Optogenetics promises precise spatiotemporal control of neural processes using light. However, the spatial extent of illumination within the brain is difficult to control and cannot be adjusted using standard fiber optics. We demonstrate that optical fibers with tapered tips can be used to illuminate either spatially restricted or large brain volumes. Remotely adjusting the light input angle to the fiber varies the light-emitting portion of the taper over several millimeters without movement of the implant. We use this mode to activate dorsal versus ventral striatum of individual mice and reveal different effects of each manipulation on motor behavior. Conversely, injecting light over the full numerical aperture of the fiber results in light emission from the entire taper surface, achieving broader and more efficient optogenetic activation of neurons, compared to standard flat-facet fiber stimulation. Thus, tapered fibers permit focal or broad illumination that can be precisely and dynamically matched to experimental needs.

Optogenetic modulation of neuronal activity has become the dominant method of examining the behavioral consequences of activity in specific neuronal populations in vivo. This is due to the synergy of advances in two distinct but well-connected fields: the development of ever-improving light-activated modulators of electrical activity1–3 and the development of technologies for delivering light within the brains of free-moving animals4–8. Nevertheless, attaining the full potential of optical neural control requires new technologies to better control the spatial extent of light delivery and to more precisely match illumination to heterogeneous brain structures.

In certain applications, it is necessary to deliver uniform illumination to large brain areas, whereas for others confined illumination of small brain volumes is preferred. Ideally, both modes of illumination could be accomplished via a single, reconfigurable device. To this aim, several approaches have been developed, including multiple implanted waveguides8–10, multiple microlight delivery devices (µLEDs)6,7,11,12, holographic illumination via head-mounted objectives13 and multipoint emitting optical fibers14,15. However, these techniques have limitations: implanting multiple waveguides is highly invasive, µLEDs can heat tissue during prolonged illumination and multipoint emitting optical fibers require higher input laser power to produce viable optogenetic control. Likely due to the difficulty and cost of building the required devices, these approaches have not been broadly used in neuroscience labs. Indeed, the most common light delivery method for optogenetic experiments remains flat-faced optical fibers (FFs), which deliver highly spatially heterogeneous illumination to a relatively small and fixed brain volume near the fiber facet. Furthermore, due to the relatively large, flat area of the cleaved end, these fibers can cause substantial tissue damage during insertion.

Here we describe a tapered optical fiber (TF) whose emission properties can be simply and dynamically reconfigured to switch between relatively homogeneous light delivery to a large volume and spatially restricted illumination. Multiple wavelengths of light can be independently modulated and directed to subvolumes of interest. The device consists of a single thin, sharp waveguide, thus minimizing invasiveness. To demonstrate the suitability of this approach for more uniform and efficient illumination of extended brain structures, experiments were performed in the primary motor cortex and striatum of awake head-restrained and freely moving mice. We demonstrate that by controlling the angle at which light is injected into the fiber, TFs can emit light from subportions of the taper to produce spatiotemporally resolved light patterns that subsample the volume of interest. We used this approach to achieve site specific optogenetic stimulation and demonstrate that activation of indirect pathway striatal projection neurons (iSPNs) in dorsal vs. ventral striatum has different effects on locomotion in mice exploring an open arena. Thus, TFs provide a simple, inexpensive and easy-to-operate multipurpose system for optical control of neural activity.

RESULTS

Design principles of tapered optical fibers

TFs are multimode fiber optics that have been engineered to taper gradually from their full width (125–225 µm) to ~500 nm. The taper angle is small (2° < Ψ < 8°), such that the taper length varies between 1.5–5.6 mm (Fig. 1). This design was chosen to permit smooth insertion into the brain, reduce the implant cross-section and expose a

Large area of the fiber for potential light emission. Ray-tracing and geometric models demonstrate the working principle of the device (Fig. 1a,b). A ray injected into the core of the fiber with an input angle θ is guided to the tapered region via total internal reflection. At each reflection of the ray, its propagation angle with respect to the fiber optical axis increases by an amount equal to the taper angle Ψ (Supplementary Fig. 1). This occurs until a critical section is met, at which total internal reflection is lost and the ray radiates into the surrounding medium. Increasing θ increases the distance between this light-emission point and the taper tip (Fig. 1b) in a manner determined by the fiber numerical aperture (NA) and taper angle (see Supplementary Fig. 2 for sample optical fibers with NA = 0.22 and NA = 0.39 and Ψ = 2.2° and Ψ = 2.9°, respectively). Therefore, the light input angle θ selects the output zone along the length of a specific taper.

