scaling law in target-hunting processes

Shi-Jie Yang

1Department of Physics, Beijing Normal University, Beijing 100875, China

We study the hunting process for a target, in which the hunter tracks the goal by smelling odors it emits. The odor intensity is supposed to decrease with the distance it diffuses. The Monte Carlo experiment is carried out on a 2-dimensional square lattice. Having no idea of the location of the target, the hunter determines its moves only by random attempts in each direction. By sorting the searching time in each simulation and introducing a variable \( x \) to reflect the sequence of searching time, we obtain a curve with a wide plateau, indicating a most probable time of successfully finding out the target. The simulations reveal a scaling law for the searching time versus the distance to the position of the target. The scaling exponent depends on the sensitivity of the hunter. Our model may be a prototype in studying such the searching processes as various foods-foraging behavior of the wild animals.

In the past years, the diffusion-controlled reactions have been extensively studied through random-walk models. Such applications range from chemical processes, electronic scavenging and recombination, to electronic and vibrational energy transfer in condensed media. Many works have been devoted to the target annihilation problem, in which randomly placed targets are annihilated by random walkers, and its dual of the trapping problem. Other models treat hindered diffusion problems which involve random point obstacles. In these models, the tracer moves from site to site on a lattice and falls into wells of various depth at the sites. The tracer does not know the depth of a well before it enters. Another possibility is a mountain model, in which all sites are at zero energy and the barriers are on the bonds joining the sites. Generally, random-walk models are ideally suited for computer simulations, a practical way to obtain results, since for the vast majority of cases no purely analytical method exists.

In this work, we focus on another class of random-walk problems. We study the so-called target-hunting processes, which frequently occurs in biological systems, such as a shark searching for foods by smelling the blood in the ocean, or honeybees flying in the countryside to locate the foraging-nectars, or in metabolic processes such as cell motions and chemotaxis. It can be viewed as the target-oriented problems, in which the hunters try to reach the targets by following some kind of behavior rules. In our model, an active hunter is trying to find out a target which emits a special kind of odor. The Monte Carlo simulations are carried out on a 2-dimensional square lattice. Since neither the distance nor the direction of the target is presumably to be known, the searcher should determine its moves by random attempts in each direction, just like a snake turns its head from side to side to test the variation of the odor intensity. There are some chance for the hunter to move in the wrong direction because of randomness. Hence it is not a traditional biased random-walk. After sorting each searching process in time sequence, we obtain a curve with a wide plateau, indicating a most probable time of successfully finding out the target. By fitting the numerical results, we find a scaling law for the searching time on the distance to the position of the target. The scaling exponent is found to be dependent on the sensitivity of the hunter. We consider this scaling law scarcely happens in ordinary biased random walks.

The game rules are as follows: The hunter at the origin \( O \) is trying to find out a target which emits a special kind of odor. Since the hunter have no way to know the location of the target, it randomly moves around its original position to test the variation of the odor intensity. \( z_0 \) is the present distance of the hunter to the target while \( z_1 \) is the corresponding distance of the next attempted step. The Monte Carlo steps are implemented as: if \((z_0/z_1)^\alpha > \zeta\), where the parameter \( \alpha \) reflects the sensitivity of the hunter and \( \zeta \) is a random number, then the attempt is accepted. Otherwise it is refused. This rule implies that the intensity of the signal emitted by the target is inversely proportional to the distance of the hunter to the target. Other choices of the relation do not alter the result qualitatively. By this way, the hunter approaches the goal in a stochastic style.

Fig.1 displays a typical route of the hunter searching for the target on a regular lattice. When the hunter is far away from the goal, the ratio \( z_0/z_1 \) is close to 1. Most of the moving attempts are accepted, even the hunter walks in the wrong direction. The hunter appears to linger around for quite a while. Hence the motion of the hunter is nearly a Brownian random walk. As the goal is nearer, the ratio of \( z_0/z_1 \) gradually approaches 0.5 and the probability of being refused for the hunter moving in the wrong direction increases. Hence the searching route seems more straightforward.

Fig.2 shows the searching time for each simulation for a distance of \( z = 31.4 \) and \( \alpha = 6 \). It is understandable that the searching time are different for different stochastic processes. The distribution is not like a white noise. There are large fluctuations away from the most probable searching time. In Fig.3, we plot the distribution of searching time for \( z = 31.4, 65.6, 137.1, 188.4 \), respectively. It is seen that the distribution is not of the Poissonian form. The curve
has a very long time tail. Instead, a power relation is found for the maximal value of the distribution with the most probable time,

\[ V_m \sim t_{p}^{-d_m} \]  

with \( d_m = 1.05 \) for \( \alpha = 6 \).

There is another power relation between the distance of the target and the most probable searching-time,

\[ t_{p} \sim z^{d_p} \]  

where \( d_p = 1.77 \) for \( \alpha = 6 \).

