) are the matrix elements of
\[
\hat{B} = \tau_{2m} - \tau_{2m}^2 + \tau_{2m}^3 - \cdots + \tau_{2m}^{2m-1},
\]
where \(\tau_{2m}\) is the \(m \times m\) version of \(\tau_N\). The inverse of this is the skew-symmetric matrix
\[
\hat{B}^{-1} = \tau_{2m}^T + \left(\tau_{2m}^{T}\right)^2 + \left(\tau_{2m}^{T}\right)^3 + \cdots + \left(\tau_{2m}^{T}\right)^{2m-1},
\]
with all components above the diagonal equal to 1, giving a non-degenerate Poisson bracket for the \(y_j\):
\[
\{y_j, y_k\} = \text{sgn}(k-j)y_jy_k, \quad 1 \leq j, k \leq 2m.
\]
(6.24)

In the variables \(y_n\), the map (for \(m \geq 2\)) is given by
\[
\hat{\phi}: (y_1, y_2, \ldots, y_{2m-1}, y_{2m}) \mapsto (y_2, y_3, \ldots, y_{2m}, y_{2m+1}),
\]
(6.25)

where
\[
y_{2m+1} = y_1y_2 \cdots y_{2m} \frac{y_2y_3 \cdots y_{2m}}{y_1y_2 \cdots y_{2m-1}}.
\]

The map is simpler for the case \(m = 1\), given in example 6.12 below.

The polynomial \(J\) is given by the repeated action of \(\mathcal{R}^p\) on \(J^{(m)} = J_0J_{m+1} - 2\) (see (6.13) for \(p = 2m\)), so can be expanded as
\[
\mathcal{K} = \sum_{j=0}^m (-1)^{m+j}I_j, \quad \text{where} \quad I_0 = 2,
\]
(6.26)
and each polynomial \(I_j\) is homogeneous of degree \(2j\) in the variables \(J_n\). The non-trivial homogeneous components \(I_0, \ldots, I_m\) provide \(m\) first integrals for (6.22) and can be rewritten in terms of the variables \(y_j\).

**Example 6.12** (The primitive \(P_3^{(1)}\)). For \(m = 1\) the map \(\phi\) for the \(x_j\) variables is (3.14), which is associated with \(P_3^{(1)}\). The matrix \(B\) has rank two, so in terms of the variables \(y_j\) given by (6.23) the induced map of the plane is
\[
\hat{\phi}: \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} \mapsto \begin{pmatrix} y_2 \\ y_1 \frac{y_2}{y_1} \end{pmatrix}.
\]
The function
\[
I_1 = J_1J_2 = \mathcal{K} + 2 = \frac{(y_1 + y_2)(y_1 + y_2 + 1)}{y_1y_2}
\]
is invariant under \(\hat{\phi}\), along with the Poisson bracket \(\{y_1, y_2\} = y_1y_2\), so the map is integrable.

**Example 6.13** (The primitive \(P_5^{(1)}\)). For \(m = 2\) the recurrence (6.22) has the first integrals \(I_1\) and \(I_2\) given by the homogeneous terms of degree 2 and 4, respectively, in the expression (6.26):
\[
\mathcal{K} = 2 - (J_1J_2 + J_1J_4 + J_1J_4 + J_2 + J_4 + J_4 + J_4) + J_1J_2J_4 = I_0 - I_1 + I_2.
\]
(6.27)
The variables \(y_j\), defined by (6.23), are endowed with the non-degenerate Poisson bracket (6.24), which is invariant under the map (6.25):
The terms in the formula (6.27) can all be expressed via the functions

\[ w_i = J_i, J_{i+1}, \quad (6.28) \]

so that \( I_i = w_1 + w_2 + w_3, I_2 = w_1 w_3 \), and these \( w_j \) can be written as functions of \( y_j \):

\[ w_1 = \frac{(y_1 + y_2)(y_2 + y_3)}{y_2^2}, \quad w_2 = \frac{(y_2 + y_3)(y_3 + y_4)}{y_3^2}, \quad w_3 = \frac{(y_3 + y_4)(y_4 y_3^2 + y_2^2 y_4)}{y_3 y_4^2 y_4}. \]