A consequence of the dependence of the position of light emission on θ is that TFs can be used to emit light along the fiber in two fundamentally different ways. First, when light is injected into the TF using its full NA, light is emitted from a broad extent of the taper (Fig. 1c1), as desired for illumination of spatially extended brain regions, for example, the entire cortical thickness or the dorsal–ventral axis of the striatum. For a fiber of a particular NA, the length of the light-emitting segment (L) depends mainly on the taper angle. Ray tracing simulations indicate that L can be tailored from a few hundred micrometers up to a few millimeters in the case of 0.22- and 0.39-NA fibers with taper angles Ψ ranging from 2.2° to 7.4° (Supplementary Fig. 3).

We experimentally verified this effect in 0.22- and 0.39-NA fibers by immersing TFs in a fluorescein solution and imaging the resulting fluorescence distribution (Supplementary Fig. 4). Decreasing the taper angle increases the length of the emitting segment to ~1 mm for 0.22-NA fibers with 50-µm core and 125-µm cladding (50/125-µm core/cladding) fibers and to ~2 mm for 0.39-NA fibers with 200/225-µm core/cladding (Fig. 1d). Thus, in this light-injection mode, a TF with the proper NA and taper angle can be chosen to match the linear extent of light output to the size of many mouse brain structures.

To compare the ray-tracing model with experimental results, we evaluated the emission length, referred to as L0.5, over which the delivered intensity is more than 50% of its peak (Supplementary Fig. 4). We found good agreement between modeling and experiments for both 0.22- and 0.39-NA fibers (Fig. 1d and Supplementary Fig. 4). The differences observed at low Ψ for 0.39-NA fibers arise because the taper is assumed to be linear in the ray-tracing model, whereas the real structure has a modestly parabolic shape (Supplementary Fig. 5). The diameter at which light starts to outcouple and the total light power delivered are nearly independent of the taper angle (Supplementary Fig. 6). As a consequence, TFs with lower taper angles spread the available power over a larger taper surface (Supplementary Figs. 7 and 8), potentially allowing light delivery to elongated brain regions.

Illumination of large brain volumes with TFs

FFs are commonly inserted just above a brain volume of interest and the delivered light is strongly attenuated by the tissue, allowing excitation of neurons located only up to a few hundred micrometers from the fiber end16–18. Significant excitation of more distant neurons requires larger increases in laser power to overcome the approximately exponential decay in power density from the fiber face. In contrast, by virtue of their thin and sharp edge, TFs can be inserted into the volume of interest and light delivered along the length of the taper (Fig. 2). To evaluate the illumination pattern achieved in light-absorbing and scattering brain tissue, we implanted TFs and FFs into fluorescein-impregnated fixed mouse brain slices and imaged the fluorescence generated by light emitted from each fiber (Fig. 2a). As expected, FFs illuminate a small brain volume and fluorescence is strongly attenuated after a few hundred micrometers from the emitting flat-ended facet (Fig. 2b). In contrast, TFs emit light along the taper length, resulting in elongated and more homogenous illumination of the tissue (Fig. 2c.d).

The differences in tissue illumination achieved by TF and FF arise from two important features: (i) TFs emit light from a larger surface, i.e., the cone defined by L and Ψ; and (ii) light emerges from the TFs at a nonzero angle with respect to the taper axis (Fig. 1c). As a consequence, tissue absorption and scattering do not determine light distribution along the fiber axis, as in FFs, but along the direction of emitted light, which has a significant component perpendicular to the taper axis. Notably, the depth of the excited volume can be tailored by selecting the fiber taper geometry and NA, instead of by increasing the laser power as commonly done in experiments with FFs. For instance, TFs with NA = 0.22 and Ψ = 2.2° illuminate the whole cortical depth, whereas TFs with NA = 0.39 and Ψ = 2.9° target most of the depth of the striatum (Fig. 2c.d).
Optogenetic control of motor cortex with TFs

