Elliptic and triangular flow of (anti)deuterons in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV

ALICE Collaboration

Abstract

The measurements of the (anti)deuterons elliptic flow ($v_2$) and the first measurements of triangular flow ($v_3$) in Pb–Pb collisions at a center-of-mass energy per nucleon–nucleon collisions $\sqrt{s_{NN}} = 5.02$ TeV are presented. A mass ordering at low transverse momentum ($p_T$) is observed when comparing these measurements with those of other identified hadrons, as expected from relativistic hydrodynamics. The measured (anti)deuterons $v_2$ lies between the predictions from the simple coalescence and blast-wave models, which provide a good description of the data only for more peripheral and for more central collisions, respectively. The mass number scaling, which is violated for $v_2$, is approximately valid for the (anti)deuterons $v_3$. The measured $v_2$ and $v_3$ are also compared with the predictions from a coalescence approach with phase-space distributions of nucleons generated by iEBE-VISHNU with AMPT initial conditions coupled with UrQMD, and from a dynamical model based on relativistic hydrodynamics coupled to the hadronic afterburner SMASH. The model predictions are consistent with the data within the uncertainties in mid-central collisions, while a deviation is observed in the most central collisions.
1 Introduction

The production mechanism of light (anti)nuclei in high-energy hadronic collisions is still not fully clear and is under intense debate in the scientific community [1–5]. The understanding of the production of loosely-bound multi-baryon states in heavy-ion collisions has additional complications due to the fact that the phase transition is followed by a hadrons gas phase with intense re-scattering of hadrons. At the Large Hadron Collider (LHC) energies, the lifetime of the hadronic phase between chemical and kinetic freezeout is in the range 4–7 fm/c [6] and the kinetic freezeout temperature, when elastic interactions cease, is of the order of 100 MeV [7, 8]. The binding energy of multi-baryon systems such as light (anti)nuclei typically does not exceed a few MeV, which is almost two orders of magnitude smaller than the temperature of the system. Considering the high density of hadrons in the post-hadronization stage and the large dissociation cross sections of light (anti)nuclei, it is not clear how such loosely-bound systems can survive under these extreme conditions.

Existing phenomenological models provide very different interpretations for this observation. In the statistical hadronization model [1–3, 9, 10], light (anti)nuclei as well as all other hadron species are assumed to be emitted by a source in local thermal and hadrochemical equilibrium. Their abundances are fixed at the chemical freeze-out, occurring at a temperature of $T_{\text{chem}} = 156 \pm 4$ MeV for Pb–Pb collisions at the LHC [11]. This model provides a good description of the measured hadron yields in central nucleus–nucleus collisions [1]. However, the mechanism of hadron production and the propagation of loosely-bound states through the hadron gas phase are not addressed by this model. In the context of the statistical hadronization model, it has been conjectured that such objects could be produced at the phase transition as compact colorless quark clusters with the same quantum numbers of the final state hadrons. The survival of these states at high temperatures is interpreted as due to the low interaction cross section with the surrounding medium [1].

In the coalescence approach, multi-baryon states are assumed to be formed by the coalescence of baryons at the kinetic freeze-out. In the simplest versions of this model [12, 13], baryons are treated as point-like particles and the coalescence happens instantaneously if the momentum difference between nucleons is smaller than a given threshold, which is typically of the order of 100 MeV/c, while spatial coordinates are ignored. In the state-of-the-art implementations of the coalescence approach [4, 14], the quantum-mechanical properties of baryons and their bound states are taken into account and the coalescence probability is calculated from the overlap between the wave functions of baryons and the Wigner density of the final-state cluster. All light (anti)nuclei produced at the phase transition are assumed to be destroyed by the interactions in the hadron gas phase and regenerated with the same amount only at the latest stage of the system evolution.

To address the open question of the survival of loosely-bound multi-baryon states in the hadron gas phase with intense re-scattering, models based on relativistic hydrodynamics coupled to a hadronic afterburner have been recently developed [4, 5]. In these models, nucleons and light nuclei are produced at the phase transition using the Cooper-Frye formula [15], which describes the hadron production based on the local energy density of the fireball, and their yields are fixed to the value predicted by the thermal model at the chemical freeze-out temperature. Their propagation through the hadronic medium is simulated based on known interaction cross sections and resonant states using different transport codes. Existing calculations are based on UrQMD [16, 17], with light nuclei being produced by nucleon coalescence, and SMASH [5], where (anti)deuterons are assumed to be destroyed and regenerated with equal rates in the hadronic stage. The model based on UrQMD with nucleon coalescence [4] provides a good description of the elliptic flow of (anti)deuterons measured in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV [18] and of that of (anti)$^3$He measured in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 5.02$ TeV [19]. The model is able to describe the low-$p_T$ spectra of deuterons, but over-predicts the deuterons data above 2.5 GeV/c and the (anti)$^3$He spectra in the full momentum interval. The hybrid model based on SMASH successfully describes the measured (anti)deuterons $p_T$-spectra and coalescence parameter $B_2$, defined as the ratio of the invariant
yield of deuterons and that of protons squared, measured in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [18].