Under the action of \( \hat{\phi} \), since the \( J_n \) cycle with period 4 under \( \phi \), the \( w_i \) transform as

\[ \hat{\phi}^4 w_1 = w_1, \quad \hat{\phi}^4 w_2 = w_3, \quad \hat{\phi}^4 w_3 = w_4 = \frac{w_1 w_3}{w_2}, \quad \hat{\phi}^4 w_4 = w_1. \]

The first three \( w_i \) form a three-dimensional Poisson subalgebra of the \( y_j \), which is non-polynomial:

\[ \{ w_1, w_2 \} = w_1 w_2 - w_1 - w_2, \quad \{ w_1, w_3 \} = w_2 - \frac{w_1 w_3}{w_2}, \quad \{ w_2, w_3 \} = w_2 w_3 - w_2 - w_3. \]

The Casimir of this algebra is \( I_1 - I_2 = w_1 + w_2 + w_3 + \frac{w_1 w_3}{w_2} - w_1 w_3 = 2 - \mathcal{K} \), and \( \{ I_1, I_2 \} = \{ I_1, \mathcal{K} \} = 0 \), so the two first integrals are in involution, as required.

### 7. Linearizable recurrences from \( P^m_{2m} - P^{m-q}_{2(m-q)} \) quivers

In this section we consider the family of recurrences (5.6) (case (iii) of theorem 5.4), which come from quivers of the form \( P^m_{2m} - P^{m-q}_{2(m-q)} \). At the beginning of this section I give some general formulae, but to avoid complications I only discuss complete integrability in the context of examples with \( q = 1 \).

The general recurrence can be written as

\[ x_{n+m} = x_{n+p} x_{n+q} + x_{n+m}, \quad p + q = N = 2m, \quad (7.1) \]

giving (for fixed \( m \)) a different recurrence for each \( q = 1, \ldots, m-1 \). The associated matrix \( B \) is given by

\[ B = \tau_{2m}^p - (\tau_{2m}^q)^T - \tau_{2m}^m + \tau_{2(m-q)}^{m-q}, \quad (7.2) \]

where \( \tau_N \) is defined in (6.17), and \( \tau_{2(m-q)} \) denotes the \( N \times N \) matrix obtained by adding \( q \) left and right columns and upper and lower rows of zeros to the \( 2(m - q) \times 2(m - q) \) matrix \( \tau_{2(m-q)} \). The simplest examples of the quivers corresponding to such \( B \) are shown in figure 8.

We can assume that \( \gcd(m, q) = 1 \), otherwise the quiver (and the recurrence) decouple. It then follows that \( \gcd(p, q) \) can only be 1 or 2. The case \( \gcd(p, q) = 1 \) has a very similar structure to that of the primitives \( P^{m}_q \) for even \( N \) and will be the only case discussed in detail here. The case \( \gcd(p, q) = 2 \) has several new features (see [12]). The quiver of figure 8(c) is in this class.
7.1 Linear relations with periodic coefficients

By analogy with (6.2), the recurrence (7.1) can be written in the form

\[ \Psi_n = + + + + \det (7.3) \]

Using Dodgson condensation on \( \Psi'_n \) (see (6.3)) now gives

\[ \Psi'_n = - - - - - - - - \det (7.1) \]

Then condensing the appropriate 4 × 4 matrix \( \Delta_n \) in terms of 3 × 3 minors yields

\[ \Delta_n = + + + + + + \det 0. \]

The left and right kernels of the singular matrix \( \Delta_n \) yield linear relations between the \( x_n \).

