**Abstract**

*Objective:* Retrospective studies suggest that women have more active brown adipose tissue (BAT) than men, but little is known of the effect of fluctuating sex steroids across the menstrual cycle on thermogenesis in women.

*Design:* To characterise the effects of sex and sex steroids on BAT activity we recruited healthy weight men (n = 14) and women at two stages of the menstrual cycle (luteal, n = 9; follicular, n = 11).

*Methods:* Infrared thermography measured supraclavicular temperature to index BAT thermogenesis in response to both cold (immersion of one hand in water at 15°C) and meal (Ensure, 10 kcal/kg body weight) stimuli.

*Results:* Adaptive BAT temperature responses were greater (P < 0.05) in women than men, irrespective of stage of menstrual cycle. Whereas during cold exposure, the increase in BAT temperature was abrogated (P < 0.05) in women during follicular phase compared to men and women during luteal phase. Plasma concentrations of progesterone, 17β-estradiol, testosterone and cortisol were measured. Regression analyses demonstrated that baseline BAT temperature was positively correlated (P < 0.05) with progesterone levels, but was inversely associated (P < 0.05) with cortisol concentration. Both cold- and meal-induced changes in BAT temperature mildly correlated (P = 0.07; P < 0.05) with 17β-estradiol levels, but not with testosterone concentrations.

*Conclusions:* Baseline supraclavicular temperature is elevated in women during the luteal phase of the menstrual cycle, which correlated with elevated progesterone concentrations. Women exhibited greater thermogenic responses than men, irrespective of the state of the menstrual cycle, which was associated with plasma levels of 17β-estradiol. We conclude that sex steroids may regulate BAT thermogenesis in healthy adults.

**Introduction**

Thermogenesis contributes to approximately 10% of total energy expenditure in lean individuals (1). In humans, brown and beige adipose tissue (BAT) as well as skeletal muscle contribute to total thermogenic capacity (2). In adult humans, BAT is located in the supraclavicular, neck, epicardial, peri-renal and para-spinal adipose depots (3). In the neck and supraclavicular regions, adipose tissue contains a heterogeneous population of white, brown and beige adipocytes (4), with the latter two cell types being capable of thermogenesis. Beige adipocytes are derived from the white adipocyte population (5), either being formed from preadipocytes (6) or being recruited by transdifferentiation of white adipocytes (7). In humans chronic activation of BAT via repeated cold exposure increases energy expenditure and decreases adiposity (8). Furthermore, cold-induced BAT activation also increases glucose and triglyceride clearance and improves insulin sensitivity in adults (9, 10). Despite this, it remains contentious as to the precise physiological role and importance of BAT in metabolism and energy expenditure in humans (11).
A number of studies have suggested that the regulation of BAT may be sexually dimorphic, yet, few studies have addressed this directly. Retrospective PET-CT studies suggest a greater prevalence of active BAT in women than in men (12) and data from animal models show that estrogen treatment increases thermogenesis in both BAT and skeletal muscle (13, 14). Despite this, recent prospective study using PET-CT imaging suggested that women had a lower suprACLavicular BAT volume than men, albeit $^{18}$F-FDG uptake being comparable in men and women suggesting that overall suprACLavicular BAT activity is similar, irrespective of sex (15). The study of Fletcher et al., however, identified a BAT depot in the superficial dorsocervical region that was more prevalent in women than men (15). Therefore, there appears to be sexual dimorphism in the distribution and activity of BAT, but whether this tissue exerts greater metabolic action in men or women remains to be elucidated. Furthermore, it is important to highlight a recent study in mice, which demonstrated that β3 adrenoceptor-induced $^{18}$F-FDG uptake was independent of uncoupling protein 1 (UCP1); CL-316,243 treatment increased glucose uptake to an equivalent degree in Ucp1 WT and knockout mice (16). This highlights the importance of validating new techniques to measure BAT activity in humans.

