Abstract. Cyber-physical systems often encompass complex concurrent behavior with timing constraints and probabilistic failures on demand. The analysis whether such systems with probabilistic timed behavior adhere to a given specification is essential. When the states of the system can be represented by graphs, the rule-based formalism of Probabilistic Timed Graph Transformation Systems (PTGTSs) can be used to suitably capture structure dynamics as well as probabilistic and timed behavior of the system. The model checking support for PTGTSs w.r.t. properties specified using Probabilistic Timed Computation Tree Logic (PTCTL) has been already presented. Moreover, for timed graph-based runtime monitoring, Metric Temporal Graph Logic (MTGL) has been developed for stating metric temporal properties on identified subgraphs and their structural changes over time.

In this paper, we (a) extend MTGL to the Probabilistic Metric Temporal Graph Logic (PMTGL) by allowing for the specification of probabilistic properties, (b) adapt our MTGL satisfaction checking approach to PTGTSs, and (c) combine the approaches for PTCTL model checking and MTGL satisfaction checking to obtain a Bounded Model Checking (BMC) approach for PMTGL. In our evaluation, we apply an implementation of our BMC approach in AutoGraph to a running example.

Keywords: cyber-physical systems, probabilistic timed systems, qualitative analysis, quantitative analysis, bounded model checking

1 Introduction

Cyber-physical systems often encompass complex concurrent behavior with timing constraints and probabilistic failures on demand [16,17]. Such behavior can then be captured in terms of probabilistic timed state sequences (or spaces) where time may elapse between successive states and where each step in such a sequence has a designated probability. The analysis whether such systems adhere to a given specification describing admissible or desired system behavior is essential in a model-driven development process.

Graph Transformation Systems (GTSs) [4] can be used for the modeling of systems when each system state can be represented by a graph and when the changes of such states can be captured by rule-based graph transformation. Moreover, timing constraints based on clocks, guards, invariants, and clock resets as in Probabilistic Timed Automata (PTA) [12] have been combined with

* Funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) - 241885098, 148420506.
graph transformation in Timed Graph Transformation Systems (TGTSs) [3] and probabilistic aspects have been added to graph transformation in Probabilistic Graph Transformation Systems (PGTSs) [10]. Finally, the formalism of PTGTSs [13] integrates both extensions and offers model checking support w.r.t. PTCTL [12,11] properties employing the Prism model checker [11]. The usage of PTCTL allows for stating probabilistic real-time properties on the induced PTGT state space where each graph in the state space is labeled with a set of Atomic Propositions (APs) obtained by evaluating that graph w.r.t. e.g. some property specified using Graph Logic (GL) [6,17].

However, structural changes over time in the state space cannot always be directly specified using APs that are locally evaluated for each graph. To express such structural changes over time, we introduced MTGL [5,17] based on GL. Using MTGL conditions, an unbounded number of subgraphs can be tracked over timed graph transformation steps in a considered state sequence once bindings have been established for them via graph matching. Moreover, MTGL conditions allow to identify graphs where certain elements have just been added to (removed from) the current graph. Similarly to MTGL, for runtime monitoring, Metric First-Order Temporal Logic (MFOTL) [2] (with limited support by the tool Monpoly) and the non-metric timed logic EAGLE [1,7] (with full tool support) have been introduced operating, instead of graphs, on sets of relations and Java objects as state descriptions, respectively.

Obviously, both logics PTCTL and MTGL have distinguishing key strengths but also lack bindings on the part of PTCTL and an operator for expressing probabilistic requirements on the part of MTGL. Furthermore, specifications using both, PTCTL and MTGL conditions, are insufficient as they cannot capture phenomena based on probabilistic effects and the tracking of subgraphs at once. Hence, a more complex combination of both logics is required. Moreover, realistic systems often induce infinite or intractably large state spaces prohibiting the usage of standard model checking techniques. Bounded Model Checking (BMC) has been proposed in [8] for such cases implementing an on-the-fly analysis. Similarly, reachability analysis w.r.t. a bounded number of steps or a bounded duration have been discussed in [9].

To combine the strengths of PTCTL and MTGL, we introduce PMTGL by enriching MTGL with an operator for expressing probabilistic requirements as in PTCTL. Moreover, we present a BMC approach for PTGTSs w.r.t. PMTGL properties by combining the PTCTL model checking approach for PTGTSs from [13] (which is based on a translation of PTGTSs into PTA) with the satisfaction checking approach for MTGL from [5,17]. In our approach, we just support bounded model checking since the binding capabilities of PMTGL conditions require non-local satisfaction checking taking possibly the entire history of a (finite) path into account as for MTGL conditions. However, we obtain even full model checking support for the case of finite loop-free state spaces and for the case where the given PMTGL condition does not need to be evaluated beyond a maximal time bound.

PTCTL model checkers such as Prism do not support the branching capabilities of PTCTL as of now due to the complexity of the corresponding algorithms.
As a running example, we consider a system in which a sender decides to send messages at nondeterministically chosen time points, which have then to be transmitted to a receiver via a network of routers within a given time bound. For this scenario, we employ MTGL allowing to identify messages that have just been sent, to track them over time, and to check whether their individual deadlines are met.

This paper is structured as follows. In section 2, we recall the formalism of PTA. In section 3, we discuss further preliminaries including graph transformation, graph conditions, and the formalism of PTGTSs. In section 4, we recall MTGL and present the extension of MTGL to PMTGL in terms of syntax and semantics. In section 5, we present our BMC approach for PTGTSs w.r.t. PMTGL properties. In section 6, we evaluate our BMC approach by applying its implementation in the tool AutoGraph to our running example. Finally, in section 7, we close the paper with a conclusion and an outlook on future work.

2 Probabilistic Timed Automata

In this section, we introduce the syntax and semantics of PTA [12] and probabilistic timed reachability problems to be solved for PTA using Prism [11].

For a set of clock variables \(X\), clock constraints \(\psi \in \mathbb{CC}(X)\) are finite conjunctions of clock comparisons of the form \(c_1 \sim n\) and \(c_1 - c_2 \sim n\) where \(c_1, c_2 \in X, \sim \in \{<, >, \leq, \geq\}\), and \(n \in \mathbb{N} \cup \{\infty\}\). A clock valuation \(v \in \mathbb{CV}(X)\) of type \(v: X \rightarrow R^+_0\) satisfies a clock constraint \(\psi\), written \(v \models \psi\), as expected. The initial clock valuation \(\mathbf{ICV}(X)\) maps all clocks to 0. For a clock valuation \(v\) and a set of clocks \(X'\), \(v[X' := 0]\) is the clock valuation mapping the clocks from \(X'\) to 0 and all other clocks according to \(v\). For a clock valuation \(v\) and a duration \(\delta \in R_0^+\), \(v + \delta\) is the clock valuation mapping each clock \(x\) to \(v(x) + \delta\).

For a countable set \(A\), \(\mu : A \rightarrow [0, 1]\) is a Discrete Probability Distribution (DPD) over \(A\), written \(\mu \in \text{DPD}(A)\), if the probabilities assigned to elements
add up to 1, i.e., $\sum \{\mu(a) \mid a \in A\} = 1$ using summation over multisets. Moreover, the support of $\mu$, written $\text{supp}(\mu)$, contains all $a \in A$ for which the probability $\mu(a)$ is non-zero.