**Lemma 7.1.** The iterates of the recurrence (7.1) satisfy the linear relations

\[ x_{n+3q} = J_{n+4m} x_{n+2q} + J_n x_{n+q} - x_n = 0, \quad (7.4) \]

\[ x_{n+3p} = K_{n+4m} x_{n+2p} + K_n x_{n+p} - x_n = 0, \quad (7.5) \]

whose coefficients are periodic functions of period \( p, q \) respectively:

\[ J_{n+p} = J_n, \quad K_{n+q} = K_n, \quad \text{for all} \ n. \]

**Remark 7.2.** The four-term linear relations (7.4) and (7.5), together with \( \det \Psi'_n = 1 \), should be compared with those of the pentagram map [31], but there the coefficients of the second and third terms are independent.

7.2 Monodromy and linear relations with constant coefficients

This subsection follows closely the discussion of subsection 6.2 for the case of primitives.
The relations (7.4) and (7.5) imply that the matrix $\Psi_n$ satisfies
\[
\Psi_n = \Psi_n \mathbf{L}_n, \quad \mathbf{L}_n = \begin{pmatrix}
0 & 0 & 1 \\
1 & 0 & -J_n \\
0 & 1 & J_{n+m}
\end{pmatrix}, \quad \text{with} \quad \mathbf{L}_{n+p} = \mathbf{L}_n, \quad (7.6)
\]

\[
\Psi_{n+p} = \mathbf{L}_n \Psi_n, \quad \mathbf{L}_n = \begin{pmatrix}
0 & 1 & 0 \\
0 & 0 & 1 \\
1 & -K_n & K_{n+m}
\end{pmatrix}, \quad \text{with} \quad \mathbf{L}_{n+q} = \mathbf{L}_n. \quad (7.7)
\]

Taking appropriate ordered products then leads to the monodromy matrices
\[
\mathbf{M}_n := \mathbf{L}_n \mathbf{L}_{n+q} \cdots \mathbf{L}_{n+p-1} = \Psi^{-1}_n \Psi_{n+pq}, \quad (7.8)
\]

\[
\hat{\mathbf{M}}_n := \hat{\mathbf{L}}_{n+q-1} \cdots \hat{\mathbf{L}}_{n+p-1} \hat{\mathbf{L}}_n = \Psi^{-1}_{n+pq} \Psi^n. \quad (7.9)
\]

From the cyclic property of the trace it follows that
\[
\mathcal{K}_n := \text{tr} \mathbf{M}_n = \text{tr} \hat{\mathbf{M}}_n. \quad (7.10)
\]

Once again, the periodicity of $\mathbf{L}_n$ implies that $\mathcal{K}_{n+p} = \mathcal{K}_n$ and $\mathcal{K}_{n+q} = \mathcal{K}_n$, so, if the periods $p$ and $q$ are coprime, $\mathcal{K}_n = \mathcal{K}_n$ is constant, for all $n$, hence $\mathcal{K}$ is a first integral for the map $\varphi$ corresponding to (7.1).

In [12] we prove the following:

**Theorem 7.3.** When $\gcd(p, q) = 1$, the iterates of the nonlinear recurrence (7.1) satisfy the linear relation
\[
x_{n+pq} - K_n x_{n+p+q} + \mathcal{K} x_{n+pq} - x_n = 0, \quad (7.11)
\]

where $\mathcal{K}$ is the first integral defined by (7.10).

**Remark 7.4.** In particular, when $q = 1$ the coefficient $K_n$ has period 1, so $K_{n+1} = K_n = \mathcal{K}$ for all $n$, and the recurrence (7.5) is just the constant coefficient, linear difference equation
\[
x_{n+3} - \mathcal{K} x_{n+2} + \mathcal{K} x_{n+1} = x_n = 0. \quad (7.12)
\]

This is the case we now consider.

### 7.3. The case $q = 1$ and examples

The discussion of this case is almost identical to that for the primitives $P_N^{(1)}$ with $N$ even. The matrix $\mathbf{B}$ is non-degenerate, so we get an invariant Poisson bracket of the form (3.13), which is specified uniquely (up to scale) by the Toeplitz matrix $\mathbf{C} = \mathbf{B}^{-1}$. However, in this case a general closed-form expression for the entries of $\mathbf{C}$, analogous to the formula (6.18) for the Poisson bracket of the even primitives, is not available to us at present.