In addition to the sex differences, body temperature fluctuates across the menstrual cycle in women being higher during the luteal phase (17) when progesterone levels are elevated. Furthermore, women have a greater tolerance to cold during the luteal phase, which is evidenced by increased latency to the onset of shivering during cold exposure compared to women during the follicular phase (18). This may be due, in part, to the changes in vasomotor control of blood flow to the skin (18), but it remains possible that alterations in thermogenesis contribute to changes in body temperature in women during different phases of the menstrual cycle. Indeed, the previous study of Fletcher et al. (15) examined women during the follicular phase only. In vitro studies have suggested that progesterone may act directly at brown adipocytes, whereby progesterone treatment increases Ucp1 mRNA expression (19) and enhances noradrenaline-induced lipolysis in cultured brown adipocytes (20), thus emphasising the possible importance of the stage of cycle. The present study recruited healthy young adults and characterised both cold- and meal-induced changes in BAT temperature in men and women. We hypothesized that thermogenesis induced by both cold and meal-stimulus is greater in women than men. We hypothesized further that baseline, cold- and diet-induced changes in suprACLavicular temperature will be greater in women during the luteal phase of the menstrual cycle than either men or women during the follicular phase. We predicted that such changes would be correlated with plasma sex steroid concentrations.

Methods

Participants

Fourteen male and 20 female healthy, young participants between the ages of 18–40 years old were recruited for this study. All participants had no history of cardiovascular disease, diabetes and were all non-smokers, not pregnant or lactating and were not taking any form of hormonal contraceptive. Ethical approval was obtained from the Monash University Human Research Ethics Committee for the study, which adhered to the requirements of the National Statement on Ethical Conduct in Human Research but also the Declaration of Helsinki, Seventh Revision, 2013. Written informed consent was obtained from each participant prior to the commencement of study.

Study design

The overall study design is outlined in Fig. 1A. Infrared thermography was used to measure temperature changes in the suprACLavicular and manubrium regions to provide assessment of altered heat production in both BAT-positive and BAT-negative sites, respectively, as discussed in detail below. Changes in heat production were measured in response to both cold and meal stimuli (see below). Female participants were required to record their onset of menstruation and measure daily basal oral temperature for 4 weeks to provide indication of the stage of menstrual cycle and the studies were performed during either the follicular or the luteal phases of the menstrual cycle. To confirm the stage of menstrual cycle, blood samples were collected and used to measure plasma progesterone and 17β-estradiol concentrations.

Infrared thermal imaging was performed during the morning between 07:00–12:00 h (Fig. 1B). Participants arrived after fasting overnight and were rested for 30 min prior to any experimentation. During this rest period, a single catheter (22G Introcan Safety IV Catheter, B. Braun Australia, VIC, Australia) was inserted into the antecubital vein and used for the collection of the baseline blood sample (10 mL). Blood samples were collected into plasma separation tubes (Becton Dickinson Pty Ltd, VIC, Australia) and plasma was harvested via centrifugation at 3,000 rpm for 10 minutes.

Figure 1
Experimental design for thermal imaging studies. Prior to experimentation, women were asked to maintain a menstrual diary recording the first and last day menstruation. In addition, women recorded daily basal body temperature using an oral thermometer (Panel A). This information was then used to estimate the stage menstrual cycle prior to thermography recordings (Panel B). On the day of experimentation, upon arrival, a cannula was inserted into the ante-cubital vein and a baseline blood sample was collected and used to measure plasma levels of progesterone, 17β-estradiol and testosterone. Participants rested for 30 min prior to temperature recordings. Cold exposure was elicited by having participants immerse one hand in a bucket of water at 15°C for 5 min, after which participants consumed a standardised meal (10 kcal/kg body weight, Ensure, Abbott Laboratories) to elicit post-prandial heat production (Panel B). Images were collected at 1-min intervals for the duration of the protocol and representative images are shown in Panel C. Regions of interest (circles) encompass both the supraclavicular BAT depots and the manubrium. Red arrows within the circles indicate the highest temperature in the region of interest, while blue arrows indicate the lowest temperature.
3730 g for 10 min. To prevent any confounding effect of movement, participants sat upright in a phlebotomy chair for the duration of the resting and imaging periods. The day prior to IR imaging, participants were provided with a standardised meal of beef or vegetarian lasagne (McCain Foods, VIC, Australia) to consume the night before. The two meals were similar in energy and nutritional composition, per serving the beef lasagne provided 1630 kJ energy, 22.8 g protein, 9.2 g fat (4.8 g saturated fat), 49.2 g carbohydrate (16.8 g sugar), whereas the vegetarian option contained 1460 kJ energy, 19.6 g protein, 6.0 g fat (3.6 g saturated) and 50 g carbohydrate (18.8 g sugar).