PTA combine the use of clocks to capture real-time phenomena and probabilism to approximate/describe the likelihood of outcomes of certain steps. A PTA (such as $A$ from Figure 1a) consists of (a) a set of locations with a distinguished initial location (such as $\ell_0$), (b) a set of clocks (such as $c_\ell$) which are initially set to 0, (c) an assignment of a set of APs (such as $\{\text{done}\}$) to each location (for subsequent analysis of e.g. reachability properties), (d) an assignment of constraints over clocks to each location as invariants such as $(c_0 \leq 5)$, and (e) a set of probabilistic timed edges. Each probabilistic timed edge consists thereof of (i) a single source location, (ii) at least one target location, (iii) an action (such as $a$ or $b$), (iv) a clock constraint (such as $c_0 \geq 3$) specifying as a guard when the edge is enabled based on the current values of the clocks, and (v) a DPD assigning a probability to each pair consisting of a set of clocks to be reset (such as $\{c_0\}$) and a target location to be reached.

**Definition 1 (PTA).** A probabilistic timed automaton (PTA) $A$ is a tuple with the following components.

- $\text{locs}(A)$ is a finite set of locations,
- $\text{iloc}(A)$ is the unique initial location from $\text{locs}(A)$,
- $\text{acts}(A)$ is a finite set of actions disjoint from $\mathbb{R}^*_+$,
- $\text{clocks}(A)$ is a finite set of clocks,
- $\text{invs}(A) : \text{locs}(A) \rightarrow \text{CC}(\text{clocks}(A))$ maps each location to an invariant for that location such that the initial clock valuation satisfies the invariant of the initial location (i.e., $\text{ICV}(\text{clocks}(A)) \models \text{invs}(A)(\text{iloc}(A))$),
- $\text{edges}(A) \subseteq \text{locs}(A) \times \text{acts}(A) \times \text{CC}(\text{clocks}(A)) \times \text{DPD}(2^{\text{clocks}(A)} \times \text{locs}(A))$ is a finite set of PTA edges of the form $(\ell_1, a, \psi, \mu)$ where $\ell_1$ is the source location, $a$ is an action, $\psi$ is a guard, and $\mu$ is a DPD mapping pairs $(\text{Res}, \ell_2)$ of clocks to be reset and target locations to probabilities,
- $\text{aps}(A)$ is a finite set of APs, and
- $\text{lab}(A) : \text{locs}(A) \rightarrow 2^{\text{aps}(A)}$ maps each location to a set of APs.

The semantics of a PTA is given in terms of the induced Probabilistic Timed System (PTS). The states of the induced PTS are pairs of locations and clock valuations. The sequences of steps between such states define timed probabilistic paths. Each successive step in a path (such as the one in Figure 1b) is determined by an adversary which resolves the nondeterminism of the PTA by selecting either a duration by which all clocks are advanced in a timed step or a PTA edge that is used in a discrete step.

**Definition 2 (PTS Induced by PTA).** Every PTA $A$ induces a unique probabilistic timed system (PTS) $\text{PTAtoPTS}(A) = P$ consisting of the following components.

- $\text{states}(P) = \{ (\ell, v) \in \text{locs}(A) \times \text{CV}(\text{clocks}(A)) \mid v \models \text{invs}(A)(\ell) \}$ contains as PTS states pairs of locations and clock valuations satisfying the location’s invariant,
- $\text{istate}(P) = (\text{iloc}(A), \text{ICV}(\text{clocks}(A)))$ is the unique initial state from $\text{states}(P)$,
- $\text{acts}(P) = \text{acts}(A)$ is the same set of actions,
In this section, we briefly recall graphs, graph transformation, graph conditions, and the formalism of PTGTSs in our notation.

Using the variation of symbolic graphs [15] from [17], we consider typed attributed graphs (short graphs) (such as $G_0$ in Figure 2b), which are typed over a type graph $TG$ (such as $TG$ in Figure 2a). In such graphs, attributes are connected to local variables and an Attribute Condition (AC) over a many sorted first-order attribute logic is used to specify the values for these variables. Morphisms $m : G_1 \rightarrow G_2$ between graphs must ensure that the AC of $G_2$ is more restrictive compared to the AC of $G_1$ (w.r.t. the mapping of variables by $m$). Hence, the AC $\bot$ (false) in $TG$ means that $TG$ does not restrict attribute values.

Lastly, we denote monomorphisms (short monos) by $m : G_1 \rightarrow G_2$.

Graph Conditions (GCs) [17,6] of GL are used to state properties on graphs requiring the presence or absence of certain subgraphs in a host graph.

Definition 4 (GCs). For a graph $H$, $\phi_H \in \text{GC}(H)$ is a graph condition (GC) over $H$ defined as follows:

$$
\phi_H ::= \top \mid \neg \phi_H \mid \phi_H \land \phi_H \mid \exists f. \phi_{H'} \mid \forall g. \phi_{H''}
$$

For model checking PTA [12], Prism does not compute the induced PTS according to Definition 2 but instead it computes a symbolic state space (as in Figure 1c). In this symbolic state space, states are given by pairs of locations and clock constraints (called zones) where one state $(\ell, \psi)$ represents all states $(\ell, v)$ such that $v \models \psi$. To allow for such a symbolic state space representation, the syntax of clock constraints has been carefully chosen.

In section 5, we will use Prism to solve the following analysis problems defined for induced PTs.

Definition 3 (Min/Max Probabilistic Timed Reachability Problems). Evaluate $P_{op=?}(F \text{ done})$ for a PTS $P$ with $op \in \{\min, \max\}$ and $ap \in \text{aps}(P)$ to obtain the infimal/supremal probability (depending on $op$) over all adversaries to reach some state in $P$ labeled with $ap$.

For example, for the PTS $P = \text{PTAtoPTS}(A)$ induced by the PTA $A$ from Figure 1a, (a) $P_{\min=?}(F \text{ done})$ is evaluated to probability 0.5 since a probability maximizing adversary would enable the discrete step using action $b$ at time point 1 to reach $\ell_1$ with probability 0.5 and (b) $P_{\min=?}(F \text{ done})$ is evaluated to probability 0 since a probability minimizing adversary would enable the discrete step using action $a$ at time point 3 to reach $\ell_3$ from which then no location labeled with done can be reached.

3 Probabilistic Timed Graph Transformation Systems

In this section, we briefly recall graphs, graph transformation, graph conditions, and the formalism of PTGTSs in our notation.

A PTS step $((\ell, v), a, \mu) \in \text{steps}(P)$ contains a source state $(\ell, v)$, an action from $\text{acts}(P)$ for a discrete step or a duration from $R^+_c$ for a timed step, and a DPD $\mu$ assigning a probability to each possible target state.

Lastly, we denote monomorphisms (short monos) by $m : G_1 \rightarrow G_2$.

For a graph $H$, $\phi_H \in \text{GC}(H)$ is a graph condition (GC) over $H$ defined as follows:

$$
\phi_H ::= \top \mid \neg \phi_H \mid \phi_H \land \phi_H \mid \exists f. \phi_{H'} \mid \forall g. \phi_{H''}
$$

See [12] for a full definition of induced timed and discrete steps.
where \( f : H \rightarrow H' \) and \( g : H'' \rightarrow H \) are monos and where additional operators such as \( \top, \land, \lor \) and \( \forall \) are derived as usual.

The satisfaction relation [17,6] for GL defines when a mono satisfies a GC. Intuitively, for a graph \( H \), the operator \( \exists \) (called exists) is used to extend a current match of \( H \) to a supergraph \( H' \) and the operator \( v \) (called restrict) is used to restrict a current match of \( H \) to a subgraph \( H'' \).