To examine the potential benefits of more uniform light delivery in vivo, TFs were tested in the primary motor cortex of awake head-restrained VGAT-ChR2-BAC adult mice\(^2\), which express ChR2 in GABAergic neurons (Fig. 4a). A TF (NA = 0.22, \(\Psi = 2.2^\circ\)) and FFs were implanted serially near a 16-contact silicon multielectrode array (Neuronexus). The FFs were placed such that the faces were at the same depth as the first emission point (shallow position) or the tip (deep position) of the TF. We delivered five 50-ms pulses of 473-nm light at 5 Hz, repeated every 3 s, 80 times. Output powers from the TF and FF were matched, to examine the efficiency of each fiber type to inhibit cortex via stimulation of GABAergic interneurons. TFs more effectively suppressed cortical activity at lower power levels (Fig. 4b and Supplementary Fig. 11): inhibition with TFs was obtained at...
Optogenetic manipulation of motor cortex with TFs and FFs.
(a) Schematic of the experimental preparation. A 16-channel multielectrode array (gray; white circles indicate the contacts) was placed in primary motor cortex of a VGAT-ChR2-BAC transgenic mouse and maintained throughout the experiment. Units were recorded throughout cortical layers. A TF or FF was placed in cortex in either a shallow or a deep position. The firing rates of individual neurons (black and red ellipses) were compared during the basal period or during 50-ms optogenetic excitation of cortical GABAergic interneurons (red ellipses). (b) Top: average normalized firing rates (FR, black line; shaded area shows s.e.m.) across cells with and without light; cyan regions show light delivery (50-ms stimulation periods). Bottom: pseudocolored representations of normalized, across-trial average firing rates of each unit as a function of time. The color scale (‘rainbow’ in Igor Pro) indicates relative firing rates of each cell (0, dark blue, to 3, red) normalized to its baseline (0–50 ms). Data (n = 45, 49, 51, 51, 28, 28, 28, 28, 28, 48, 49, 49 and 49 cells) are shown for each fiber configuration (left, TF; middle, FF-shallow; right, FF-deep) and at four power levels (10-, 50-, 100- and 200-µW total emissions from each fiber before implantation in the brain.

~10 µW (~0.20 mW per mm²; see Supplementary Fig. 8 for estimated power density distribution along the taper) whereas FFs (NA = 0.22) required ~5-fold higher power output to obtain a comparable effect at both depths (50 µW; ~25 mW per mm²; see the brain tissue light transmission calculator at http://web.stanford.edu/group/dlab/optogenetics/). Moreover, even at higher powers, inhibition was more pronounced with TFs, suggesting that tapered fibers stimulate a higher number of ChR2-expressing GABAergic neurons.

Dynamical selection of illuminated brain regions
A further benefit provided by TFs is the ability to dynamically control the illumination volume by changing the light entry angle θ at the input end of the fiber. The angle θ defines the subset of guided modes injected into the fiber⁴¹,¹⁴,¹⁵, which in turn determines the cross-section of the taper at which light emits. The position of the emitting section along the taper depends on θ, as expected from the ray tracing simulations (Supplementary Fig. 12 and Supplementary Video 1). In particular, with low input angles, light outcouples close to the taper tip, whereas light injected at high input angles is mainly emitted at sections farther from the tip.

To characterize the geometrical emission properties of TFs as a function of θ (Fig. 5), we implemented a simple optical path in which θ is changed by translating a mirror (Supplementary Fig. 13a). Monitoring the fluorescein generated by a TF inserted into a fluorescein solution showed that the emitting segment (~300 µm long) could be moved almost continuously along a segment of taper ~1 mm or ~1.5 mm long, respectively, in 0.22-NA, Ψ = 2.2° or 0.39-NA, Ψ = 2.9° TFs (Fig. 5a,b). Notably, total delivered light power was nearly independent of θ, except for input angles very close to the maximum acceptance angle (Fig. 5c). To rapidly scan the illumination across brain volumes, we used a launching system with a scanning galvanometer and relay optics to change θ (Supplementary Fig. 13b). This permitted rapid switching between different emission segments (Supplementary Video 2) and near continuous movement of the emitting segment along the taper (Supplementary Video 3). Several launching paths could be combined to outcouple multiple wavelengths at the same time from independently addressable emission segments (Supplementary Fig. 13 and Supplementary Video 4).