Cold- and meal-induced thermogenesis

The average room temperature (19.36±0.29°C) and humidity (43.35±1.39%) were recorded across the experimental period. The FLIR T640 thermal imaging camera (FLIR Systems Australia Pty Ltd, VIC, Australia) was configured 1 m from the participant and focussed at the level of the clavicles. Emissivity was set to 0.98 as detailed for the measurement of skin temperatures by the FLIR manual. All participants wore a sleeveless shirt that exposed the supraclavicular and manubrium regions, participants changed into this prior to the acclimation period. An outline of the temperature recording protocol is detailed in Fig. 1B. Images were collected at 1-min intervals across the duration of the experiment.

Five baseline images were collected and to induce moderate cold exposure participants immersed one hand into water at 15°C for 5 min. Images were collected for a further 30 min following cold exposure. Once supraclavicular temperature had returned to baseline, another five baseline images were collected, after which participants consumed a standardised liquid meal (10 kcal/kg body weight, Ensure Powder, Abbott Laboratories). The meal was consumed at room temperature within a 5-min period. Post-prandial temperature recordings were collected for 30 min (Fig. 1B). Representative thermal images from a single participant from each group are shown in Fig. 1C.

All thermal images were analysed using the program FLIR Tools (FLIR Systems, OR, USA). The maximum temperature within the supraclavicular region was measured bilaterally (Fig. 1C). As a means of negative control within each participant, the minimum temperature of the manubrium, the most superior portion of the sternum, was also measured. The skin of the manubrium overlies the sternum, hence any changes in temperature observed at this site reflects alterations in overall cutaneous heat circulation rather than that caused by thermogenesis such as in BAT and has been used in previous studies as a reference negative control region (21, 22). Any image in which the regions of interest were obscured (which occurred during the consumption of the meal replacement drink) were omitted from analysis.

Cold-induced thermogenesis was considered biphasic. Temperature was analysed as the area-under-the-curve (AUC) during cold exposure itself. The mean change in temperature was also calculated at 15–30 min following cold exposure and at 20–30 min post meal consumption.

Blood sample analysis

A single blood sample was collected from fasted participants to measure plasma concentrations of total cortisol, testosterone, 17β-estradiol and progesterone.

Plasma cortisol was measured using a 3H-based double-antibody RIA as described previously (23), with an intra-assay coefficient of variation (CV) of 3.56%. Plasma testosterone, 17β-estradiol and progesterone were all measured using 125I-based ImmuChem double antibody RIA kits (MP Biomedicals, OH, USA), with an intra-assay CV of 12.06, 8.56 and 14.02% respectively.

Statistical analysis

Statistical analyses were undertaken using IBM SPSS v 22.0. All data were checked for homogeneity and equal variance with Levene’s test. Baseline temperature as well as the effects of both cold and meal stimuli on BAT heat production were analysed using a one-way ANOVA and post hoc comparisons were made using the Fisher’s least significant difference test. Sex differences were analysed by unpaired Student’s t-test comparing men to women, irrespective of stage of menstrual cycle. To take into account the effects across time, a repeated-measures two-way ANOVA was performed on the temperature changes observed in the supraclavicular and manubrium regions respectively. The between subject variables were group and sex. Linear regression analyses were used to determine the correlation between plasma cortisol and sex steroid concentrations and all thermogenic measures. Linear regression normality was assessed through the examination of predicted probability (P–P) plots for each relationship and scatterplots of the predicted values versus the residuals for homoscedasticity. All regressions involving testosterone were not normal, so regressions were performed within sex, which restored normality. Statistical significance was taken as a P<0.05. Unless otherwise stated, all data are presented as the mean ± s.e.m.

Post hoc statistical power calculations

Prior power calculations were not possible due to the novelty of the longitudinal mode of temperature recording, the method of data analysis, the nature of the stimuli and the inclusion of menstrual cycle as a grouping variable. However, to affirm that a true null hypothesis was not falsely rejected, post hoc statistical power calculations were made using the freely available Statistical Power Calculator Using Average Values from DSS Research (https://www.dssresearch.com/resources/calculators/statistical-power-calculator-average/). All power calculations were performed assuming a two-tailed alpha of 0.05. Based on study data, the significant difference (0.53°C) between women measured during the luteal phase and those during the follicular phase, was 100% powered. The difference between men and women with regards to post-cold adaptive and meal-induced thermogenesis had a power of 95.9 and 97.9%. Thus the group numbers attained were adequate to detect the fundamental differences in thermogenesis between men and women.