**Definition 5 (Satisfaction of GCs).** A mono \( m : H \rightarrow G \) satisfies a GC \( \varphi \) over \( H \), written \( m \models \varphi \), if an item applies.

- \( \varphi = \top \).
- \( \varphi = \neg \varphi' \) and \( m \not\models \varphi' \).
- \( \varphi = \varphi_1 \land \varphi_2 \), \( m \models \varphi_1 \), and \( m \models \varphi_2 \).
- \( \varphi = \exists f : H \rightarrow H', \varphi' \) and \( \exists m' : H' \rightarrow G. m' \circ f = m \land m' \models \varphi' \).
- \( \varphi = v(g : H'' \rightarrow H, \varphi') \) and \( m \circ g \models \varphi' \).

Moreover, if \( \varphi \in GC(\emptyset) \) is a GC over the empty graph, \( i(G) : \emptyset \rightarrow G \) is an initial morphism, and \( i(G) \models \varphi \), then the host graph \( G \) satisfies \( \varphi \), written \( G \models \varphi \).

A Graph Transformation (GT) step is performed by applying a GT rule \( \rho = (\ell : K \rightarrow L, r : K \rightarrow R, \gamma) \) for a match \( m : L \leftarrow G \) on the graph to be transformed (see [17] for technical details). A GT rule specifies that (a) the graph elements in \( L - \ell(K) \) are to be deleted and the graph elements in \( R - r(K) \) are to be added using the monos \( \ell \) and \( r \), respectively, according to a Double Pushout (DPO) diagram and (b) the values of variables of \( R \) are derived from those of \( L \) using the AC \( \gamma \) (e.g. \( x' = x + 2 \)) in which the variables from \( L \) and \( R \) are used in unprimed and primed form, respectively. Nested application conditions given by GCs are straightforwardly supported by our approach but, to improve readability, not used in the running example and omitted subsequently.

PTGTSs introduced in [13] are a probabilistic real-time extension of Graph Transformation Systems (GTSs) [4]. We have shown in [13] that PTGTSs can be translated into equivalent PTA and, hence, PTGTSs can be understood as a high-level language for PTA.

Similarly to PTA, a PTGT state is given by a pair \((G, v)\) of a graph and a clock valuation. The initial state is given by a distinguished initial graph and a valuation mapping all clocks to 0. For our running example, the initial graph (given in Figure 2b) captures a sender, which is connected via a network of routers to a receiver, and three messages to be send. The type graph of a PTGT also identifies attributes representing clocks.\(^3\) For our running example, the type graph \( TG \) is given in Figure 2a where each clock attribute of a message represents such a clock. PTGT invariants are specified using GCs. Their evaluation for reachable graphs then results in clock constraints representing invariants as for PTA. For our running example, the PTGT invariant \( \phi_{inv} \) from Figure 2c prevents that time elapses once a message was at one router for 5 time units. PTGT APs are also specified using GCs but a state \((G, v)\) is labeled by such an PTGT AP if the evaluation of the GC for \( G \) results in a satisfiable clock constraint (i.e., the labeling of \((G, v)\) is independent from \( v \)). For our running example, the AP \( \phi_{fin} \) from Figure 2d labels states where each message has been successfully delivered to the receiver as indicated by the done loop.

---

\(^3\) For a PTGT state \((G, v)\), the values of clocks of \( G \) are stored in \( v \) and not in \( G \).
Probabilistic Metric Temporal Graph Logic

(a) Type graph TG.

(b) Initial graph G₀.

(c) PTGT invariant φ₁

d) PTGT AP φ₂

(e) PTGT rules σ₁send, σ₁receive, and σ₁transmit.

(f) PMTGC χₘₐₓ where the additional MTGL operator forall-new (written ∀₁N) is derived from the operator exists-new by ∀₁N(f, θ') = ¬∃₁N(f, ¬θ').

Fig. 2: Elements of the PTGTS and PMTGC χₘₐₓ for the running example.
PTGT rules of a PTGTS then correspond to edges of a PTA and contain (a) a left-hand side graph \( L \), (b) an AC specifying as an attribute guard non-clock attributes of \( L \), (c) an AC specifying as a clock guard clock attributes of \( L \), (d) a natural number describing a priority where higher numbers denote higher priorities, and (e) a nonempty set of tuples of the form \( (\ell : K \leftarrow L, r : K \leftarrow R, \gamma, C, p) \) where \( (\ell, r, \gamma) \) is an underlying GT rule, \( C \) is a set of clocks contained in \( R \) to be reset, and \( p \) is a real-valued probability from \([0,1]\) where the probabilities of all such tuples must add up to 1. See Figure 2e for the three PTGT rules \( \sigma_{\text{send}} \), \( \sigma_{\text{receive}} \), and \( \sigma_{\text{transmit}} \) from our running example where the first two PTGT rules have each a unique underlying GT rule \( \rho_{\text{send,done}} \) and \( \rho_{\text{receive,done}} \), respectively, and where the last PTGT rule has two underlying GT rules \( \rho_{\text{transmit,success}} \) and \( \rho_{\text{transmit,failure}} \). For each of these underlying GT rules, we depict the graphs \( L, K, \) and \( R \) in a single graph where graph elements to be removed and to be added are annotated with \( \ominus \) and \( \oplus \), respectively. Further information about the PTGT rule (i.e., the attribute guard, clock guard, and priority) and each of its underlying GT rules (i.e., the attribute effect \( \gamma \), set of clocks to be reset called \( \text{reset} \), and probability) is given in red (for ACs) and gray boxes (for the rest). The PTGT rule \( \sigma_{\text{send}} \) is used to push the next message into the network by connecting it to the router that is adjacent to the sender. Thereby, the attribute \( \text{num} \) of the sender is used to push the messages in the order of their id attributes. The PTGT rule \( \sigma_{\text{receive}} \) has the higher priority 1 and is used to pull a message from the router that is adjacent to the receiver by marking the message with a \text{done} \ loop. Lastly, the PTGT rule \( \sigma_{\text{transmit}} \) is used to transmit a message from one router to the next one. This transmission is successful with probability 0.8 and fails with probability 0.2. The clock guard of \( \sigma_{\text{transmit}} \) (together with the fact that the clock of the message is reset to 0 whenever \( \sigma_{\text{transmit}} \) is applied or when the message was pushed into the network using \( \sigma_{\text{send}} \)) ensures that transmission attempts may happen not faster than every 2 time units.

The semantics of a PTGTS is given by its induced PTS as in [13] using here concrete PTGT states instead of their equivalence classes for brevity.

**Definition 6 (PTS Induced by PTGTS).** Every PTGTS \( S \) induces a unique PTS \( \text{PTGTS}^\text{PTS}(S) = P \) consisting of the following components.