The functions $J_n$ are of period $p$, while $K_n = \mathcal{K}$ is constant, with the first integral $\mathcal{K}$, defined by (7.10), a cyclically symmetric polynomial in the $J_n, n = 1, \ldots, p$.

From the log-canonical bracket $\{x_i, x_j\}$ it is possible to derive the brackets $\{J_i, J_j\}$. In general (excluding $m = 2$), this Poisson bracket consists of three homogeneous parts (of degrees 0, 1 and 2), which (unlike the bracket (6.19) for the primitive $P_N^{(1)}$) does not have an obvious splitting into a bi-Hamiltonian pair. Moreover, while every cyclically symmetric polynomial function of the $J_n$ is a first integral of the map $\varphi$, we do not yet have an algorithm for selecting an involutive set of them.
Example 7.5  (The quiver $P_4^{(1)} - P_4^{(2)} + P_2^{(1)}$). This example was first studied in an ad hoc way in [19]. The appropriate matrix (7.2), which corresponds to the quiver in figure 8(a), is obtained by setting $c = 1$ in (4.3). The explicit form of the map is

$$\phi: \quad (x_1, x_2, x_3, x_4) \mapsto (x_2, x_3, x_4, x_5), \quad x_5 = \frac{x_2 x_3 + x_3}{x_1}. \quad (7.13)$$

The invariant Poisson bracket (3.13) for this map is given by the Toeplitz matrix $C = B^{-1}$, with top row $(c_{ij}) = (0, 1, 1, 2)$. The period 3 functions $J_i$ take the form

$$J_1 = \frac{x_1 (x_2 + x_1 x_3) + x_4 (x_1^2 + x_2^2)}{x_1 x_2 x_4}, \quad J_2 = \frac{x_1 x_4 + x_3^2 + x_2^2}{x_2 x_3}, \quad J_3 = \frac{x_3 (x_2 + x_1 x_3) + x_4 (x_1 x_4 + x_2^2)}{x_1 x_3 x_4}. \quad (7.14)$$

The Poisson brackets between these three functions follow by the cyclic property from

$$\{J_i, J_j\} = J_i J_j - 2J_i. \quad (7.15)$$

This example is exceptional, in that the bracket for the $J_i$ is the sum of only two homogeneous terms:

$$P = P^{(2)} + P^{(1)}, \quad \text{where} \quad P^{(2)} = \begin{pmatrix} 0 & J_{12} & -J_{13} \\ -J_{12} & 0 & J_{13} \\ J_{13} & -J_{12} & 0 \end{pmatrix}, \quad P^{(1)} = \begin{pmatrix} 0 & -2J_1 & 2J_2 \\ 2J_1 & 0 & -2J_2 \\ -2J_2 & 2J_1 & 0 \end{pmatrix}. \quad (7.16)$$

Each of the tensors specified by $P^{(1)}$ and $P^{(2)}$ satisfies the Jacobi identity, so (since their sum is a Poisson tensor) they define a compatible pair of Poisson brackets.

The first integrals

$$\mathcal{H}_1 = J_1^2 + J_2^2 + J_3^2, \quad \mathcal{H}_2 = J_1 J_2 J_3$$

satisfy the bi-Hamiltonian ladder

$$PV^V \mathcal{H}_1 = 0, \quad PV^V \mathcal{H}_1 = PV^V \mathcal{H}_2, \quad PV^V \mathcal{H}_2 = 0,$$

so they commute with respect to the bracket defined by (7.14). The quantity

$$K = 3 - \mathcal{H}_1 + \mathcal{H}_2 \quad (7.17)$$

provides the Casimir of this bracket.