Results

Participant characteristics

Thirty-four young, healthy participants attended and completed all components of the study. Women during the follicular phase (n = 11) or the luteal phase (n = 9) of the menstrual cycle and 14 men were studied. The average age of participants was 24.1 ± 0.65 years, with no difference between men (23.1 ± 0.7 years) and women (follicular phase: 24.6 ± 1.2 years, luteal phase: 25.22 ± 1.7 years). Morphometric characteristics are described in Table 1. Plasma 17β-estradiol concentrations were lower (P < 0.01) and testosterone concentrations were higher (P < 0.0001) in men than in women, irrespective of the stage of menstrual cycle (Table 2). Concentrations of 17β-estradiol were similar in women during the luteal and follicular phases of the menstrual cycle and progesterone concentrations were higher (P < 0.0001) during the luteal phase, than in women during follicular phase and in men (Table 2). Basal plasma cortisol concentrations were similar in men and women, but were lower (P < 0.05) in women during luteal phase than during the follicular phase of the menstrual cycle (Table 2).

Basal BAT temperature was elevated in women during the luteal phase of the menstrual cycle

Baseline supraclavicular temperature was greater (P < 0.05) in women during the luteal phase than in women during the follicular phase of the menstrual cycle and in men (Fig. 2A). This difference was specific to the BAT region as the manubrium temperature was similar across all 3 groups (Fig. 2B). Baseline supraclavicular temperature was inversely

Table 2  Plasma concentration of steroids.

| Group                | Follicular phase women | Luteal phase women | Men | P value |

Sex steroids and thermogenesis

183:3 | 348

Correlated \((\beta = -0.001, R^2 = 0.16)\) with plasma cortisol concentration (Fig. 2C) and positively correlated \((\beta = 0.36, R^2 = 0.34)\) with plasma progesterone concentration (Fig. 2E). Baseline supraclavicular temperature did not correlate with either 17\(\beta\)-estradiol or testosterone concentrations (Fig. 2D and F). There was no association between baseline manubrium temperature and the concentration of any of the sex steroids or cortisol (Table 3).

Cold-induced thermogenesis is abrogated in women during the follicular phase of the menstrual cycle

Temperature responses to cold exposure in the supraclavicular and manubrium regions are shown in Fig. 3. None of the participants reported shivering during or after the moderate cold stimulus. There was no effect of mild acute cold exposure on manubrium temperature (Fig. 3A), whereas the supraclavicular temperature increased (Fig. 3B), indicating a specific effect of cold-stimulus on BAT. During the cold stimulus itself, supraclavicular temperature increased in all three groups, albeit to varying degrees. The AUC was greater \((P < 0.05)\) in men and in women during luteal phase than in women during the follicular phase of the menstrual cycle \((1.66 \pm 0.44 \text{ AUC in men, } 1.56 \pm 0.26 \text{ AUC in women during luteal phase, } 0.50 \pm 0.23 \text{ AUC in women during the follicular phase); Fig. 3B and C.\) The AUC of the temperature change in the manubrium did not differ between groups (Fig. 3E).

Cold-induced adaptive thermogenesis is greater in women than men

After cold exposure, supraclavicular temperature initially returned to baseline and then increased again approximately 20 min after the cessation of the cold exposure period (Fig. 3B); this response will be referred to as the cold-induced adaptive response. The adaptive increase in supraclavicular temperature was evident in women, but appeared to be absent in men \((P < 0.05; 0.16 \pm 0.04 \degree C \text{ increase in women vs } 0.00 \pm 0.08 \degree C \text{ in men}),\) irrespective of the stage in the menstrual cycle (Fig. 3B and D). This was not observed in the manubrium (Fig. 3A and F).