A conceptually similar approach, based on the analogy between the evolution of the early universe after the Big Bang and the space–time evolution of the system created in heavy-ion collisions, has recently been developed [20]. The production of light (anti)(hyper)nuclei in heavy-ion collisions at the LHC is considered in the framework of the Saha equation assuming that disintegration and regeneration reactions involving light nuclei proceed in relative chemical equilibrium after the chemical freeze-out of hadrons.

The existing models depict radically different pictures of the post-hadronization stage for loosely-bound states. Considering this scenario, the measurements of radial and anisotropic flow of light (anti)nuclei, i.e. the harmonics ($v_n$) of the Fourier decomposition of their azimuthal production distribution with respect to a symmetry plane of the collision, are relevant to study their propagation through the hadron gas phase and the dynamics of their interactions with other particles. Compared to the elliptic flow, the triangular flow of light (anti)nuclei has a better sensitivity to the fluctuating initial conditions as well as the properties of the created systems. Therefore, tighter constrains to on theoretical model that describe the production mechanism of light (anti)nuclei can be set.

The elliptic flow of (anti)deuterons was measured as a function of the transverse momentum ($p_T$) for different centrality classes in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [18]. A clear mass ordering is observed at low $p_T$ ($p_T < 3$ GeV/c) when this measurement is compared to that of other hadrons species [21], as expected from relativistic hydrodynamics. The simple coalescence model, based on the assumption that the (anti)deuterons invariant yield is proportional to the invariant yield of (anti)protons squared, is found to overestimate the measured $v_2$ in all centrality intervals. The data are better described by the blast-wave model, a simplified version of the relativistic hydrodynamic approach in which the collective expansion is described using a parameterized hydrodynamic flow field. The elliptic flow of (anti)$^3$He was measured in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV [19]. Also in the case of (anti)$^3$He, the mass ordering is observed for $p_T < 3$ GeV/c and the measured elliptic flow lies between the predictions of the blast-wave [22] and the simple coalescence model. A better description of the measurement is provided by a more sophisticated coalescence model where the phase-space distributions of protons and neutrons are generated by the iEBE-VISHNU hybrid model with AMPT initial conditions [4]. The picture that has emerged so far, regarding the elliptic flow of (anti)nuclei measured at LHC energies, is that the simple coalescence and blast-wave models represent the upper and lower edges of a region where the data are mostly located. Recent developments in the coalescence approach, which take into account momentum-space correlations of nucleons and their quantum-mechanical properties, provide a better description of the data [4,8].

In this paper, a precision measurement of the (anti)deuterons elliptic flow and first ever measurement of (anti)deuterons triangular flow for different $p_T$ and centrality intervals in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV are presented. Thanks to the large data sample collected at higher energy, the elliptic flow measurement is performed in wider $p_T$ and up to a higher centrality intervals compared to that in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV, allowing for a more differential comparison with the theoretical models.

2 The ALICE detector

A detailed description of the ALICE detector can be found in [23] and references therein. The main subdetectors used for the present analysis are the V0 detector, the Inner Tracking System (ITS), the Time Projection Chamber (TPC), and the Time-of-Flight detector (TOF), which are located inside a solenoidal magnet that provides a uniform field of 0.5 T directed along the beam direction. The V0 detector [24] consists of two arrays of scintillation counters placed around the beam vacuum tube on either side of the interaction point: one covering the pseudorapidity interval $2 < \eta < 5.1$ (V0A) and the other one covering $-3.7 < \eta < -1.7$ (V0C). Each V0 array consists of four rings in the radial direction, with each ring comprising eight cells with the same azimuthal size. The scintillator arrays have an intrinsic time
resolution better than 0.5 ns, and their timing information is used in coincidence for offline rejection of events produced by the interaction of the beams with residual gas in the vacuum pipe. The V0 scintillators are used to determine the collision centrality from the measured charged-particle multiplicity \[25–27\] and to measure the orientation of the symmetry plane of the collision.

The ITS \[28\], designed to provide high-resolution track points in the vicinity of the nominal vertex position, is composed of three subsystems of silicon detectors placed around the interaction region with a cylindrical symmetry. The Silicon Pixel Detector (SPD) is the subsystem closest to the beam vacuum tube and it is made of two layers of pixel detectors. The third and the fourth layers are formed by Silicon Drift Detectors (SDD), while the outermost two layers are equipped with double-sided Silicon Strip Detectors (SSD). The ITS covers the pseudorapidity interval \(|\eta| < 0.9\).

The same pseudorapidity interval is covered by the TPC, which is the main tracking detector, consisting of a hollow cylinder whose axis coincides with the nominal beam axis.

The active volume of 90 m\(^3\) is filled with a gas mixture containing 88% Ar and 12% CO\(_2\).

The trajectory of a charged particle is estimated using up to 159 space points. The charged-particle tracks are then built by combining the hits in the ITS and the reconstructed space points in the TPC. The TPC is also used for particle identification (PID) by measuring the specific energy loss (d\(E/dx\)) in the TPC gas.