To examine the suitability of this technique for restricted light delivery in brain tissue, site-selective light delivery as a function of θ was evaluated in fluorescein-stained acute mouse brain slices. Both 0.22-NA, Ψ = 2.2° and 0.39-NA, Ψ = 2.9° TFs allowed near-continuous tuning of the illuminated brain region in both cortex and striatum (Fig. 5d–g). Tissue absorption and scattering shortened the propagation of emitted light into the tissue, further constraining the spatial geometry of the illuminated area. This led to spatially separated light delivery volumes, resulting in an easy-to-use and versatile method to direct the light stimulus along a ~2 mm segment by implanting a single fixed fiber.

In vivo multisite stimulation
Selection of the emitting region of the taper is possible because different input angles generate different sets of guided modes in the fiber¹⁵ that outcouple at different taper sections. However, while propagating into the fiber, subsets of guided modes may undergo modal mixing induced by fiber impurities and bends. This could redistribute part of the guided light power to other modes and rearrange light emission along the taper. To evaluate the viability of using TFs for site-selective light delivery in moving mice, we measured the effects of bending and shaking on TF light output (Supplementary Fig. 14). For a fixed input angle (θ = 17°), the patch fiber carrying light to a TF with NA = 0.39...
and \( \Psi = 2.9^\circ \) was shaken and bent while emission into a fluorescein droplet was recorded at high frame rate (~100 frames per s (fps); Supplementary Videos 5–7). The fluctuations in fluorescence peak intensity, full-width-at-half-maximum and center were each less than 5% with fiber shaking and bending (Supplementary Fig. 14).

To demonstrate the feasibility of multisite optogenetic stimulation through a TF in an individual animal, TFs were designed \((NA = 0.39, \Psi = 2.3^\circ)\) and implanted spanning the dorsal and ventral medial striatum of adult mice expressing ChR2 in iSPNs \((Ador2a-Cre;Ai32)\). An optical pathway was designed (Fig. 6a) and calibrated to deliver a similar power density from the distal (ventral striatum) and proximal (dorsal striatum) sites (Fig. 6c) using, respectively, \(8^\circ (\theta_1)\) and \(22.5^\circ (\theta_2)\) launch angles (Fig. 6a and Supplementary Fig. 15).

Eight days after implant surgery, mouse spontaneous locomotion was monitored in an open circular arena with 3D time-of-flight cameras\(^{22}\). Light was delivered to the brain via an optical commutator, a lightweight patch cord \((200-\mu m\) core, \(0.39\)-NA, 1 m long) and two fiber–fiber conjunctions as typically used for unrestrained mouse behavior experiments (Fig. 6a,b). The experimental paradigm consisted of 3-min blocks of either no stimulation (NS) or laser input to the fiber at angle 1 \((\theta_1)\) or angle 2 \((\theta_2)\), repeated in the following pattern: NS–\(\theta_1\)–NS–\(\theta_2\)–NS–\(\theta_1\)–NS–\(\theta_2\)–NS, corresponding to alternating stimulation of ventral \((\theta_1)\) and dorsal \((\theta_2)\) striatum separated by periods of no stimulation (Fig. 6c,d). On the subsequent day, the order of ventral \((\theta_1)\) and dorsal \((\theta_2)\) stimulations were reversed, such that nine blocks per session were recorded in each of 2 d. Basic analyses of locomotion speed and orientation (Fig. 6e) reveal that stimulation at either dorsal or ventral striatum reduced locomotion and triggered contraversive spinning in individual mice (Fig. 6f), as expected for unilateral activation of iSPNs\(^{23}\). Ventral stimulation via light injection at angle \(\theta_1\) inducing more profound effects (distance traversed in 3 min: NS: 3.16 ± 1.45 m, \(n = 10\) 3-min blocks over 2 imaging...
corresponding to the animal’s postural dynamics\textsuperscript{22}. This technique produces a hidden Markov model in which each state encapsulates the postural dynamics of the mouse in each expressed behavioral syllable. The model is built using 3D information derived from video collected at 30 Hz for all mice across all imaging sessions and stimulation conditions. In this case, 14 syllables were sufficient to explain \(\sim\)94\% of locomotion behavior in all sessions (NS, 87\%; ventral (\(\theta_1\)), 98\%; dorsal (\(\theta_2\)), 97\%; Fig. 7b).