Sex steroids are associated with cold-induced adaptive thermogenesis

Despite the apparent effect of the stage of menstrual cycle on BAT temperature during cold exposure, there was no significant association between the cold-induced AUC response and plasma concentrations of cortisol, progesterone, 17\(\beta\)-estradiol or testosterone (Fig. 3G, H, I and J). In contrast, cold-induced adaptive thermogenesis was positively correlated \((\beta = 0.20, R^2 = 0.13, P < 0.05)\) with plasma...
17β-estradiol levels (Fig. 3L). There was no association between the cold-induced adaptive change in supraclavicular temperature and plasma concentrations of either cortisol, progesterone or testosterone (Fig. 3K, M and N).

**Meal-induced thermogenesis is higher in women than men**

Changes in the temperature of the supraclavicular region and the manubrium in response to a standardised liquid meal are displayed in Fig. 4. The temperature of both the supraclavicular and the manubrium increased approximately 15 min after meal consumption (Fig. 4A and B). The meal-induced increase in supraclavicular temperature was greater in women than men, irrespective of the stage of the menstrual cycle. The difference was determined by measuring both the change in AUC (2.29 ± 0.33 AUC in women vs 0.97 ± 0.52 AUC in men; Fig. 4C) and the post-prandial change in supraclavicular temperature (0.23 ± 0.03°C in women vs 0.11 ± 0.06°C in men; Fig. 4D). In contrast, the manubrium temperature was similar in men and women (Figs. 4A, E and F).

**17β-Estradiol and testosterone levels predict meal-induced thermogenesis**

There was a weak correlation between the supraclavicular temperature response to meal ingestion (AUC) and plasma 17β-estradiol concentration (β=1.28, \( R^2=0.10, P=0.07 \)) (Fig. 4H), whereas there was no association with the change in supraclavicular temperature and plasma cortisol, progesterone or testosterone levels (Fig. 4G, I and J).

**Discussion**

The regulation of body temperature is sexually dimorphic and is influenced by fluctuating sex steroid concentrations (17). Furthermore, retrospective studies indicate that women may possess more functional BAT than men (12, 24, 25), but no studies have heretofore determined whether BAT activity changes across the menstrual cycle in women. The present study employed infrared thermography to demonstrate that BAT heat production in response to both cold exposure and meal consumption was greater in women than in men. Furthermore, we demonstrate that cold-induced thermogenesis varies across the menstrual cycle, such that activation of BAT is attenuated during the follicular phase relative to the luteal phase of the cycle. Thus, sex and the stage of menstrual cycle impact on BAT activity in healthy women of normal body weight.

It is well known that body temperature fluctuates in women across the menstrual cycle and is higher during the luteal phase than either the follicular or ovulatory phases (17, 26). A recent study utilised wrist temperature biosensors to demonstrate that night time cutaneous temperature was elevated by 0.33°C during the early luteal phase compared to the period of ovulation (27). The present study further demonstrates that, in fasted subjects, baseline BAT temperature is greater in women during the luteal phase than in women during the follicular phase and in men. Sex differences with respect to thermoregulation have been acknowledged for over 50 years, whereby women maintain a greater core body temperature during cold exposure (28, 29). Despite this, women experience lower cutaneous temperature during cold exposure, which coincides with increased perception of cold compared to men (28). As indicated above, retrospective analysis of PET-CT scans have shown active BAT is more readily detected in women than in men (12), but these studies did not relate such findings to fluctuations in sex steroids or stage of menstrual cycle. To our knowledge, the present study is the first to describe elevated basal BAT temperatures in women during the luteal phase.

In addition to the differences in baseline BAT temperature, we demonstrate that both sex and the stage...
Figure 3
Cold-induced thermogenesis in men ($n = 14$) and women during the luteal phase of the menstrual cycle ($n = 9$) was greater than in women during the follicular phase ($n = 11$). Temperature changes during cold exposure (hand immersed in water at 15°C) and for 30 min thereafter were tracked at the manubrium (A) and BAT (B). The area under the curve (AUC) was calculated over the course of the cold exposure temperature response (0–5 min) in BAT (C) and the manubrium (E). The mean temperature changes were calculated at 20–35 min after cold exposure, which was in line with the adaptive thermogenic response in men and women at both BAT (D) and manubrium (F). Simple linear regressions were established between measured steroid hormones and cold response AUC (G–J) as well as the cold-induced adaptive temperature change (K, L, M and N). In the case of the regressions, indication of grouping is purely for qualitative purposes. A logarithmic transformation was applied to the variables 17β-estradiol, testosterone and progesterone. The squared correlation coefficient ($R^2$) and $P$ value ($P$) are indicated except in cases of the $P$ value exceeding 0.1, in which case only non-significance (NS) is indicated. Data presented as the mean ± S.E.M. * indicates a significant difference of $P < 0.05$ as determined with an unpaired Student's $t$-test or a one-way ANOVA with post hoc Fisher's least significant difference test where appropriate. ## indicates an effect of sex with $P < 0.01$ as determined with a repeated measures two-way ANOVA with post hoc Fisher's least significant difference test.
Figure 4