The TOF detector \[29\] covers the full azimuth in the pseudorapidity interval \(|\eta| < 0.9\). The detector is based on the Multi-gap Resistive Plate Chambers (MRPCs) technology and it is located, with a cylindrical symmetry, at an average radial distance of 380 cm from the beam axis. The TOF allows for PID, based on the difference between the measured time-of-flight and its expected value, computed for each mass hypothesis from the track momentum and length. The resolution on the measurement of the time-of-flight is about 60 ps in heavy-ion collisions.

### 3 Data sample and analysis techniques

#### 3.1 Event and track selections

The data sample used for the measurements presented in this paper was recorded by ALICE in 2015 during the LHC Pb–Pb run at \(\sqrt{s_{NN}} = 5.02\) TeV. A minimum bias trigger was used during the data taking, which required coincident signals in both V0 detectors. An offline event selection is applied to remove beam-gas collisions using the timing information provided by the V0 detectors and the Zero-Degree Calorimeters \[23\]. Events with multiple primary vertices identified with the SPD are tagged as pileup and removed from the analysis. In addition, events with significantly different charged-particle multiplicities measured by the V0 detector and by the tracking detectors at midrapidity, which have different readout times, are rejected. After the offline event selection, the remaining contribution of beam-gas events is smaller than 0.02\% \[23\] and the fraction of pileup events is found to be negligible. The primary vertex position is determined from tracks reconstructed in the ITS and TPC as described in \[23\] and only events with a reconstructed primary vertex position along the beam axis within 10 cm from the nominal interaction point are selected. The total number of events selected for the analysis for centrality 0–70\% is about 73 million.

Deuteron (d) and antideuteron (\(\bar{d}\)) candidates are selected from charged-particle tracks reconstructed in the ITS and TPC in the kinematic range \(|\eta| < 0.8\) and \(0.8 < p_T < 6\) GeV/c. Only tracks with at least 70 clusters out of a maximum of 159 and with a \(\chi^2\) per degree-of-freedom for the track fit lower than 2 are accepted. In addition, in order to guarantee a track-momentum resolution of 2\% in the measured \(p_T\) range and a \(dE/dx\) resolution of about 6\%, each track is required to be reconstructed from at least 80\% of the number of expected TPC clusters and to have at least one hit in either of the two innermost layers of the ITS. The distances of closest approach (DCA) to the primary vertex in the
Elliptic and triangular flow of (anti)deuterons

The (anti)deuterons identification technique used in this analysis is similar to that used in the previous measurement in Pb–Pb collisions at \( \sqrt{s_{NN}} = 2.76 \) TeV [38]. For transverse momenta up to 1.4 GeV/c (anti)deuterons are identified using the only the TPC information by requiring that the average dE/dx is within 3\( \sigma \) from the expected average value for the (anti)deuteron mass hypothesis. For \( p_T > 1.4 \) GeV/c the 3\( \sigma \) TPC identification is complemented by the signal provided by the TOF detector. The number of (anti)deuterons in each \( p_T \) interval is extracted from a fit of the \( \Delta M = m_{\text{TOF}} - m_{\text{nom}} \), where \( m_{\text{TOF}} \) is the particle mass calculated using the time-of-flight measured by the TOF and \( m_{\text{nom}} \) is the nominal mass of deuterons taken from [33]. In the left panel of Fig. 1 the \( \Delta M \) distribution for (anti)deuterons with \( 2.2 \leq p_T < 2.4 \) GeV/c in the centrality interval 20–30%, is shown. The \( \bar{d}+d \) signal is fitted using a Gaussian with an exponential tail, while the background, originating from TOF hits incorrectly associated to tracks extrapolated from the TPC, is modeled with an exponential function.

Deuterons and antideuterons are summed together (\( d+d \)) in all the centrality intervals and for \( p_T \) larger than 1.4 GeV/c. This is possible since the \( v_2 \) and \( v_3 \) measured for \( v_2 \) and \( v_3 \) for \( d \) and \( \bar{d} \) are consistent within the statistical uncertainties. At lower \( p_T \), deuterons produced by spallation in interactions between particles and the detector material or in the beam vacuum tube constitute a significant background. For this reason, for \( p_T < 1.4 \) GeV/c only antideuterons, which are not affected by this background, are used in the analysis. Since no difference is expected for the \( v_2 \) and \( v_3 \) of \( \bar{d} \) and \( d \), hereafter deuterons will denote results for antideuteron for \( p_T < 1.4 \) GeV/c and the sum of \( d \) and \( \bar{d} \) elsewhere. The contribution of secondary deuterons produced in weak decays of hypertritons is negligible considering that the production rate of (hyper)nuclei with mass number \( A = 3 \) is suppressed compared to that of \( A = 2 \) by a factor of approximately 300 in Pb–Pb collisions at \( \sqrt{s_{NN}} = 2.76 \) TeV [31]. A similar suppression is expected in Pb–Pb collisions at \( \sqrt{s_{NN}} = 5.02 \) TeV.