Consistent with the previously described effects of iSPN stimulation on locomotion\textsuperscript{23} and those revealed by simple video tracking (Fig. 6), the most strongly induced behavior during stimulation was pausing (captured in syllables 1 and 2; percent of time spent in syllables 1 and 2: NS: 1\%; ventral (\(\theta_1\)): 74\%; dorsal (\(\theta_2\)): 38\%), corresponding to a motionless mouse (Fig. 7b and Supplementary Video 8). The expression of these pause syllables varied across conditions and was most prominent during ventral stimulation (Fig. 7b).

Movement related syllables (syllables 3–14) were also differentially expressed across stimulation condition (percent of time spent in syllables 3–14: NS, 86\%; ventral (\(\theta_1\)), 24\%; dorsal (\(\theta_2\)), 59\%; Fig. 7b). Furthermore, specific movement-related syllables were more strongly induced by dorsal stimulation (for example, syllables 4–6), whereas others showed the converse pattern (for example, syllables 3 and 7; Fig. 7c). Thus, these results are not consistent with ventral stimulation simply being more effective, as discrete motor actions were evoked by stimulation at each site. Each differentially modulated syllable represented a consistent but distinct motor action: syllable 6, more strongly evoked by dorsal stimulation, involved the animal shaking its body left and right, whereas syllable 7 was a spin to the left (head moved left while tail moved right; Fig. 7d and Supplementary Videos 9 and 10). Notably, the head and tail trajectories were similar during epochs of stimulation of the dorsal versus ventral striatum, despite their differences in expression frequency (Fig. 7c,d).

**DISCUSSION**

We demonstrate that TFs have several advantages for light delivery in the brain that might allow this tool to replace the flat-cleaved optical fibers that are typically used for optogenetic experiments. First, TFs are multipurpose, such that the same device allows either large-volume or site-selective light delivery. Second, by virtue of their tapered and smaller average cross section, TFs are minimally invasive and can be implanted directly into the brain region of interest. Third, they are simple to operate and compatible with optical equipment commonly present in neuroscience labs employing optogenetics.

**Illumination of large brain volumes**

When used to deliver light from the entire taper surface, TFs overcome one of the principal difficulties facing experiments in \textit{in vivo} optogenetics: achieving uniform effective illumination of large brain structures with minimal invasiveness and light power. Although effective stimulation of neuron cell bodies expressing ChR2 can be obtained\textsuperscript{24,25} with power densities in the range 1–5 mW per mm\(^2\) (and sometimes <1 mW per mm\(^2\), depending on the sensitivity of the ChR2-expressing cells)\textsuperscript{26}, many published studies utilize orders of magnitude higher power\textsuperscript{16,27–29}. This likely arises because the FF is often positioned above the brain region of interest to minimize damage. Due to the exponential decrease in power density with distance from the FF, this necessitates the use of high light powers in order to stimulate cells throughout the nucleus\textsuperscript{16,17,30} and can result in local tissue heating by up to several degrees Centigrade\textsuperscript{18}. By both permitting insertion of the fiber into the nucleus of interest and by delivering light along
the linear extent of the taper, TFs achieve efficient light stimulation. This feature may be even more important when considering inhibitory and spectrally shifted opsins that may require more light to achieve effective neuronal perturbation.

Large brain area illumination with TFs is easily achieved with standard fiber-coupled lasers or light-emitting diodes (LEDs), including inexpensive LED-based commercial fiber launch systems (Supplementary Fig. 15) that naturally inject light over a large NA and produce emission over the fiber face. Furthermore, this approach is viable for chronic use in freely moving, tethered mice and for acute insertion in head-fixed mice.