- \( \text{states}(P) \) contains as PTS states pairs \((G, v)\) where \( G \) is a graph and \( v \) is a valuation of the clocks of \( G \) satisfying the PTGT invariants of \( S \),
- \( \text{isstate}(P) \) is the unique initial state from \( \text{states}(P) \) consisting of the initial graph of \( S \) and the initial clock valuation of its clocks,
- \( \text{acts}(P) \) contains tuples of the form \((\sigma, m, sp)\) consisting of the used PTGT rule \( \sigma \), the used match \( m \), and a mapping \( sp \) of each GT rule \( \rho \) in \( \text{rules}(\sigma) \) to the GT span \((k_1 : D \leftarrow G, k_2 : D \leftarrow H)\) constructed for a GT step from \( G \) to \( H \) using \( \rho \).
- \( \text{steps}(P) \subseteq \text{states}(P) \times (\text{acts}(P) \cup \text{R}_{\text{d}}^\Downarrow) \times \text{DPD}(\text{states}(P)) \) is the set of PTS steps:
  - A PTS step \((G, v), a, \mu \) ∈ \( \text{steps}(P) \) contains a source state \((G, v)\), an action from \( \text{acts}(P) \) for a discrete step or a duration from \( \text{R}_{\text{d}}^\Downarrow \) for a timed step, and a DPD \( \mu \) assigning a probability to each possible target state.
- \( \text{aps}(P) = \text{aps}(S) \) is the same set of PTGT APs, and
- \( \text{lab}(P)(G, v) = \{ \phi \in \text{aps}(S) \mid G \models \phi \} \) labels states in \( P \) with PTGT APs based only on the satisfaction of GCs for graphs.

\(^4\) See [13] for a full definition of induced timed and discrete steps.
4 Probabilistic Metric Temporal Graph Logic

Before introducing PMTGL, we recall MTGL \([5,17]\) and adapt it to PTGTSs. To simplify our presentation, we focus on a restricted set of MTGL operators and conjecture that the presented adaptations of MTGL are compatible with full MTGL from [17] as well as with the orthogonal MTGL developments in [18].

The Metric Temporal Graph Conditions (MTGCs) of MTGL are specified using (a) the GC operators to express properties on a single graph in a path and (b) metric temporal operators to navigate through the path. For the latter, the operator \(\exists^N\) (called \(\text{exists-new}\)) is used to extend a current match of a graph \(H\) to a supergraph \(H'\) in the future such that some additionally matched graph element could not have been matched earlier. Moreover, the operator \(U\) (called \(\text{until}\)) is used to check whether an MTGC \(\theta_2\) is eventually satisfied in the future within a given time interval while another MTGC \(\theta_1\) is satisfied until then.

**Definition 7 (MTGCs).** For a graph \(H, \theta_H \in \text{MTGC}(H)\) is a metric temporal graph condition (MTGC) over \(H\) defined as follows:

\[
\theta_H := \top \ | \ \neg \theta_H \ | \ \theta_H \land \theta_H \ | \ \exists(f, \theta_H') \ | \ \nu(g, \theta_H') \ | \ \exists^N(f, \theta_H') \ | \ \theta_H \ U \ \theta_H
\]

where \(f : H \rightarrowtail H'\) and \(g : H'' \rightarrow H\) are monos and where \(I\) is an interval over \(R^0_\Delta\).

For our running example, consider the MTGC given in Figure 2f inside the operator \(P_{\max=?}(\cdot)\). Intuitively, this MTGC states that \((\forall\text{-new})\) whenever a message has just been sent from the sender to the first router, \((\text{restrict})\) when only tracking this message (since at least the edge \(e_2\) can be assumed to be removed in between), \((\text{until})\) eventually within 5 time units, \((\exists\text{st})\) this message is delivered to the receiver as indicated by the \(\text{done}\) loop.

In [5,17], MTGL was defined for timed graph sequences in which only discrete steps are allowed each having a duration \(\delta > 0\). We now adapt MTGL to PTGTSs in which discrete steps and timed steps are interleaved and where zero time may elapse between two discrete steps.

To be able to track subgraphs in a PTS path \(\pi\) over time using matches, we first identify the graph \(\pi(t)\) in \(\pi\) at a position \(t = (t, s) \in R^0_\Delta \times N\) where \(t\) is a total time point and \(s\) is a step index.\(^5\)

**Definition 8 (Graph at Position).** A graph \(G\) is at position \(\pi = (t, s)\) in a path \(\pi\) of PTS \(P\), written \(\pi(t) = G\), if \(\pi(t, s, i) = G\) for some index \(i\) is defined as follows.

- If \(\pi_0 = ((G, v), a, \mu, (G', v'))\), then \(\pi_0(t, 0, 0, 0) = G\).
- If \(\pi_i = ((G, v), a, \mu, (G', v'))\), \(\pi_i(t, s, i) = G\), and \(a \in R^+\), then \(\pi_i(t + \delta, s, i) = G\) for each \(\delta \in [0, a]\) and \(\pi_i(t + a, 0, i + 1) = G'\).
- If \(\pi_i = ((G, v), a, \mu, (G', v'))\), \(\pi_i(t, s, i) = G\), and \(a \notin R^+\), then \(\pi_i(t, s + 1, i + 1) = G'\).

A match \(m : H \rightarrowtail \pi(t)\) into the graph at position \(\pi\) can be propagated forwards/backwards over the PTS steps in a path to the graph \(\pi(t')\). Such a propagated match \(m' : H \rightarrowtail \pi(t')\), written \(m' \in \text{PM}(\pi(m, \tau, \tau'))\), can be obtained uniquely if all matched graph elements \(m(H)\) are preserved by the considered PTS steps, which is trivially the case for timed steps. When some graph element is not preserved, \(\text{PM}(\pi(m, \tau, \tau'))\) is empty.

\(^5\) To compare positions, we define \((t, s) < (t', s')\) if either \(t < t'\) or \(t = t'\) and \(s < s'\).
We now present the semantics of MTGL by providing a satisfaction relation, which is defined as for GL for the operators inherited from GL and as explained above for the operators exists-new and until.

**Definition 9 (Satisfaction of MTGCs).** An MTGC $\theta \in \text{MTGC}(H)$ over a graph $H$ is satisfied by a path $\pi$ of the PTS $P$, a position $\tau \in R_0^+ \times \mathbb{N}$, and a mono $m : H \rightsquigarrow \pi(\tau)$, written $(\pi, \tau, m) \models \psi$, if an item applies.

- $\theta = \top$.
- $\theta \equiv \neg \theta'$ and $(\pi, \tau, m) \not\models \theta'$.
- $\theta = \theta_1 \land \theta_2$, $(\pi, \tau, m) \models \theta_1$, and $(\pi, \tau, m) \models \theta_2$.
- $\theta = \exists f : H \rightsquigarrow H', \theta')$ and $\exists m' : H' \rightsquigarrow \pi(\tau)$. $m' \circ f = m \land (\pi, \tau, m') \models \theta$.
- $\theta = \nu(g) : H'' \rightsquigarrow H, \theta')$ and $(\pi, \tau, m \circ g) \models \theta'$.
- $\theta = \exists f : H \rightsquigarrow H', \theta')$ and there are $\tau' \geq \tau$, $m' \in \text{PM}(\pi, m, \tau, \tau')$, and $m'' : H' \rightsquigarrow \pi(\tau')$ s.t. $m'' \circ f = m', (\pi, \tau', m'') \models \theta$, and for each $\tau'' < \tau'$ it holds that $\text{PM}(\pi, m'', \tau', \tau'') = \emptyset$.
- $\theta = \theta_1 \cup \theta_2$ and there is $\tau' \in 1 \times \mathbb{N}$ s.t.
  - there is $m' \in \text{PM}(\pi, m, \tau, \tau')$ s.t. $(\pi, \tau', m') \models \theta_2$ and
  - for every $\tau \leq \tau'' < \tau'$ there is $m'' \in \text{PM}(\pi, m, \tau, \tau'')$ s.t. $(\pi, \tau'', m'') \models \theta_1$.