3.3 Flow analysis techniques

The particle azimuthal distribution of charged particles with respect to the \( n \)-th order flow symmetry plane \( \Psi_n [32, 35] \) can be expressed as a Fourier series

\[
E \frac{d^3N}{dp^3} = \frac{1}{2\pi p_T dp_T dy} \left( 1 + \sum_{n=1}^{\infty} 2v_n \cos(n(\varphi - \Psi_n)) \right),
\]

where \( E \) is the energy of the particle, \( p \) the momentum, \( \varphi \) the azimuthal angle, \( y \) the rapidity, and

\[
v_n = \langle \cos(n(\varphi - \Psi_n)) \rangle.
\]

The second coefficient of the Fourier series \( (v_2) \) is called elliptic flow and is related to the initial geometrical anisotropy of the overlap region of the colliding nuclei. The third-order flow coefficient \( (v_3) \), called triangular flow, is generated by fluctuations in the initial distribution of nucleons and gluons in the overlap region [34, 36, 37]. The same fluctuations are responsible for the \( v_2 \) measured in most central collisions (centrality < 5%) [38]. The \( v_n \) coefficients are measured using the Scalar Product (SP) method [32, 39]. This is a two-particle correlation technique based on the scalar product of the unit flow vector of the particle of interest, \( k \), and the Q-vector. The unit flow vector is denoted by \( \mathbf{u}_{n,k} = \exp(in\varphi_k) \), where \( \varphi_k \) is the azimuthal angle of the particle \( k \).
The Q-vector is computed from a set of reference flow particles and is defined as:

$$Q_n = \sum w_i e^{i n \phi_i}$$ (3)

where, in general, $\phi_i$ is the azimuthal angle for the i-th reference flow particle, $n$ is the order of the harmonic, and $w_i$ is a weight applied to correct for reference flow.

The $v_n$ flow coefficients are calculated as

$$v_n \{\text{SP}\} = \frac{\langle (u_{n,k} Q_n^u) \rangle}{\langle (Q_n Q_n^u) \rangle}$$ (4)

Single brackets $\langle \ldots \rangle$ denote an average over all events, while double brackets $\langle \langle \ldots \rangle \rangle$ indicate an average over all particles in all events, and $^*$ denotes the complex conjugate. The denominator is a correction factor that is introduced to take into account the resolution of the $Q_n$ vector. In this analysis, the $Q_n$ vector is calculated from the azimuthal distribution of the energy deposition measured in the V0A, while the $Q_n^A$ and $Q_n^B$ vectors are determined from the azimuthal distribution of the energy deposited in the VO and the azimuthal distribution of tracks reconstructed in the TPC, respectively. Using these detectors, a pseudorapidity gap $|\Delta \eta| > 2$ between the particle of interest and the reference flow particles is introduced. Such a pseudorapidity gap reduces non-flow effects, which are correlations not arising from the collective expansion of the system (e.g. resonances decays and jets).

The purity of the sample of deuterons identified using the TPC in the $0.8 < p_T < 1.4$ GeV/$c$ interval is around 100%. In this transverse momentum interval the $v_2$ and $v_3$ coefficients were evaluated on a track-by-track basis and then averaged in each $p_T$ interval. For higher $p_T$, the $v_n$ coefficients are calculated in different ranges of $\Delta M$. The $v_n(\Delta M)$ contains contributions from the signal ($v_n^{\text{sig}}$) and from the background ($v_n^{\text{bkg}}$)

$$v_n(\Delta M) = v_n^{\text{sig}} \frac{N_n^{\text{sig}}}{N_n^{\text{tot}}(\Delta M)} + v_n^{\text{bkg}} \frac{N_n^{\text{bkg}}}{N_n^{\text{tot}}(\Delta M)},$$ (5)

where $N_n^{\text{sig}}$ is the number of deuterons, $N_n^{\text{bkg}}$ the number of background particles and $N_n^{\text{tot}}$ is their sum. The signal $v_n$ is extracted from a fit to the observed $v_n$ as a function of $\Delta M$, in which $v_n^{\text{bkg}}$ is described using a first-order polynomial function, and $v_n^{\text{sig}}$ is a free fit parameter. $N_n^{\text{sig}}$ and $N_n^{\text{bkg}}$ are obtained from the fit to the $\Delta M$ distribution using a Gaussian with an exponential tail for the signal and an exponential for the background. The signal extraction procedure is illustrated in Fig. 1 for $2.2 \leq p_T < 2.4$ GeV/$c$ for $v_3$ in the centrality interval 20–30%.

The elliptic and triangular flow of deuterons are measured in centrality intervals of 5% width and then the results in wider centrality intervals are obtained as weighted averages of these measurements using the number of deuteron candidates, in the same centrality interval of 5% width as a weight, similarly to what was performed in [19].

### 3.4 Systematic uncertainties

The sources of systematic uncertainties for the elliptic and triangular flow of deuterons are related to event selection, tracking, (anti-)deuterons identification, and the technique used for the signal extraction. The contribution related to the event selection is estimated by taking into account the differences in the $v_2$ and $v_3$ measurements obtained using different event-selection criteria. In particular, the fiducial region for the vertex position along the beam axis is varied from the range $[-10, 10]$ cm to $[-7, 7]$ cm to probe the magnitude of potential edge effects. To investigate possible effects due to charge asymmetries during tracking and geometrical asymmetries in the detector, the differences between the results obtained by
Elliptic and triangular flow of (anti)deuterons

ALICE Collaboration

Figure 1: (Color online) Raw yield (left), \( v_2 \) (middle) and \( v_3 \) (right) of \( d+\bar{p} \) candidates as a function of \( \Delta M \) for \( 2.2 \leq p_T < 2.4 \text{ GeV/c} \) (2.0 \( \leq p_T < 2.4 \text{ GeV/c} \) for \( v_3 \)) and in the centrality interval 20–30%. The data points represent the measurements. The curve on the left panel is the total fit (signal plus background) as described in the text. The curves in the middle and right panel are the fits performed using Eq. 5. Vertical bars represent the statistical uncertainties.