Spatially restricted and dynamically controlled light delivery TFs also permit rapidly adjusted delivery of light, even of multiple wavelengths, to subvolumes of brain tissue (Figs. 5–7 and Supplementary Videos 1–4). Site-selective light delivery is achieved using a simple optical setup that injects light into the fiber with a defined and adjustable angle, θ. At minimum, this setup consists of one lens and one translating mirror for slowly adjusting θ (Supplementary Fig. 13a). For high-speed control, three lenses and one galvanometric mirror (Supplementary Fig. 13b) can be used to change θ quickly. With this approach, the emitting region can be modified step-by-step (every 20 ms in Supplementary Video 2) or continuously at various speeds (Supplementary Video 3).

Previous use of tapered fibers Although the ability of TFs to provide uniform as well as dynamically controlled, restricted illumination has not been previously recognized, sharpened fibers have been sporadically used to increase light delivery angle, to reduce invasiveness and for biological discovery31–33. This prior work exploits chemical etching of fibers 34, which can produce steep tapers of short lengths and has not been demonstrated to be capable of producing the long, gradual, tightly controlled tapers needed to illuminate large brain structures. In contrast, we pulled the fibers rapidly, after laser-heating, with very small taper angles, and we demonstrated reproducible fabrication of fibers with customized taper lengths and angles. Previous use of chemically etched fibers appears to have been intended to minimize tissue damage31,33 and provide a broader illumination angle from the tip33. These studies may draw inspiration from previous work32 in which chemically etched fibers were attached to tetrodes to generate arrays of optrodes capable of both photostimulation and recording neural activity. In that study, light emission appears to be only from the taper tip and results in a broader illumination angle.
It is unclear in these studies if light was injected at the fiber back aperture using its full NA, as necessary to achieve light output from the entire fiber face. As far as we know, no previous study demonstrates, as we have done here, scanning output along the taper length (Fig. 5) or its application in freely moving animals (Figs. 6 and 7).

In addition, TFs can be coated with metal, with small openings to restrict light delivery. Lambele et al. used TFs covered with aluminum to restrict light emission and collection to a ~100-nm fiber tip, as needed for near-field fluorescence. We previously restricted light emission from a fiber by coating it in gold and making small holes in the coating. These metalized and milled fibers were hand-crafted, requiring hours of work by an individual at a highly specialized machine that combines focused ion beam milling within a scanning electron microscope and resulting in production costs of ~US$1,000 per fiber. Furthermore, they could not be used for large volume illumination and provided only unidirectional illumination at fixed, predefined spots, whereas the new technology allows continuous and dynamic selection of illumination zones at a low cost.

Previously impossible classes of optogenetic experiment for biological discovery

From the perspective of an experimental neuroscientist, several classes of optogenetics experiments are enabled by exploiting the flexible and controllable nature of light delivery TFs provide. For example, subregions of the striatum subserve different functions, with specialized contributions to behavior evident along the dorsal–ventral as well as medial–lateral axes and coarse topographic mapping to cortex laid out along the anterior–posterior axis. We demonstrate (Figs. 3, 6 and 7) that with a TF it is possible to illuminate an elongated column of striatum that spans the dorsal–ventral axis and compare, in a single animal, the effects of selective optogenetic manipulation of subregions along the fiber axis. Given that the striatum spans several millimeters in the mouse, these experiments are impractical with standard FFs, as these can neither deliver light to the entire structure nor be repositioned for selective stimulation. Furthermore, with extended TFs, a single fiber can be inserted to deliver light to both cortex and striatum. Since light of different wavelengths can be outcoupled from different zones and independently controlled (Supplementary Video 4), TFs make it possible to examine the effects of interactions between areas. For example, one could examine whether the motor effects of motor cortex inhibition can be overcome by excitation of the striatum.

In addition, as optogenetics becomes accessible in primates, the larger brain structure will require the use of TFs for effective perturbations. For example, the visual cortex of macaque is several millimeters thick, with different cellular and receptive field properties in different layers. In the classic experimental system, current light delivery devices are unable to manipulate cells throughout all layers or, through a single device, test the effects of manipulations of superficial versus deep layer neurons. Furthermore, given the tight topographic organization of primate visual cortex and the use of individual animals for many recording sessions, it will be valuable to have a device such as a TF with gentle taper for multiple insertions in each recording session.