Meal-induced thermogenesis was higher in women during either follicular (n = 11) or luteal (n = 9) phases of the menstrual cycle than men (n = 14). Temperature changes were tracked from baseline for 30 min following meal-replacement drink administration at the manubrium (A) and BAT (B). The area under the curve (AUC) was calculated for the temperature changes during the final 10 min of post-meal thermogenesis (20–30 min) in both men and women for both the supraclavicular (C) and manubrium (E). The mean temperature changes at the supraclavicular (D) and manubrium (F), during the final 10 min of post-meal thermogenesis (20–30 min) are presented in both men and women. Simple linear regressions were established between measured steroid hormones and meal response AUC (G, H, I and J). The indication of grouping among regressions is for qualitative purposes. A logarithmic transformation was applied to the variables 17β-estradiol, testosterone and progesterone. The squared correlation coefficient (R²) and P value (P) are indicated except in cases of the P value exceeding 0.1, in which case only non-significance (NS) is indicated. Data presented as the mean ± S.E.M. * indicates a significant difference of P < 0.05 as determined with an unpaired Student’s t-test.
Sex steroids and thermogenesis

of menstrual cycle impact on the activation of BAT in response to either a cold stimulus or a meal stimulus. Thermogenic responses to cold stimuli were biphasic and were segregated into two responses, being firstly, the response during the period of cold stimulus and the adaptive response occurring approximately 20 min after cessation of the stimulus. Importantly, temperature changes in response to cold exposure were specific to the supravacular region, with no effect on the temperature of the manubrium, suggesting that responses were specific to BAT and were not caused by a generalised increase in core body temperature. During cold exposure, BAT temperature increased in both men and women, but this effect was attenuated in women during the follicular phase of the menstrual cycle. Previous studies have shown that, in response to very mild cold exposure (23°C), the increase in metabolic rate is also attenuated in women during the follicular phase relative to the luteal phase of the menstrual cycle (30). Indeed, a recent cold acclimation study suggested that¹⁸F-FDG uptake within the supravacular region was similar in men and women, but this work only characterised women during the follicular phase of the menstrual cycle (15). Together these studies, along with the current work, highlight the importance of the stage of menstrual cycle and thus the possible role of endogenous sex steroids in modulating metabolic responses to cold. Despite this, the vast majority of studies characterising BAT function in humans are predominantly in men and do not account for the stage of menstrual cycle in women on the occasions when they are included (31, 32).

Supravacular temperature increased approximately 20 min after either meal intake or cold stimulus, indicative of adaptive thermogenesis. In contrast to cold exposure when the temperature increase was localised to the supravacular region, a generalised increase in temperature was observed in both the supravacular and manubrium regions following meal consumption. Various studies in rodents, show BAT thermogenesis to be increased in response to intake of a single meal (33, 34), but the role of BAT in diet-induced thermogenesis in humans has been contentious. In contrast, work using PET-CT demonstrated that BAT thermogenesis was increased after consumption of a carbohydrate enriched mixed meal (35). Furthermore, the increase in BAT activity was correlated with increased energy expenditure during the post-prandial period (35). Herein, we demonstrate that consumption of a standardised mixed liquid (Ensure) meal increases supravacular temperature in men and women, indicative of post-prandial thermogenesis in BAT. Because this was also associated with an increase in temperature of the manubrium, the response is generalised and cannot be regarded as specifically related to BAT thermogenesis and in fact may relate to altered skin perfusion. Nonetheless, our previous work in sheep demonstrated that skeletal muscle mounts a post-prandial temperature response without an associated change in blood flow, which was taken to indicate thermogenesis in this tissue (36). Further studies are required to determine the differential contribution of skeletal muscle and BAT (and/or other tissues) to the post-prandial rise in temperature in humans.