To estimate the systematic uncertainties due to reconstruction and identification of deuterons, the track selection and the TPC PID criteria are varied with respect to the default choice and the \( v_n \) measurements are repeated for each of these different settings. The RMS of the distribution of \( v_n \) measurements in each \( p_T \) interval is considered as systematic uncertainty. To minimize the effect of statistical fluctuations, all variations smaller than \( 2 \sqrt{\sigma_0^2 - \sigma_i^2} \) are not included in the estimate of the systematic uncertainties [40], where \( \sigma_0 \) is the statistical uncertainty of the default value while \( \sigma_i \) is that corresponding to the \( i \)th selection criterion. The probability distribution for the variations of data points due to systematic effects related to tracking and PID is assumed to be uniform in each \( p_T \) interval and the difference between the maximum and minimum value divided by \( \sqrt{12} \) is assigned as systematic uncertainty. This contribution ranges from 1% and 3% depending on \( p_T \) and centrality.

To estimate the contribution to the systematic uncertainties due to the signal extraction, the function used to describe the \( v_n \) is changed. In addition to a first-order polynomial, a constant function and a second-order polynomial are also used, and the maximum difference with respect to the default measurement is considered as systematic uncertainty. A contribution up to 5% is observed for central collisions and for \( p_T < 2 \text{ GeV/c} \). Moreover, different functions and fitting ranges are used to describe the signal and the background of Eq. 5. More specifically, besides a Gaussian function with an exponential tail, a Gaussian is also used for the signal, while single and double exponential, and linear functions are also used for the background. This contribution is relevant only for \( p_T > 1.4 \text{ GeV/c} \), where the TOF is used to extract the signal, and is found to vary from 1% to 6% depending on \( p_T \) and centrality. Table 1 shows the summary of the different contributions to the systematic uncertainties for the \( v_2 \) and \( v_3 \) of deuterons. The total uncertainties are given by their sum in quadrature, assuming that all contributions are independent.

4 Results and discussion

The \( v_2 \) and \( v_3 \) of deuterons measured in Pb–Pb collisions at \( \sqrt{s_{NN}} = 5.02 \text{ TeV} \) are shown in Fig. 2 as a function of \( p_T \) for different centrality intervals. In the measured \( p_T \) interval, an increasing trend is observed with increasing \( p_T \) and going from central to more peripheral Pb–Pb collisions, as expected based on the relativistic hydrodynamic description of the collective expansion of a hot and dense medium [41].
Table 1: Summary of the systematic uncertainties for the deuterons $v_2$ and $v_3$. The maximum deviation of the systematic uncertainty is reported.

| Source                        | $v_2$  | $v_3$  |
|-------------------------------|--------|--------|
| Event selections              | 1.5%   | 1.5%   |
| Tracking and particle identification | 1–3%   | 1–2%   |
| Signal extraction             | 1–4%   | 2–6%   |
| Total                         | 2–7%   | 3–7%   |

Initial state fluctuations of the energy density distribution of partons in the colliding nuclei imply a non-zero $v_3$.

The measurement presented in this paper shows that these initial state effects, already observed for other hadron species at LHC energies [42, 43], are also visible for deuterons.

The measurement of the deuterons $v_2$ in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV is compared to that in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV [18] in Fig. 3 for two centrality intervals. The observed $v_2$ and their trend are similar at the two center-of-mass energies, but a decrease of the observed elliptic flow for a given $p_T$ is observed with increasing center-of-mass energy. This effect is more pronounced in peripheral rather than in central collisions. A similar effect was observed for the proton $v_2$ measurements [43] and is interpreted as partially due to the increasing radial flow with increasing collision energy, which produces a shift of the $v_2$ towards higher $p_T$.

The effect due to radial flow is assessed quantitatively by comparing the ratio of the deuteron and proton $v_2$ as a function of $p_T$ at the two energies. The ratio between the deuteron $v_2$ in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV to that measured at $\sqrt{s_{NN}} = 2.76$ TeV, with $v_2$ and $p_T$ scaled by the mass number $A = 2$, is shown in Fig. 4 for two centrality intervals in comparison with the same ratio for protons. As indicated by these ratios, the radial flow effects are quantitatively very similar for protons and deuterons. It has to be noted that a mass scaling would lead to the same conclusion since the binding energy of
deuteron is of 2.2 MeV, i.e. the deuteron mass is approximately equal to $2m_p$, where $m_p$ is the proton mass.