In summary, we exploited TFs with small taper angles to achieve near-uniform illumination of extended brain structures as well as to sample subregions of interest along a taper segment up to 2 mm long, while causing substantially less damage to the brain than use of FFs would. The devices were tested in both mouse motor cortex and striatum and showed that they required a ~5-fold lower excitation power threshold and excited a larger volume compared to flat-faced fibers. Furthermore, we demonstrated their effective use through optical commutators and patch cords to compare the effects of stimulation of dorsal versus ventral striatum in individual unrestrained mice spontaneously exploring an arena. Coupled to the minimum invasiveness of the device, the simplicity of the technique and its intrinsic compatibility with both laser and LED sources, we suggest that this approach can greatly complement existing methods for light delivery in optogenetics experiments and has the potential to replace commonly used flat-faced fibers for many applications.

Women mice (age > P60). We used thethe Care and Use of Laboratory Animals from Charles River (C57BL/6NCrl, stock #027). In addition, we used C57BL mice following guidelines described in the US National Institutes of Health with protocols approved by the Harvard Standing Committee on Animal Care.

ONLINE METHODS

Ray-tracing simulations. We used commercial optical ray-tracing software Zemax-OpticStudio (http://www.zemax.com/) to design and simulate the performances of TFs. The single TF modeled was a straight core/cladding segment followed by a conical taper. The materials forming all the components of the TFs and the surrounding media were assumed to be homogeneous (refractive index constant in space). The core/cladding diameters were 50/125 µm and 200/225 µm for fibers with numerical apertures NA = 0.22 and NA = 0.39, respectively. Core/cladding refractive indices were set as specified by the fiber producer: 1.464/1.447 for NA = 0.22 and 1.464/1.411 for NA = 0.39. Since the tapers were obtained by heating and pulling, commonly resulting in a melting of core and cladding materials in the tapered regions, the taper refractive index was assumed to be the average of core and cladding refractive indices, weighted by the respective cross sectional areas of core and cladding. This resulted in taper refractive indices of 1.450 for fibers with NA = 0.22 and 1.453 for fibers with NA = 0.39. The length of the core/cladding block was set to 4 mm, whereas the length of the taper was a function of the taper angle.

For results of simulations reported in Figure 1b and Supplementary Figure 2, the source was modeled as a single ray injected into the fiber, with a defined angle of incidence with respect to the fiber optical axis. For simulations reported in Figure 1 and Supplementary Figures 3 and 4, a monochromatic source (λ = 473 nm) was modeled as a bundle of unpolarized parallel rays with a Gaussian intensity profile. The source was focused into the core/cladding section of the fiber through a Zemax model of the experimentally used aspheric condenser (Rochester Precision Optics; http://www.roptrons.com/). We used model A-375-A, with focal length f = 7.49 mm, NA = 0.29 and clear aperture of 4.50 mm, for TFs with NA = 0.22 (input Gaussian beam radius = 1.66 mm, measured at 1/e2, resulting in a focused waist of 1.6 µm RMS spot radius), and used model A-390-A, with f = 4.60 mm, NA = 0.47 and clear aperture of 4.90 mm, for fibers with NA = 0.39 (input Gaussian beam radius = 1.84 mm, measured at 1/e2, resulting in a focused spot of 1.9 µm RMS spot radius). The former coupler was used only with the NA = 0.22 optical fiber, with a Gaussian beam radius of 1.66 mm focused on the fiber core (with a 1.6-µm RMS spot radius); the latter was used with both fibers, with a Gaussian beam radius of 1.84 mm, producing a 1.9-µm RMS spot radius. For simulations displayed in Supplementary Figure 12, a parallel and unpolarized Gaussian beam with radius 25 µm at 1/e2 intensity was injected at different input angles.