Example 7.6  (The quiver $P_6^{(1)} - P_4^{(2)} + P_2^{(1)}$). Mutation of the quiver in figure 8(b) gives the map

$$\phi: \quad (x_1, x_2, x_3, x_4, x_5, x_6) \mapsto (x_2, x_3, x_4, x_5, x_6, x_7), \quad x_7 = \frac{x_2 x_6 + x_4}{x_1}. \quad (7.18)$$

The invariant Poisson bracket for this map is given by (3.13), with the coefficients specified by the Toeplitz matrix $C = B^{-1}$ with top row $(c_{ij}) = (0, 0, 1, 0, 1, 1)$. The functions $J_i$, which cycle with period 5 under the action of $\phi$, take the form
\[
J_1 = \frac{x_1 x_5 + x_2 x_6 + x_3 x_4}{x_2 x_5}, \quad J_2 = \frac{x_2 (x_3 + x_1 x_5) + (x_1 + x_3) x_2 x_6}{x_1 x_3 x_6},
\]
\[
J_3 = \frac{x_3 (x_4 + x_1) + x_2 x_4}{x_2 x_4},
\]
\[
J_4 = \frac{x_4 (x_3 + x_1 x_4) + x_2 x_4}{x_3 x_5},
\]
\[
J_5 = \frac{x_4 (x_3 + x_1 x_4) + (x_1 x_5 + x_2 x_4) x_6}{x_1 x_4 x_6}.
\]

The Poisson bracket between these five functions follow by the cyclic property from
\[
\{J_i, J_j\} = -J_i J_j - J_i + 1, \quad \{J_i, J_j\} = 2J_i J_j.
\]

This Poisson bracket is the sum of three homogeneous terms,
\[
P = P^{(2)} + P^{(1)} + P^{(0)}, \quad \text{with} \quad P^{(2)}_{ij} = c^{(2)}_{ik} J_k, \quad P^{(1)}_{ik} = c^{(1)}_{ik} J_{i+j}, \quad P^{(0)}_{ik} = c^{(0)}_{ik},
\]
where \(c^{(f)}_{ik}\) are the Toeplitz matrices with top rows given by
\[
\left( c^{(2)}_{1, k} \right) = (0, -1, 2, -2, 1), \quad \left( c^{(1)}_{1, k} \right) = (0, -1, 0, 0, 1), \quad \left( c^{(0)}_{1, k} \right) = (0, 1, 0, -1).
\]

Both \(P^{(0)}\) and \(P^{(2)}\) satisfy the Jacobi identity, but \(P^{(1)}\) does not, so we cannot think of this sum as some sort of Poisson compatibility.

The Casimir for the 5-dimensional Poisson algebra generated by the \(J_i\) is the trace of the monodromy matrix, as in (7.10). It can be written as the sum
\[
\mathcal{K} = \mathcal{H}_1 + \mathcal{H}_2 - \mathcal{H}_i, \quad \text{(7.16)}
\]
where each of the components is a first integral:
\[
\mathcal{H}_1 = \sum_{i=1}^{5} (J_i - J_{i+1}), \quad \mathcal{H}_2 = \sum_{i=1}^{5} \left( J_i J_{i+1} J_{i+2} - J_i J_{i+2} J_{i+1} \right), \quad \mathcal{H}_3 = \prod_{i=1}^{5} J_i.
\]

We find that \(\{\mathcal{H}_i, \mathcal{H}_j\} = 0\) for all \(i, j\), so the 6-dimensional Poisson map \(\varphi\) has the correct number of first integrals in involution.