The elliptic flow of deuterons is compared to that of pions, kaons, protons and (anti)$^3$He measured at the same center-of-mass energy in Fig. 5. Since the (anti)$^3$He elliptic flow is measured in centrality intervals of 20% width due to its rarer production compared to that of lighter hadrons, the $v_2$ of pions, kaons, protons and deuterons are re-calculated to match the same centrality intervals. This is achieved
by averaging the $v_2$ measurements of these particles in narrower centrality intervals weighted by the corresponding $p_T$ spectra [8, 44]. A clear mass ordering of $v_2$ is observed at low $p_T$, as expected for a system expansion driven by the pressure gradient as described by relativistic hydrodynamics [41, 45, 46].

**Figure 5:** (Color online) Comparison of the elliptic flow of pions, kaons, protons, deuterons and (anti)$^3$He in different centrality intervals for Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV. (Anti)$^3$He $v_2$ is measured using the Event Plane method [19]. Vertical bars and boxes represent the statistical and systematic uncertainties, respectively.

In Fig. 6, the deuterons $v_3$ is compared to that of pions, kaons, and protons at the same center-of-mass energy [43] for the centrality intervals 0–20% (left) and 20–40% (right). Also for the $v_3$, a clear mass ordering is observed for $p_T \lesssim 2.5$ GeV/$c$ and $p_T \lesssim 3$ GeV/$c$ for the centrality intervals 0–20% and 20–40%, respectively.

**Figure 6:** (Color online) Triangular flow ($v_3$) of deuterons, pions, kaons, and protons [43] as a function of $p_T$ for the centrality intervals 0–20% and 20–40%. Vertical bars and boxes represent the statistical and systematic uncertainties, respectively.

4.1 Comparison with the blast-wave model predictions

The elliptic flow of deuterons is compared with the expectations of the blast-wave model [22, 47, 48], which is based on the assumption that the system produced in heavy-ion collisions is locally thermalized and expands collectively with a common velocity field. The system is assumed to undergo an instantaneous kinetic freeze-out at the temperature $T_{\text{kin}}$ and to be characterized by a common transverse radial flow velocity at the freeze-out surface. A simultaneous fit of the $v_2$ and the $p_T$ spectra of pions, kaons, and protons [8, 43] with the blast-wave model is performed in the transverse-momentum ranges

\[ 10 \]
0.5 ≤ p_{T}^{2} < 1 GeV/c, 0.7 ≤ p_{T}^{K} < 2 GeV/c, and 0.7 ≤ p_{T}^{p} < 2.5 GeV/c. The four free parameters of the blast-wave function are the kinetic freeze-out temperature (T_{kin}), the variation in the azimuthal density of the source (s_{2}), the mean transverse expansion rapidity (ρ_{0}), and the amplitude of its azimuthal variation (ρ_{a}), as described in [47]. The values of these parameters extracted from the fits are reported in Table 2 for each centrality interval. These values are employed to predict the elliptic flow of deuterons under the assumption that the same kinetic freeze-out conditions apply for all particles produced in the collision. The deuteron mass is taken from [30].

The results of this calculation for different centrality intervals for v_{2} are shown in the left panel of Fig. 9. The measured elliptic flow in 10–20% and 40–50% centrality intervals of deuterons is compared with coalescence model predictions from Eq. 6 using the measured v_{n} of protons. Similarly, the right panel of Fig. 9 shows a comparison between the calculated and measured v_{3} in the 0–20% and 20–40% centrality intervals.

The coalescence model overestimates the deuteron v_{2} by about 20% to 30% in central collisions and is close to the data for semi-peripheral collisions, as illustrated in Fig. 10 which shows the centrality evolution of the data-to-model ratios.

### Table 2: Blast-wave parameters extracted from the simultaneous fits of the p_{T} spectra and v_{2} of pions, kaons, and protons measured at √s_{NN} = 5.02 TeV. See text for details. The error assigned to each parameter is shown only with one significant digit.

| Centrality | T_{kin} (MeV) | s_{2} (10^{-2}) | ρ_{0} (10^{-1}) | ρ_{a} (10^{-2}) |
|------------|---------------|-----------------|-----------------|-----------------|
| 0–5%       | 104 ± 1       | 2.63 ± 0.01     | 8.57 ± 0.01     | 0.83 ± 0.01     |
| 5–10%      | 106 ± 1       | 4.15 ± 0.01     | 8.85 ± 0.01     | 1.47 ± 0.01     |
| 10–20%     | 107 ± 1       | 6.09 ± 0.01     | 9.12 ± 0.01     | 2.17 ± 0.01     |
| 20–30%     | 109 ± 1       | 8.25 ± 0.01     | 9.02 ± 0.01     | 2.85 ± 0.01     |
| 30–40%     | 111 ± 1       | 10.1 ± 0.01     | 8.61 ± 0.01     | 3.25 ± 0.01     |
| 40–50%     | 116 ± 1       | 12.3 ± 0.01     | 7.73 ± 0.01     | 3.30 ± 0.01     |
| 50–60%     | 121 ± 1       | 14.5 ± 0.01     | 6.93 ± 0.01     | 2.85 ± 0.01     |
| 60–70%     | 129 ± 1       | 17.4 ± 0.01     | 5.95 ± 0.01     | 1.74 ± 0.01     |

The blast-wave fits to the v_{2} of pions, kaons, and protons and the predictions for the deuterons v_{2} are reported in Fig. 7 for the centrality intervals 10–20% and 40–50%. In the lower panels, the data-to-fit ratios for pions, kaons, and protons and the ratios of the deuterons v_{2} to the model are shown. Because of the finite size of the p_{T} intervals, the average of the blast-wave function within the interval, weighted by the p_{T} spectrum of the corresponding particle species, is considered in the calculation of these ratios.