Moreover, if $\theta \in \text{MTGC}(\emptyset)$, $\tau = (0, 0)$, and $(\pi, \tau, \iota(\pi(\tau))) \models \theta$, then $\pi \models \theta$.

We now introduce the Probabilistic Metric Temporal Graph Conditions (PMTGCs) of MTGL, which are defined based on MTGCs.

**Definition 10 (PMTGCs).** Each probabilistic metric temporal graph condition (PMTGC) is of the form $\chi = \mathcal{P}_\sim^c(\theta)$ where $\sim \in \{\leq, <, >, \geq\}$ is a probability, and $\theta \in \text{MTGC}(\emptyset)$ is an MTGC over the empty graph. Moreover, we also call expressions of the form $\mathcal{P}_{\min=\gamma}^\sim(\theta)$ and $\mathcal{P}_{\max=\gamma}^\sim(\theta)$ PMTGCs.

The satisfaction relation for PMTGL defines when a PTS satisfies a PMTGC.

**Definition 11 (Satisfaction of PMTGCs).** A PTS $P$ satisfies the PMTGC $\chi = \mathcal{P}_\sim^c(\theta)$, written $P \models \chi$, if, for any adversary $\text{Adv}$, the probability over all paths of $\text{Adv}$ that satisfy $\theta$ is $\sim c$. Moreover, $\mathcal{P}_{\min=\gamma}^\sim(\theta)$ and $\mathcal{P}_{\max=\gamma}^\sim(\theta)$ denote the infimal and supremal expected probabilities over all adversaries to satisfy $\theta$ (cf. Definition 3).

For our running example, the evaluation of the PMTGC $\chi_{\text{max}}$ from Figure 2f for the PTS induced by the PTGTS from Figure 2 results in the probability of $0.8^5 = 0.262144$ using a probability maximizing adversary $\text{Adv}$ as follows. Whenever the first graph of the PTGTC can be matched, this is the result of an application of the PTGT rule $\sigma_{\text{send}}$. The adversary $\text{Adv}$ ensures then that each message is transmitted as fast as possible to the destination router $R_3$ by (a) letting time pass only when this is unavoidable to satisfy some guard and (b) never allowing to match the router $R_4$ by the PTGT rule $\sigma_{\text{transmit}}$ as this leads to a transmission with 3 hops. For each message, the only transmission requiring at most 5 time units transmits the message via the router $R_2$ to router $R_3$ using 2 hops in $2 + 2$ time units. The urgently (i.e., without prior delay) applied PTGT rule $\sigma_{\text{receive}}$ then attaches a done loop to the message as required by $\chi_{\text{max}}$. Since the transmissions of the messages do not affect each other and messages are successfully transmitted only when both transmission attempts succeeded, the maximal probability to satisfy the inner MTGC is $(0.8 \times 0.8)^3$.

Table 1: Overview of the steps of our BMC approach.

| Step | Inputs                          | Outputs                       |
|------|---------------------------------|-------------------------------|
| 1    | PTGTS S                          | PTGTS S'                      |
| 2    | PTGTS S'                         | PTA A                         |
| 3    | PTA A                            | GH-Map M_{GH}                |
| 4    | PMTGC \chi                      | GC \phi                       |
| 5    | GC \phi                          | AC-Map M_{AC}                |
| 6    | PTA A                            | Zone-Map M_{Zone}             |
| 7    | PMTGC \chi                       | AP-Map M_{AP}                |
| 8    | PTA A                            | Probability Interval I        |

5 Bounded Model Checking Approach

We now present our approach for reducing the BMC problem for a fixed PTGTS \( S \), a fixed PMTGC \( \chi = \mathcal{P}_{\leq c}(\theta) \), and an optional time bound \( T \in \mathbb{R}_0^+ \cup \{ \infty \} \) to a model checking problem for a PTA and an analysis problem from Definition 3. Using this approach, we can analyze whether \( S \) satisfies \( \chi \) when restricting the discrete behavior of \( S \) to the time interval \([0, T)\). In fact, we only consider PMTGCs of the form \( \mathcal{P}_{\min=?}(\theta) \) or \( \mathcal{P}_{\max=?}(\theta) \) for computing expected probabilities since they are sufficient to analyze the PMTGC \( \mathcal{P}_{\leq c}(\theta) \).

See Table 1 for an overview of the subsequently discussed steps of our approach.

Step 1: Encoding the Time Bound into the PTGTS

For the given PTGTS \( S \) and time bound \( T \), we construct an adapted PTGTS \( S' \) into which the time bound \( T \) is encoded (for \( T = \infty \), we use \( S' = S \)). In \( S' \), we ensure that all discrete PTGT steps and all PTGT invariants are disabled when time bound \( T \) is reached. For this purpose, we (a) add an additional node \( b \) of a fresh node type \( \text{Bound} \) with a clock \( x \) to the initial graph of \( S \) and to the graphs \( L, K \), and \( R \) of each underlying GT rule \( \rho = (\ell : K \leftarrow L, r : K \leftarrow R, \gamma) \) of each PTGT rule \( \sigma \) of \( S \), (b) add a PTGT rule with a priority higher than all other used priorities deleting the node \( b \) urgently with a guard \( x = T \), and (c) extend each PTGT invariant \( \phi \) to \( \phi \lor \neg \exists (b: \text{Bound}, \top) \) disabling it for states where the \( b \) node has been removed. For the resulting PTGTS \( S' \), we then solve the model checking problem for the given PMTGC \( \chi \).

Step 2: Construction of an Equivalent PTA

For the PTGTS \( S' \) from step 1, we now construct an equivalent PTA \( A \) using the operation \( \text{PTGTS}_{\to}^{\text{PTA}} \), which is based on a similar operation from [13].

As a first step, we obtain the underlying GTS \((G_0, P)\) of \( S' \) where \( G_0 \) is the initial graph of \( S' \) and \( P \) contains all underlying GT rules \( \rho \) of all PTGT rules \( \sigma \) of \( S' \) as in [13]. As a second step, we construct for this GTS its GT state space \((Q, E)\) consisting of states \( Q \) and edges \( E \) as in [13] but deviate by not identifying isomorphic states, which results in a tree-shaped GT state space with root \( G_0 \). Note that the paths through \((Q, E)\) symbolically describe all

---

6 For example, \( \mathcal{P}_{\min=?}(\theta) = c \) implies satisfaction of \( \mathcal{P}_{\geq c}(\theta) \) for any \( c' \geq c \).

7 Our BMC approach cannot be used if the PTGTS \( S' \) results in an infinite \((Q, E)\).
timed probabilistic paths through $S'$. As a third step, we again deviate from [13] and modify $(Q, E)$ into $(Q', E')$ by adding time point clocks throughout the paths of $(Q, E)$ as follows. If $N$ is the maximal number of graphs in any path $\pi$ of $(Q, E)$, we (a) create additional time point clocks $tpc_i$ to $tpc_N$, (b) add the $i$ time point clocks $tpc_i$ to $tpc_j$ to the $i$th graph in any path of the state space, and (c) add the clock $tpc_i$ to the reset set of the step leading to the graph $G_i$ in any path of the state space. Consequently, the AC $tpc_i - tpc_j$ for $j \geq i$ expresses the time expired between the graphs $G_i$ and $G_j$. Finally, as in [13], we construct the resulting PTA $A$ from the given PTGTS $S'$ and the state space $(Q', E')$ by (a) aggregating GT steps with a common source state and a match belonging to one PTGT rule, (b) annotating such aggregated GT steps with the clock-based timing constraints given by the guards and resets of the used PTGT rule, and (c) adding the clock-based timing constraints given by the PTGT invariants to the resulting PTA. This PTA construction ensures that the resulting PTA $A$ is equivalent to the given PTGTS $S'$.