**Example 7.7** (The quiver \(P_8^{(1)} - P_8^{(4)} + P_6^{(3)})\). The map obtained from mutation of this quiver is
\[
\varphi: \quad (x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8) \mapsto (x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9), \quad x_9 = \frac{x_2 x_6 + x_5}{x_1}.
\]

The corresponding non-singular matrix \(B\) defines an invariant Poisson bracket (3.13) with matrix \(C = B^{-1}\). The top row of the Toeplitz matrix \(C\) is \((c_{1j}) = (0, 1, 0, 1, 0, 1, 0, 1)\). The functions \(J_i\) with period 7 can be determined from \(J_1\), which takes the form
\[
J_1 = \frac{x_1 x_6 + x_2 x_7 + x_3 x_4}{x_2 x_6}.
\]

The remaining six functions are obtained by applying \(\varphi^7 J_i = J_{i+1}\), with \((\varphi^7) J_i = J_i\). The Poisson bracket relations between these functions follow by the cyclic property from
\[
\{J_i, J_j\} = 2J_i J_j - J_i J_j, \quad \{J_i, J_j\} = -J_i J_j + 1, \quad \{J_i, J_j\} = -J_i J_j.
\]

Again, this Poisson bracket is the sum of three homogeneous terms, \(P = P^{(2)} + P^{(1)} + P^{(0)}\), where \(P^{(0)}\) and \(P^{(2)}\) satisfy the Jacobi identity, but \(P^{(1)}\) does not.

The Casimir of the Poisson subalgebra generated by the \(J_i\) is again \(\mathcal{K}\) (the trace of the monodromy matrix), but in this case it is not clear how to split the Casimir into four pieces that Poisson commute, as required for Liouville integrability. Of course, there are still seven...
functionally independent invariant functions (built from cyclically symmetric combinations of the $J_i$) and we expect that four commuting functions exist.

8. Gale–Robinson recurrences

We now consider the final class of recurrence (5.7),

$$ x_{n+N} x_n = x_{n+N-p} x_{n+p} + x_{n+N-q} x_{n+q}, \quad (8.1) $$

listed in theorem 5.4 (case (iv)). These are known as three-term Gale–Robinson recurrences [14] and include Somos-4 (2.6), Somos-5 (2.11) and the reductions of Somos-6 (see equations (2.12), (2.13), and (2.14)) as special cases. We can no longer expect to linearize these, since their solutions are given in terms of elliptic functions [18, 20, 21].

The relations (8.1) all arise by reduction of the Hirota–Miwa (discrete KP) equation (see [36]), which is the bilinear partial difference equation

$$ T_{j,1} T_{j,-1} = T_{j,2} T_{j,-2} + T_{j,3} T_{j,-3}. \quad (8.2) $$

In the above, $T = T(n_1, n_2, n_3)$ is a function of three independent variables, and shifts are denoted by $T_{j,k} = T(n_j, n_k, n_l)$. If we set

$$ T(n_1, n_2, n_3) = \exp \left( \sum_{i,j} S_{ij} n_i n_j \right) \tau(n), \quad (8.3) $$

where $S = (S_{ij})$ is a symmetric matrix and $n = n_0 + \delta_1 n_1 + \delta_2 n_2 + \delta_3 n_3$, then $\tau(n)$ satisfies the ordinary difference equation

$$ \tau(n + \delta_1) \tau(n - \delta_1) = \alpha \tau(n + \delta_2) \tau(n - \delta_2) + \beta \tau(n + \delta_3) \tau(n - \delta_3), $$

where $\alpha = \exp(2(S_{22} - S_{11}))$, $\beta = \exp(2(S_{33} - S_{11}))$. Upon taking $x_0 = \tau(n - \delta_1)$ with $\delta_1 = \frac{1}{N} N_1$, $\delta_2 = \frac{1}{N} (N - 2p)$, $\delta_3 = \frac{1}{N} (N - 2q)$, this becomes (8.1) (with some additional parameters $\alpha, \beta$, which I have dropped from this presentation).

**Remark 8.1** (Octahedron recurrence). In the combinatorics literature, equation (8.2) is referred to as the octahedron recurrence, which has the Laurent property (shown in [9]). The Laurent property for three-term Somos (or Gale–Robinson) recurrences of the form (8.1) then follows by the reduction (8.3).