The predictions of the blast-wave model underestimate the deuterons elliptic flow experimental values in semi-peripheral collisions for p_{T} > 1.4 GeV/c, while they are close to the measurements for central events in the measured p_{T} interval. This is better observed in Fig. 8 which shows the centrality evolution of the data-to-model ratios.

### 4.2 Test of the coalescence hypothesis

The deuterons v_{2} and v_{3} are compared to the expectations of a coalescence approach based on mass number scaling and isospin symmetry, for which the proton and neutron v_{2} (v_{3}) are identical. In particular, the v_{2} (v_{3}) measured for protons [43] was used to predict the v_{2} (v_{3}) of deuterons using the following relation [49]:

\[
v_{2(3),d}(p_{T}) = \frac{2v_{2(3),p}(p_{T}/2)}{1 + 2v_{2(3),p}^{2}(p_{T}/2)}. \tag{6}
\]

The results of this calculation for different centrality intervals for v_{2} are shown in the left panel of Fig. 9. The measured elliptic flow in 10–20% and 40–50% centrality intervals of deuterons is compared with coalescence model predictions from Eq. 6 using the measured v_{n} of protons. Similarly, the right panel of Fig. 9 shows a comparison between the calculated and measured v_{3} in the 0–20% and 20–40% centrality intervals.

The coalescence model overestimates the deuteron v_{2} by about 20% to 30% in central collisions and is close to the data for semi-peripheral collisions, as illustrated in Fig. 10 which shows the centrality evolution of the data-to-model ratios.
Figure 7: (Color online) Blast-wave fits to the $v_2 (p_T)$ of pions, kaons, and protons [43] and predictions of the deuterons $v_2 (p_T)$ for the centrality intervals 10–20% (left) and 40–50% (right). In the lower panels, the data-to-fit ratios are shown for pions, kaons, and protons as well as the ratio of the deuterons $v_2$ to the blast-wave predictions. Vertical bars and boxes sent the statistical and systematic uncertainties, respectively. The dashed line at one is to guide the eye.

Figure 8: (Color online) Data-to-model ratios of the deuterons $v_2$ to the blast-wave predictions as a function of $p_T$ for different centrality intervals as indicated in each pad. Vertical bars and boxes represent the statistical and systematic uncertainties, respectively.

evolution of the data-to-model ratio. The coalescence approach seems to have a slightly better agreement
with deuterons $v_3$; however, the large statistical uncertainties on the $v_3$ measurements do not allow for conclusive statements.

4.3 Comparison with iEBE-VISHNU and coalescence calculations

In Fig. 11 the deuterons $v_2$ and $v_3$ are compared to a model [4] implementing light nuclei formation via coalescence of nucleons originating from a hydrodynamical evolution of the fireball coupled to an UrQMD simulation of the hadronic cascade [16, 17]. In this model, the coalescence probability is calculated as the superposition of the wave functions of protons and neutrons and the Wigner function of
the deuterons. The coalescence happens in a flowing medium introducing position-momentum correlations, which are absent in the simple coalescence approach. The phase-space distributions of protons and neutrons are generated from the iEBE-VISHNU hybrid model with AMPT \cite{50} initial conditions. This model provides a good description of the protons spectra up to 3 GeV/c and of the deuterons $v_2$ measured in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV \cite{4}. The predictions are consistent with the measured deuterons $v_2$ for events with centrality larger than 20% and for measured $v_3$ within the statistical and systematical uncertainties, while some discrepancy at the level of $2\sigma$ (taking into account statistical and systematical uncertainties in quadrature) are observed for for the centrality interval 10–20% as shown in Fig. 11.

![Graph showing elliptic and triangular flow of deuterons](image)

**Figure 11**: Elliptic (left) and triangular (right) flow of deuterons compared to the predictions iEBE-VISHNU hybrid model with AMPT initial conditions \cite{4}. The predictions are shown as bands whose widths represent the statistical uncertainties associated with the model. The data-to-model differences are shown in the lower panels. Vertical bars and boxes represent the statistical and systematic uncertainties, respectively.