**Lemma 1 (Soundness of PTA Construction).** If the PTGTS $S'$ has a finite tree-shaped state space $(Q, E)$, then the two PTs PTAtoPTS($PTGTS\rightarrow\text{PTA}(S')$) and PTGTstoPTS($S'$) return the same results for the analysis problems from Definition 3. See appendix for a proof sketch.

In step 8, we will apply the Prism model checker [11] to the obtained PTA $A$ and an analysis problem from Definition 3 corresponding to the given PMTGC $\chi$. For this purpose, we obtain in steps 3–7 the set of leaf-locations of the PTA, in which the MTGC $\theta$ used inside the PMTGC $\chi$ is not violated, and then label precisely those locations from that set with an additional AP success. Employing this AP, the analysis problems from Definition 3 can be used to express the minimal/maximal probability to reach no violation.

**Step 3: Folding of Paths into Graphs with History**

For the given PTA $A$, we consider its structural paths $\pi$, which are the paths through the GT state space $(Q', E')$ from which $A$ was constructed. Such paths $\pi$ may have timed realizations $\pi'$ in which timed steps and discrete steps using the PTA edges of $\pi$ are interleaved. Following the satisfaction checking approach for MTGL from [5,17], we translate the MTGC satisfaction problem into an equivalent GC satisfaction problem using an operation fold (introduced subsequently) and an operation encode (introduced in step 4). Both operations together ensure for each timed realization $\pi'$ of a structural path $\pi$ of the given PTA $A$ that $\pi' \models \theta$ iff $\phi_G \models \phi$ when fold($\pi$) = $G_H$ is a Graph with History (GH), the graph $G_H$ is obtained from $G_H$ by adding the durations of steps in $\pi'$ as ACs over the time point variables of $G_H$, and encode($\theta$) = $\phi$.

The operation fold is applied to each structural path $\pi$ of the given PTA $A$ aggregating the information about the nature and timing of all GT steps into a single resulting GH. As a first step, we construct the colimit $G_H$ for the diagram of the GT spans of $\pi$ (given by the $sp$ components of step actions according to Definition 6), which contains all graph elements that existed at some time point in $\pi$. As a second step, each node and edge in $G_H$ is equipped with additional creation/deletion time stamp attributes $cts/dts$ and creation/deletion index attributes $cidx/didx$. As a third step, the ACs $cts = tpc_0 - tpc_j$ and $cidx = j$ are added for
each node/edge that appeared first in the graph $G_i$ in the path $\pi$. As a fourth step, the ACs $dts = tpc_0 - tpc_j$ and $didx = j$ are added for each node/edge that is removed in the step reaching $G_j$ in the path $\pi$. Finally, the ACs $dts = -1$ and $didx = -1$ are added for nodes/edges that are never removed in $\pi$.\footnote{The presented operations fold and encode are adaptations of the corresponding operations from [5,17] to the modified MTGL satisfaction relation defined for PTSs (see Definition 9). The adapted operation fold uses ACs to express clock differences instead of concrete assignments and employs additional index attributes $cidx/didx$. The adapted operation encode uses the additional step index variable $x_s$ in the alive and earliest ACs to take not only the time stamp but also the step index into account.}

As output, we obtain the so-called $GH$-restrictions $GH$-Map $M_{GH}$ mapping all leaf-locations $\ell$ of the PTA $A$ to the GH constructed for the path ending in $\ell$.

**Step 4: Encoding of an MTGC as a GC**

We now discuss the operation encode for translating the MTGC $\theta$ contained in the given PMTGC $\chi$ into a corresponding GC $\phi$. Intuitively, this operation recursively encodes the requirements (see the items of Definition 9) expressed using MTGL operators on a timed realization $\pi'$ (of a structural path $\pi$ of the PTA $A$ folded in step 3) using GL operators on the GH $G_H$ (obtained by folding $\pi$) with additional ACs. In particular, quantification over positions $\tau = (t,s)$, as for the operators $\exists$-new and until, is encoded by quantifying over additional variables $x_t$ and $x_s$ representing $t$ and $s$, respectively. Moreover, matching of graphs, as for the operators $\exists$ and $\exists$-new, is encoded by an additional AC alive. This AC requires that each matched graph element in the GH $G_H$ has $cts$, $dts$, $cidx$, and $didx$ attributes implying that this graph element exists for the position $(x_t,x_s)$ in $\pi'$. Lastly, matching of new graph elements in the $\exists$-new operator is encoded by an additional AC earliest. This AC requires, in addition to alive, that one of the matched graph elements has $cts$ and $cidx$ attributes equal to $x_t$ and $x_s$, respectively.\footnote{As output, we obtain the GC $\phi$, which expresses the MTGC $\theta$ based on the graph $G'_{H}$ obtained from the timed realization $\pi'$ in step 3.}

**Step 5: Construction of AC-Restrictions of Violations**

For each GH $G'_{H}$ (from the given $GH$-Map $M_{GH}$) obtained in step 3 for some path $\pi$, we evaluate the negation of the given GC $\phi$ obtained in step 4 for this $G'_{H}$. The result of this evaluation is an AC $\gamma$, which describes valuations of the variables contained in $G_H$. Each such valuation describes a timed realization $\pi'$ of $\pi$ not satisfying the MTGC $\theta$ (i.e., a violation) by providing real-valued time points for the additional time point clocks contained in $G'_{H}$. In the sense of the equivalence discussed in step 3, such a valuation represents the durations of timed steps in $\pi'$, which can be added in the form of an AC to $G'_{H}$ resulting in the graph $G''_{H}$ such that $\pi' \models \theta$ and $G''_{H} \not\models \phi$.

For our running example, any path $\pi$ ends with all messages being received. The obtained AC $\gamma$ describes then that a violation has occurred when, for one of the messages, the sum of the timed steps between sending and receiving exceeds 5 time units. Certainly, due to possible interleavings of discrete steps and different routes from $R_1$ to $R_3$, there are various structural paths of $A$ ending in different GHs each resulting in a different AC $\gamma$.\footnote{As output, we obtain the so-called $GH$-restrictions $GH$-Map $M_{GH}$ mapping all leaf-locations $\ell$ of the PTA $A$ to the GH constructed for the path ending in $\ell$.}
As output, we obtain the so-called AC-restrictions AC-Map $M_{AC}$ mapping all leaf-locations $\ell$ of the PTA $A$ to the AC $\gamma$ constructed for the GH $G_H$ (which is obtained for the path $\pi$ ending in $\ell$).

**Step 6: Construction of Zone-Restrictions of Violations**

We adapt the given PTA $A$ from step 2 to a resulting PTA $A'$ by adding an additional AP terminal and labeling all leaf-locations with this AP. We then construct the symbolic zone-based state space for the PTA $A'$ by evaluating $P_{\max=\gamma}(F \ terminal)$ (see Definition 3) using a minor adaptation of the PRISM model checker that outputs the states $s = (\ell, \psi)$ labeled with the AP terminal containing a location $\ell$ and a clock constraint $\psi$ as a zone (which is unique due to the tree-shaped form of the PTA $A$). For each structural path $\pi$ of the PTA $A$ ending in the location $\ell$, the zone $\psi$ symbolically represents all timed realizations $\pi'$ of $\pi$, which respect the timing constraints of the PTA $A$, in terms of differences between the additional time point clocks added in step 2.