In Fig. 4 we redistribute the data in Fig.2 by sorting with increasing time. Fig. 4(a) is for various distances \( z \) from the origin, with \( z = 31.4, 65.6, 137.1, 188.4 \) from bottom to top and \( \alpha = 6 \). The horizontal axis is the sequence of searching time represented in percentage. A wide plateau is formed in the intermediate range. Fig. 4(b) shows that after proper displacement, all of the curves collapse into one, implying these curves be parallel to each other. Hence each curve can be described by a single function \( f(x, \alpha) \) plus a \( z \)-dependent function \( \phi(z, \alpha) \),

\[ \ln t(x, z, \alpha) = f(x, \alpha) + \phi(z, \alpha) \]  

with \( x \) the sequence of searching time represented in percentage. The function \( f(x) \) is of Arabic Ogive-like. It can be checked that

\[ \ln t(\sqrt{z_1 \cdot z_2}, x) = \frac{1}{2}(\ln t(z_1, x) + \ln t(z_2, x)). \]  

Formula 3 can be written as

\[ \ln t(x, z, \alpha) = f(x, \alpha) + \eta(\alpha) \ln z. \]  

In figure 5 we studied the dependence of the searching-time with respect to the sensitivity parameter \( \alpha \). Fig. 5(a) shows the curves for \( \alpha = 4, 8, 12, 16, 20 \). After properly rescaling the curves in (a) by times \( \ln t \) with a coefficient \( \alpha^\beta \), where \( \beta \) is determined below, all of the curves become parallel. From Fig. 5(b), we deduce \( \alpha^\beta \ln t = \tilde{f}(x) + \tilde{\phi}(z, \alpha) \). By comparing with eq. (5), one gets

\[ \ln t(x, z, \alpha) = \alpha^{-\beta} f(x) + \eta(\alpha) \ln z. \]  

The index \( \beta \) can be derived by considering the dependence of the slope \( k_2 \) of the plateau in figure 5(a) on parameter \( \alpha \). There is a good linear relation between \( \ln k_2 \) and \( \ln \alpha \), as show in the inset of figure 6,

\[ \ln k_2 \sim -\beta \ln \alpha. \]  

We measured \( \beta = 0.623 \). It is noteworthy that \( \beta \) is a constant independent of sensitivity parameter \( \alpha \). It results from the stochastic process.

Finally, we try to found out the relation between \( \eta \) and \( \alpha \). Fig. 7(a) depicts the relation of \( \ln t \) versus \( \ln z \) at \( x = 0.6 \) for various parameter \( \alpha \). From figure 7(b),

\[ \ln \eta(\alpha) \sim -\delta \alpha \]  

with \( \delta = 0.01 \).

Combining all the above factors, we consequently obtain a complete relation of the searching-time with respect to the distance as well as sensitivity parameter \( \alpha \),

\[ \ln t(x, z, \alpha) = \alpha^{-\beta} f(x) + c_0 e^{-\delta \alpha} \ln z, \]  

or

\[ t(x, z, \alpha) = e^{f(x)/\alpha^\delta} \cdot z^d. \]  

We find that there is a generalized scaling-law between \( t \) and \( z \) with exponent

\[ d = c_0 e^{-\delta \alpha}. \]
From formula (2), \( \alpha = 6, d = d_p = 1.77 \). We get \( c_0 = 1.88 \). It shows that the power-law exponent is \( \alpha \)-dependent. As \( \alpha \) increases from zero to infinity, the exponent decreases from 1.88 to zero. In Eq. (10), the contributions of variable \( x \), which sorts the searching time in each simulation, are completely merged into a prefactor and the scaling exponent is \( x \)-independent. It should be noted that it is a functional relation between the searching time and the distance in such stochastic processes.

In summery, we introduced a variable \( x \) to denote the sequence of searching time. We plot a curve with a wide plateau, indicating a most probable time of successfully finding out the goal. In stead of calculating the mean square root, we introduce a sort parameter \( x \) to figure out an analytical expression. The simulations reveal a scaling law for the searching time versus the distance to the position of the target. The scaling exponent is dependent on the sensitivity of the hunter. We believe that our treatment of the statistical data may be useful in other cases. The existence of the scaling law may have implications with the possibility for the hunter to walk in a wrong direction or stay at the same place for quite a while. It scarcely happens in an ordinary biased random walk. We point out that the results are valid not only on the square lattice, but also for continuous moving (with fixed step length) in the two-dimensional plane. However, the explicit form of function \( f(x) \) is still lack. It is also desirable to deduce an analytical express of Eq. (10) from the first principle of statistics.

We suggest that the scaling law in the hunting process may be an additional behavior rule in the foods-foraging processes of wild animals, which has not caught much attention. In turn, verifications of the law from direct observations by zoologists or entomologists are also expected. Our target-oriented model may be a prototype in studying the foods-foraging processes in wildlife as well as in other searching games.