It is important to emphasise that the adaptive thermogenic responses to both meal and cold stimuli differed in men and women, irrespective of the stage of the menstrual cycle; the increase in supravacular temperature was greater in women than men. This is consistent with the observation that there is greater BAT volume and activity in women than in men under thermoneutral conditions (25). To further elucidate the effect of sex and stage of menstrual cycle on BAT temperature and activation we sought to characterise the possible relationship between supravacular temperature and plasma concentrations of cortisol, progesterone, 17β-estradiol and testosterone. We demonstrate that baseline supravacular temperature was positively correlated with plasma progesterone levels, but there was a negative association with plasma cortisol concentration. Previous studies in human brown adipocytes show that dexamethasone treatment blocks adrenergic stimulation of UCP1 expression (37). Furthermore, prednisolone treatment attenuates both cold-induced and post-prandial thermogenesis (38). In the current study, there was no association with plasma cortisol concentration and innate variation in either diet- or cold-induced supravacular heat production. Despite this, we demonstrate that circulating cortisol is associated with variations in basal supravacular temperature, whereby endogenous cortisol may negatively regulate basal BAT activity.

Progesterone is considered to be the primary driver of the thermoregulatory vicissitudes across the menstrual cycle (39), perhaps by reducing cutaneous circulation with a consequent increase in core body temperature (40, 41) or via thermosensitive neurons within the preoptic area of the hypothalamus as observed in rats (42). Previous studies have suggested that during the luteal phase, women defend a higher body temperature and therefore exhibit increased shivering and greater vasodilation in response to cold exposure (18). In addition, in response to lower ambient temperature, women exhibit an exacerbated increase in energy expenditure during the luteal phase compared to the follicular phase (5). The current work, highlight the importance of the stage of menstrual cycle (43).
to those during the follicular phase, despite showing no differences in perception of cold (43). As indicated earlier, we demonstrate supraclavicular temperature was greater in women during the luteal phase than in women during the follicular phase and that this correlated with plasma progesterone levels. Therefore, an increase in basal BAT activity may also contribute to increased body temperature in the luteal phase (39), and furthermore, greater activation of BAT may be a physiological means to maintain the increased core body temperature during episodes of cold exposure.

The adaptive supraclavicular temperature responses to both cold- and meal-stimuli were positively correlated with plasma 17β-estradiol levels. Although there is a paucity of studies in humans, sex steroids have been shown to modulate thermogenesis in various animal models, such that estrogens are known to increase BAT activity (13, 44). In rodents, 17β-estradiol is thought to inhibit AMPK neurons within the ventromedial hypothalamus, leading to sympathetic activation of BAT (45). This supports the hypothesis that inherent differences in BAT thermogenesis between healthy men and women are due, at least in part, to variation in the peripheral concentration of estrogen. Despite the association between supraclavicular temperature and female sex steroids, there was no association with circulating testosterone concentrations and any indices of BAT thermogenesis. This is consistent with our previous work demonstrating that clinically elevated testosterone levels are correlated with reduced supraclavicular temperature in women with polycystic ovarian syndrome, but there is no association between the two measurements in control women (46); further work is required to elucidate any possible effects of androgens on BAT function.

In conclusion, we demonstrate sexual dimorphism in basal supraclavicular temperature and in response to both cold and dietary stimuli. However, to our knowledge, this is the first study that has sought to link these differences with endogenous circulating concentrations of sex steroids in humans. Herein we have shown that the female sex steroids, progesterone and 17β-estradiol are associated with innate differences in basal supraclavicular temperature and the temperature responses to thermogenic stimuli, respectively. Furthermore we demonstrate that the stage of menstrual cycle can impact on temperature responses during cold exposure, an effect that appears to be independent of sex steroids. As eluded to above the vast majority of previous studies investigating BAT physiology are carried out in men, and thus this highlights the fundamental importance to investigate sex differences as well as the impact of the stage of menstrual cycle on BAT activation and energy expenditure.

Declaration of interest
The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of this study.

Funding
This work was funded by a Monash University Advancing Women’s Success in Science grant awarded to Dr Belinda Henry

Author contribution statement
The study was designed by B A Henry, J P Fuller-Jackson and I J Clarke. Data analyses was performed by J P Fuller-Jackson and B A Henry. All authors contributed to the preparation of the manuscript.