### 4.4 Comparison with a hybrid (hydrodynamics + transport) approach expectations

The deuterons $v_2$ measured in the centrality intervals 10–20%, 20–30%, and 30–40% is compared in Fig. 12 with the predictions from a hybrid model based on relativistic viscous hydrodynamics, with fluctuating initial conditions generated by TRAMETo \cite{51}, coupled to the hadronic afterburner SMASH \cite{5}. The simulations are obtained by using the JETSCAPE 1.0 event generator \cite{52}. The parameters of this model, including the shear and bulk viscosities, are tuned to the measurements of $p_T$ spectra and azimuthal flow of pions, kaons, and protons obtained by ALICE in Pb–Pb collisions at $\sqrt{s_{\text{NN}}} = 2.76$ TeV \cite{7,21} and by PHENIX and STAR in Au–Au collisions at $\sqrt{s_{\text{NN}}} = 200$ GeV \cite{53–55}. The interactions of deuterons with other hadrons in the hadron gas phase are simulated using SMASH in which all known resonances and the experimentally known cross sections, most importantly $\pi d \rightarrow \pi np$ and its inverse reaction, are included.

In this model, the number of deuterons at the kinetic freezeout is independent from their primordial abundance at the Cooper-Frye hypersurface. It was found that even when their initial number is set to zero, the number of deuterons regenerated in the hadronic phase converges towards the equilibrium value, which is the same as that predicted by the statistical hadronization model. Considering that in this
model only $\sim 1\%$ of the primordial deuterons survive the hadronic stage, the elliptic flow of deuterons observed after the kinetic freezeout is almost identical to that of the regenerated ones. For this reason, deuterons are not sampled at the Cooper-Frye hypersurface for these predictions.

The model predictions are consistent with the measured $v_2$ within the uncertainties in the centrality intervals 20–30% and 30–40% for $0.8 < p_T < 4$ GeV/$c$, while the data are overestimated by up to 30% in the centrality interval 10–20% for $p_T > 2$ GeV/$c$.

![Graph Showing $v_2$ vs. $p_T$](image)

**Figure 12:** Measured deuterons $v_2$ compared to the predictions from a microscopic model [5] based on the JETSCAPE generator [53]. The model predictions, based on SMASH afterburner and which used TRENTo [51] initial conditions, are shown as bands. The width of the band represents the statistical uncertainty associated with the model. In the lower panel the data-to-model differences are shown. Vertical bars and boxes represent the statistical and systematic uncertainties, respectively.

5 Summary

The measurements of the deuterons $v_2$ and the first measurement of $v_3$ in Pb–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV are presented. The observed centrality and $p_T$ dependence are consistent with the expectations from relativistic hydrodynamics. A mass ordering is observed for $p_T < 3$ GeV/$c$ when comparing these results with the measured $v_2$ and $v_3$ of pions, kaons, and protons. The shift of the deuterons $v_2$ towards higher $p_T$ with respect to the measurement in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV, mainly due to a stronger radial flow at higher center-of-mass energy, is consistent with that observed for the proton $v_2$ measurement.

The results of this measurement are compared with the expectations from the simple coalescence approach, in which the deuterons $v_2$ is obtained from that of protons assuming that the deuterons invariant yield is proportional to that of protons squared, and with the predictions of the blast-wave model. The deuterons $v_2$ is overestimated by a simple coalescence approach, which describes the data only in periph-
eral (centrality > 50%) collisions. On the other hand, the blast-wave model underestimates the peripheral measurements and it is close to the data in central collisions. These results are consistent with the scenario previously seen for deuterons and $^3$He elliptic flow: these simplified models bracket a region where the light nuclei $v_2$ is located and describe reasonably the data in different multiplicity regimes, indicating that none of these two models is able to describe the deuterons production measurement from low to high multiplicity environments.

Similar considerations are valid for the deuterons $v_3$ with some limitations due to the rather large statistical uncertainties. This specific aspect will be addressed with the larger data sample that will be collected in Run 3 following the ALICE upgrade, where a significant improvement of the statistical precision is expected. This measurement will be crucial to better constrain models that describe the production of light nuclei in heavy-ion collisions.

A more advanced coalescence model coupled to hydrodynamics and the hadronic afterburner UrQMD, which takes into account the quantum-mechanical properties of nucleons and nuclei and space-momentum correlations of nucleons, provides a good description of the deuterons $v_2$ and $v_3$ for $p_T > 2.5$ GeV/c. The model predictions deviate from the data at lower $p_T$, in particular for the centrality interval 10–20%. The same model provides a good description of the deuterons $v_2$ measured in Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV and that of $^3$He at $\sqrt{s_{NN}} = 5.02$ TeV. The deuterons $v_2$ is also compared to the predictions from a hybrid model based on relativistic hydrodynamics coupled to the hadronic afterburner SMASH. The model predictions are consistent with the data within the uncertainties in the centrality intervals 20–30% and 30–40%, while a deviation of up to 30% is observed in the centrality interval 10–20% for $2 < p_T < 3$ GeV/c.

In general, the state-of-the-art implementations of coalescence and the hybrid approach based on hydrodynamics coupled to hadronic afterburners provide better descriptions of the data compared to the simple coalescence and blast-wave models. Further efforts, both on experimental and theoretical side, are needed to have a more comprehensive understanding of dynamics and production of light nuclei.

**Acknowledgements**

The ALICE Collaboration would like to thank all its engineers and technicians for their invaluable contributions to the construction of the experiment and the CERN accelerator teams for the outstanding performance of the LHC complex. The ALICE Collaboration gratefully acknowledges the resources and support provided by all Grid centres and the Worldwide LHC Computing Grid (WLCG) collaboration.