For our running example, the zone $\psi$ obtained for some leaf-location then contains the clock constraints capturing for each message that (a) 2 to 5 time units elapsed before each transmission attempt and (b) no time elapsed between the arrival of that message at router $R_3$ and its reception by the receiver.

As output, we obtain the so-called zone-restrictions Zone-Map $M_{Zone}$ mapping all leaf-locations $\ell$ of the PTA $A$ to the zone $\psi$ obtained for $\ell$.

**Step 7: Construction of Violations**

We now combine the restrictions captured by the given mappings GH-Map $M_{GH}$, AC-Map $M_{AC}$, and Zone-Map $M_{Zone}$ to determine the leaf-locations of the PTA $A$ representing violations. A leaf-location $\ell$ represents a violation when it is reached by a structural path $\pi$ of $A$ that is realizable in terms of a timed realization $\pi'$ such that the interleaving of timed and discrete steps in $\pi'$ (which depends on the considered adversary) results in a violation when reaching $\ell$.

For this purpose, we compare the AC-restrictions with the zone-restrictions in a way that depends on whether the given PMTGC $\chi$ is of the form $P_{\max=\gamma}(\theta)$ or $P_{\min=\gamma}(\theta)$. In the following, we consider the case for $\max$ (and the case for $\min$ in brackets). We define the AC $\gamma_{\text{check}}$ as $M_{Zone}(\ell) \land \neg(M_{AC}(\ell) \land M_{GH}(\ell), \text{ac})$ (for $\min$: $M_{Zone}(\ell) \land M_{AC}(\ell) \land M_{GH}(\ell), \text{ac}$) where $M_{GH}(\ell), \text{ac}$ denotes the AC of the GH $M_{GH}(\ell)$. This AC is satisfiable (for $\min$: unsatisfiable) iff a violation is avoidable (for $\min$: unreachable) for any probability maximizing (for $\min$: probability minimizing) adversary based on interleavings of timed steps. We use the SMT solver Z3 [14] to decide whether the obtained $\gamma_{\text{check}}$ is satisfiable (for $\min$: unsatisfiable).

As output, we obtain the so-called AP-Map $M_{AP}$, which maps all leaf-locations $\ell$ of the PTA $A$ to a set of APs. The set of APs $M_{AP}(\ell)$ contains (a) the APs success and maybe, if $Z_3$ returns that the checked AC $\gamma_{\text{check}}$ is satisfiable (for $\min$: unsatisfiable) and (b) the AP maybe, if $Z_3$ does not return a result. Hence, structural paths of the PTA $A$ ending in locations labeled with the AP success represent PTGTS paths definitely (for $\min$: possibly) satisfying the considered MTGC whereas PTGTS paths ending in locations labeled with the AP maybe may or may not represent such paths.
Step 8: Computation of Resulting Probabilities

In steps 1–7, we reduced the considered BMC problem to one of the analysis problems from Definition 3 for which Prism can be applied. For this last step, we adapt the given PTA A from step 2 to a PTA A’ by adding the labeling captured by the given AP-Map M_{AP} from step 7. We compute and output the probability intervals \( I = [P_{\min=2(\text{success})}, P_{\min=2(\text{maybe})}]\) and \( I = [P_{\max=2(\text{success})}, P_{\max=2(\text{maybe})}]\) of possible expected probability values for \( P_{\min=2(\theta)} \) and \( P_{\max=2(\theta)} \), respectively. If Z3 always succeeded in step 7, this probability interval I will be a singleton. Lastly, we state that the presented BMC approach is sound (up to the imprecision possibly induced by Z3).

Theorem 1 (Soundness of BMC Approach). The presented BMC approach correctly analyzes (correctly approximates) satisfaction of PMTGCs when the returned probability interval I is (is not) a singleton. See appendix for a proof sketch.

6 Evaluation

To evaluate our BMC approach, we applied its implementation in the tool AutoGraph (where Prism and Z3 are used as explained before) to our running example given by the PMTGC \( \chi_{\max} \) from Figure 2f and the PTGTS from Figure 2. In this application, we used the time bound \( T = \infty \) for which the PTGTS was not adapted in step 1 because it already resulted in a finite tree-shaped GT state space \((Q, E)\) in step 2.\(^9\) The constraint solver Z3 was always able to decide all satisfaction problems in step 7, and the probability interval obtained in step 8 using Prism was \([0.262144, 0.262144]\), which is in accordance with our detailed explanations below Definition 11.

We also applied our BMC approach to the same PTGTS (again using the time bound \( T = \infty \)) and the PMTGC \( P_{\min=2(\theta)} \) where \( \theta \) is the MTGC used in the PMTGC \( \chi_{\max} \) from Figure 2f. In this case, we obtained in step 8 the probability interval \([0, 0]\) since there is a probability minimizing adversary that sends the first message at time point 0 and then delays the first two transmission attempts of that message to time points 5 and 10 ensuring that the message is not received within 5 time units as required in the MTGC \( \theta \).

Both discussed applications of our BMC approach (where steps 1–7 can be reused for the second application) required negligible runtime and memory.

7 Conclusion and Future Work

In this paper, we introduced the Probabilistic Metric Temporal Graph Logic (PMTGL) for the specification of cyber-physical systems with probabilistic timed behavior modeled as PTGTSs. PMTGL combines (a) MTGL with its binding capabilities for the specification of timed graph sequences and (b) the probabilistic operator from PTCTL to express best-case/worst-case probabilistic timed reachability properties. Moreover, we presented a novel Bounded Model Checking (BMC) approach for PTGTSs w.r.t. PMTGL properties.

\(^9\) In \((Q, E)\), each of the three messages has either not yet been sent, is at one of the five routers, or has been received resulting in at most \(7^3\) states.
In the future, we will consider the case study \[16,13\] of a cyber-physical system where, in accordance with real-time constraints, autonomous shuttles exhibiting probabilistic failures on demand navigate on a track topology. For this case study, we will evaluate the expressiveness and usability of PMTGL as well as the performance of our BMC approach. Also, we will integrate our MTGL-based approach from \[18\] for deriving so-called optimistic violations.

A  Proofs

In this appendix, we provide proof sketches omitted in the main body of this paper.

Proof (Lemma 1, p. 12: Soundness of PTA Construction). The nonidentification of isomorphic states and the addition of time point clocks does not affect the possible steps of the resulting PTA. This PTA is therefore, following [13], equivalent to the given PTGTS $S'$ w.r.t. the analysis problems from Definition 3.

Proof (Theorem 1, p. 15: Soundness of BMC Approach). We conclude that the presented BMC approach computes the correct results (a) by encoding the time bound $T$ properly in step 1, (b) from the soundness of the operation PTGTS$\rightarrow$PTA according to Lemma 1 (following [13]), (c) from the soundness of the adapted translation of MTGC satisfaction problem into an equivalent GC satisfaction problem along the lines of [5,17], and (d) from the correct computation of zones in Prism.