The Hirota–Miwa equation (8.2) has a scalar Lax pair, being the compatibility condition for the linear system given by

$$ T_{-1,3} \psi_{1,2} + T_{+1,3} \psi_{2,3} = T_{1,3} \psi_{1,2}, \quad T_{-1,1} \psi_{+1,2} + T_{+1,1} \psi_{2,-3} = T_{1,1} \psi_{+1,2}, \quad (8.4) $$

where the scalar function $\psi = \psi(n_1, n_2, n_3)$, with the same notation for shifts as before. Using the latter, one can use the reduction (8.3) to obtain Lax pairs for all of the Gale–Robinson recurrences (8.1), which leads directly to spectral curves whose coefficients are conserved quantities.

The process becomes quite involved for large $N$, but for $N = 4$ and $N = 5$ we can derive Lax pairs for Somos-4 and 5 (in terms of the the reduced variables $y_j$ for the (degenerate) pre-symplectic form (4.2)).
Example 8.2 (Somos-4 Lax pair). The Lax pair for the map (3.17) takes the form
\[ \mathbf{L} \mathbf{w} = \xi \mathbf{w}, \quad \mathbf{\dot{w}} = \mathbf{M} \mathbf{w}, \]
where the tilde denotes the shift \( n \to n + 1 \). The matrices \( \mathbf{L} = \mathbf{L}(\xi), \mathbf{M} = \mathbf{M}(\xi) \) are functions of \( y_j \) and the spectral parameter \( \xi \), given by
\[
\mathbf{L} = \begin{pmatrix}
- \frac{\gamma_1 + 1}{\gamma_1 \gamma_2} & - \gamma_2 & - \gamma_1 & \alpha \\
- \frac{\gamma_1 + 1}{\gamma_1 \gamma_2} & - \gamma_2 & - \gamma_1 & \alpha \\
\frac{1}{\gamma_1} \xi - \xi & - \gamma_2 & - \gamma_1 & \alpha + 1 \\
\frac{1}{\gamma_1} \xi - \xi & - \gamma_2 & - \gamma_1 & \alpha + 1
\end{pmatrix}, \quad \mathbf{M} = \begin{pmatrix}
0 & 1 & 0 \\
\frac{1}{\gamma_1 \gamma_2} \xi & \frac{1}{\gamma_1 \gamma_2} \xi + 1 & 0 \\
0 & 1 & 0
\end{pmatrix}.
\]
The discrete Lax equation \( \mathbf{L} \mathbf{M} = \mathbf{M} \mathbf{L} \) holds if and only if the map (3.17) does. The spectral curve is
\[
\det (\mathbf{L}(\xi) - \xi I) = \xi^2 + (H_1 \xi - 1)\xi + \xi^3 + \xi^2 = 0,
\]
in which the coefficient of \( \xi^2 \) is the first integral
\[
H_1 = \frac{\gamma_2}{\gamma_1} + \frac{1}{\gamma_1} + \frac{1}{\gamma_2} + \frac{1}{\gamma_1 \gamma_2}.
\]
The level sets of \( H_1 \) are biquadratic curves of genus one in the \((y_j, y_{j+1})\) plane, and the map is a particular instance of the QRT family [32].