The irradiance profile of the light outcoupled from the taper was recorded through a rectangular, pixelated detector laid along the taper sidewall (Supplementary Fig. 4). The detector length was set as the taper side length and its width was set to 20 µm. These profiles were then averaged along the short side of the detector and fitted with a Gaussian function. The full-width-at-half-maximum criterion was used to retrieve the emission length (Lem, measured axially from the taper tip) from the irradiance profiles. For each single ray tracing session, 5 million rays were launched into the system, and each ray was split axially from the taper tip but rather over the whole extent of the tapered fiber, and they mostly occur at fiber diameters well above a few micrometers. Ray-tracing is used to characterize the full-NA injection method, with good agreement with experimental results (Fig. 1d). In the section "In vivo multisite stimulation" we describe the working principles of the device, based on selective modal outcoupling along the taper.
that the fluorescence per hemisphere was expressed as a fraction of the total for that section. No comparisons were made between sections.

**Multielectrode array recordings.** Recordings in primary motor cortex of adult (VGAT-ChR2) animals (age > P60) and offline analysis of spiking rates were accomplished as previously described. Mice were habituated to head-restraint before the recording session. Only one fiberoptic (TF or FF) was inserted at a time and the effects of cortical stimulation of motor inhibitory neurons on identified units were examined. For each unit, spiking rates were normalized to the preillumination rate. Averages were calculated across neurons.

**Open field surgery.** The surgery for TF implant was as described above in the “Analysis of c-Fos induction” section, with coordinates for the TF in striatum being 0.85 mm anterior, 1.4 mm lateral and 4.1 mm dorsal of bregma. Adult (Ador2a-Cre;Ai32) animals (age > P60) recovered for 5 d after surgery and were handled for 3 d before experimentation.

**Behavior.** On the day of the experiment, animals were placed in the open field arena. The experimental model consisted of 3-min blocks of either no stimulation (NS), laser input to the fiber at angle 1 (θ₁) or laser input at angle 2 (θ₂), repeated in the following pattern: NS–θ₁–NS–θ₂–NS–θ₁–NS–θ₂–NS, alternating stimulation of ventral (θ₁) and dorsal (θ₂) striatum separated by periods of no stimulation. On the subsequent day of analysis, the order of ventral (θ₁) and dorsal (θ₂) stimulations were reversed.

**Open field analysis.** Mice were recorded using a Microsoft Kinect (v1), which records 3D video data at 30 frames per second. For data in Figure 6, scalar features were extracted using previously published methods. For modeling data presented in Figure 7, the open field behavior was analyzed using previously published methods. In brief, the data were subjected to machine-learning methods that describe the mouse’s behavior as reusable subsecond modules, or syllables. All free parameters were set to the values described in Wiltschko et al., with the exception of the stickiness parameter, kappa, which sets the model’s tendency to remain in the same syllable over time (rather than switch between different syllables). This parameter is tuned so that the overall syllable duration distribution qualitatively matched a model-free analysis of behavioral change-points, as in Wiltschko et al. For this analysis we set kappa to 291,600. For positioning of the mouse in Figure 7, the head and tail position were computed first by fitting an ellipse to the image of the mouse. The head and tail positions were defined as the two points of the ellipse most distant from each other (i.e., the points of the ellipse that intersect with its principal axis).

**Statistics.** Statistical comparisons were performed in Prism (Graphpad) using nonparametric tests. For the data in Figure 6, a two-tailed Mann-Whitney U test was performed with n = 10, 4 and 4 for NS, θ₁ stimulation and θ₂ stimulation, respectively. For further details, see the main text and Figure 6 legend. Each n value represents one 3-min imaging session, with half the sessions collected on day one and half on day 2. For the data in Supplementary Figure 11, a Kruskal Wallis ANOVA with Dunn’s multiple-comparison correction was performed using n = 45, 49, 51, 28, 28, 48, 49, 49 and 49 cells for 10-, 50-, 100- and 200-µW power for the TF, shallow FF and deep FF. See the Supplementary Figure 11 legend for further details. See the Supplementary Methods Checklist for further details. No statistical methods were used to determine sample sizes a priori. The sample size was chosen based on prior experience with similar experiments. Normality was not assumed and no per-sample calculation of variance was performed. No randomization or blind analysis was used. However, for Figures 6 and 7 analysis was performed with automated routines with no user intervention and the stimuli were delivered in interleaved and counterbalanced orders. No criteria for data exclusion were used.

**Data and code availability.** All data and code are available from the authors upon reasonable request.