B  Details for Simplified Running Example

In this appendix, we present figures for the steps of our BMC approach for a simplified form of our running example where only a single message is transmitted to the receiver.
Fig. 3: Visualization for step 2 of our BMC approach: A structural path $\pi$ of the PTA $A$ (using an adapted initial graph with a single message).
Fig. 4: Visualization for step 3 of our BMC approach: $G_{H}$ obtained for the structural path $\pi$ from Figure 3.
Fig. 5: Visualization for step 4 of our BMC approach: GC $\phi$ obtained by encoding of the MTGC from the PMTGC $\chi_{\max}$. 

$\Theta_0 = \{x_{i,0} = 0, x_{i,0} = 0\}$

$\Theta_1 = \Theta_0 \cup \left\{ x_{i,0} < x_{i,1} \lor (x_{i,0} = x_{i,1} \land x_{i,0} < x_{i,1}) \right\}$

$\Theta_2 = \Theta_1 \cup \{ \text{alive}(x_{i,1}, x_{i,1}, \{S, R_i, M, c_i, c_2\}), \text{earliest}(x_{i,1}, x_{i,1}, \{S, R_i, M, c_i, c_2\}) \}$

$\Theta_3 = \Theta_2 \cup \{ \text{alive}(x_{i,1}, x_{i,1}, \{M\}) \}$

$\Theta_4 = \Theta_3 \cup \left\{ x_{i,1} < x_{i,2} \lor (x_{i,1} = x_{i,2} \land x_{i,1} < x_{i,2}), x_{i,2} \leq x_{i,1} + 5 \right\}$

$\Theta_5 = \Theta_4 \cup \{ \text{alive}(x_{i,2}, x_{i,2}, \{M, c_2\}) \}$
$$\neg \exists x_{t,0} \text{real}, x_{s,0} \text{int}.$$  
$$x_{t,0} = 0 \land x_{s,0} = 0$$  
$$\land \forall x_{t,1} \text{real}, x_{s,1} \text{int}.$$  
$$x_{t,0} < x_{t,1} \lor (x_{t,0} = x_{t,1} \land x_{s,0} < x_{s,1})$$  
$$\land$$  
$$\text{alive}(x_{t,1}, x_{s,1}), \{ S, R_1, M_1, e_1, e_8 \})$$  
$$\land$$  
$$\text{earliest}(x_{t,1}, x_{s,1}), \{ S, R_1, M_1, e_1, e_8 \})$$  
$$\Rightarrow \exists x_{t,2} \text{real}, x_{s,2} \text{int}.$$  
$$x_{t,1} < x_{t,2} \lor (x_{t,1} = x_{t,2} \land x_{s,1} < x_{s,2})$$  
$$\land$$  
$$x_{t,2} \leq x_{t,1} + 5$$  
$$\land$$  
$$\text{alive}(x_{t,2}, x_{s,2}), \{ M_1, e_11 \})$$

Intuitively, this expression captures an untimely reception in the sense of:

$$(tpc_4 - tpc_0) > (tpc_1 - tpc_0) + 5$$

or even in the simplest form:

$$tpc_4 > tpc_1 + 5$$

Technically, it refers to all attributes of the GH $G_H$ (in the alive and earliest ACs), which makes the usage of $G_H$ in step 7 necessary.

Fig. 6: Visualization for step 5 of our BMC approach: AC-restriction of violations (result of evaluating the negation of the GC $\phi$ from Figure 5 for the GH $G_H$ from Figure 4).

$$tpc_1 - tpc_0 \geq 0$$  
$$\land tpc_2 - tpc_1 \geq 2$$  
$$\land tpc_2 - tpc_1 \leq 5$$  
$$\land tpc_3 - tpc_2 \geq 2$$  
$$\land tpc_3 - tpc_2 \leq 5$$  
$$\land tpc_4 - tpc_3 \leq 0$$  
$$\land e_1 \geq 0$$

Intuitively, the guards and invariants stated for the clock of the message result in a restriction of the time point clock variables.

Fig. 7: Visualization for step 6 of our BMC approach: Zone-restriction of violations (result for the structural path $\pi$ from Figure 3).
For the case of $P_{\text{max}} = \gamma(\theta)$, we construct the AC $\gamma_{\text{check}}$ using the AC from Figure 6, the AC from Figure 7, and the AC of the GH from Figure 4 (given by the conjunction of all ACs contained in the graph). $\gamma_{\text{check}}$ is equivalent to the following simplified AC.

$$
\gamma_{\text{check}} \equiv 4 \leq \text{tpc}_4 - \text{tpc}_1 \leq 10 \land \neg(\text{tpc}_4 > \text{tpc}_1 + 5)
$$

This AC $\gamma_{\text{check}}$ is satisfiable. In fact, it is satisfied by the clock valuation $\{\text{tpc}_1 \mapsto 0, \text{tpc}_4 \mapsto 4\}$ describing the fastest transmission of the message $M_1$. From the satisfiability, we obtain the labeling of $G_H$ from Figure 4 using the APs $\text{success}$ and $\text{maybe}$.

Fig. 8: Visualization for step 7 of our BMC approach: Derivation of labeling.

The probability maximizing adversary, will find at least the path to the location given by the GH $G_H$ from Figure 4. This path has a probability of $1 \times 0.8 \times 0.8 \times 1$ and is labeled with the APs $\text{success}$ and $\text{maybe}$. Prism returns the probability interval $I = [0.64, 0.64]$ since all other paths will not be labeled with one of these APs because the timing constraint of at most 5 time units from the PMTGC $\chi_{\text{max}}$ is not satisfied by the other paths.

Fig. 9: Visualization for step 8 of our BMC approach: Derivation of probabilities.
C Example for Step 7 of the BMC Approach

In this appendix, we provide a short example on why step 7 is defined as described. For this purpose, we consider different combinations of zone-restrictions and AC-restrictions for the two cases of $P_{\text{max}=?}(\theta)$ and $P_{\text{min}=?}(\theta)$.

Example 1 (Computation of Labeling in Step 7). We consider a zone-restriction $4 \leq x \leq 10$ as well as AC-restrictions $x \geq 3$, $x \geq 5$, and $x \geq 12$. For the two cases from above, we then determine whether the corresponding leaf-location should be labeled with success and maybe.

| max          | Formula                                      | Labeling           |
|--------------|----------------------------------------------|--------------------|
| $(4 \leq x \leq 10) \land \neg(x \geq 3)$ | is unsatisfiable, hence no labeling          |                    |
| $(4 \leq x \leq 10) \land \neg(x \geq 5)$ | is satisfiable, hence labeling with $\{\text{success, maybe}\}$ |                    |
| $(4 \leq x \leq 10) \land \neg(x \geq 12)$ | is satisfiable, hence labeling with $\{\text{success, maybe}\}$ |                    |

| min          | Formula                                      | Labeling           |
|--------------|----------------------------------------------|--------------------|
| $(4 \leq x \leq 10) \land (x \geq 3)$ | is satisfiable, hence no labeling          |                    |
| $(4 \leq x \leq 10) \land (x \geq 5)$ | is satisfiable, hence no labeling          |                    |
| $(4 \leq x \leq 10) \land (x \geq 12)$ | is unsatisfiable, hence labeling with $\{\text{success, maybe}\}$ |                    |

For the case of $P_{\text{max}=?}(\theta)$, satisfiability means that some interleaving with timed steps does not result in a violation.

For the case of $P_{\text{min}=?}(\theta)$, unsatisfiability means that each interleaving with timed steps does not result in a violation.