Example 8.3 (Somos-5 Lax pair). The matrix \( \mathbf{B} \) for the recurrence (2.11) has rank 2, so in coordinates \((y_j, y_{j+1})\) the form (4.2) reduces to (4.9) (see [11]) and the map takes the form
\[
\phi: (y_j, y_{j+1}) \mapsto \left( y_{j+1}, \frac{1}{y_j} \right)
\]
This arises as the compatibility condition \( \mathbf{L} \mathbf{M} = \mathbf{M} \mathbf{L} \) for a linear system of the form (8.5), where
\[
\mathbf{L} = \mathbf{C}_0 + \mathbf{C}_1 \xi + \mathbf{C}_2 \xi^2, \quad \mathbf{M} = \mathbf{C}_0 + \begin{pmatrix} 0 & 0 \\ -\gamma_1 & 0 \end{pmatrix} \xi,
\]
with
\[
\mathbf{C}_0 = \begin{pmatrix} 0 & 1 \\ 0 & 1 \end{pmatrix}, \quad \mathbf{C}_1 = \begin{pmatrix}
-\gamma_1 & -\gamma_1 - \left( y_2 + \frac{1}{y_1} \right) \\
-\gamma_1 & -\gamma_1 - \left( y_2 + \frac{1}{y_1} + \frac{1}{y_2} + \frac{1}{\gamma_1 \gamma_2} \right)
\end{pmatrix}, \quad \mathbf{C}_2 = \begin{pmatrix}
1 & \frac{1}{y_1} + \frac{1}{y_2} \\
1 & \frac{1}{y_1} + \frac{1}{y_2}
\end{pmatrix}.
\]
The coefficient of \( \xi^2 \) in the equation for the spectral curve, that is
\[
\det (\mathbf{L}(\xi) - \xi I) = \xi^2 + (2\gamma_2^2 - J \xi + 1)\xi + \xi^4 + \xi^3 = 0,
\]
gives a first integral whose level sets are cubic (also biquadratic) curves of genus one, that is
\[
J = \gamma_1 + \gamma_2 + \frac{1}{\gamma_1} + \frac{1}{\gamma_2} + \frac{1}{\gamma_1 \gamma_2}.
\]
9. Conclusions

One of the main thrusts of this work has been to understand how to build special types of quiver so that a particular sequence of cluster mutations generated a recurrence. The relation to cluster algebras guarantees that this recurrence will have the Laurent property. Given such a recurrence we can consider the associated map and ask about its properties. The relationship with mutation periodic quivers implies that such maps preserve a pre-symplectic form, leading us to Poisson maps. For the period 1 case we classified the cases with zero algebraic entropy and analysed them in the framework of Liouville integrability. In [13] it was shown how to include parameters in the coefficients of our recurrences, using the theory of ‘ice quivers’, but for simplicity we have not included this here. A relationship between period 1 primitive recurrences and Pell’s equation was also discussed. In [10] it was shown that the map associated with the primitive $P_m^{(1)}$ (see section 6.4) can be seen as Bäcklund transformations for Liouville’s equation (a well-known partial differential equation, which arises in differential geometry and many other contexts). In [12] there are many details which I omitted here. In particular, there are numerous new and interesting examples of integrable maps.

There are many things which are still not understood. We only have a partial classification of period 2 quivers and only examples of ones with higher periods. Almost nothing is known about the integrability of maps associated with quivers of period 2 and above. Even in the period 1 case there are open questions about the Liouville integrability of cases (iii) and (iv) of theorem 5.4.

Recently, with the introduction of ‘Laurent phenomenon algebras’ [24] it has been possible to include such recurrences as (1.4) (Somos-6), with more than two terms on the ‘right hand side’. Some of the results of [13] are generalized to this case in [1].

In [13] we showed an intriguing connection between our results and those of quiver gauge theories and D-branes. The quivers arising in supersymmetric quiver gauge theories often have periodicity properties. Indeed, the Somos-5 quiver (see figure 5) also appears in [30] (with a relabelling) in the context of a $dP_2$ brane tiling. The combinatorial rule for Seiberg-dualising a quiver coincides with the rule for Fomin–Zelevinsky quiver mutation (definition 2.1) (see [35] for a discussion of this relationship). Recently, the authors of [22] have taken our decomposition (from theorem 2.11) of a Gale–Robinson quiver to form an infinite, doubly periodic quiver on the plane, whose dual is a brane tiling.

The existence of these diverse links to many parts of mathematics and physics is one of the remarkable features of cluster algebras, as can be seen elsewhere in this volume.

Acknowledgments

Most of the work reported here was carried out in collaboration with Robert Marsh and Andy Hone. The research with Robert Marsh was completely unexpected: it arose out of some questions I had about a short lecture course he gave on cluster algebras and opened up a whole new area of research for me. The research with Andy Hone began during the Programme on Discrete Integrable Systems, Newton Institute, Cambridge, 2009.
