Ultraviolet-responsive self-assembled metallomicelles for photocontrollable catalysis of asymmetric sulfoxidation in water†

Mengqiao Gao, Rong Tan, Pengbo Hao, Yaoyao Zhang, Jiang Deng and Donghong Yin

Self-assembled metallomicelles with ultraviolet (UV)-controlled morphologies were constructed from a synthesized azobenzene-containing amphiphilic chiral salen TiIV catalyst. The morphologies of the metallomicelles could be well adjusted by changing the UV irradiation time, and this was confirmed by TEM analyses. The UV-induced change in morphology potentially adjusted the catalyst concentration and/or accessibility in real-time, allowing photocontrollable catalysis of asymmetric sulfoxidation in water. UV-responsive catalytic activities with excellent selectivities were observed over the metallomicelles for a wide range of alkyl aryl sulfoxides. Moreover, a thermo-responsive NIPAAm block in the catalyst enables it to be easily recovered for steady reuse by thermo-controlled separation. This work constructed a photo-responsive metallomicellar system to carry out metallomicellar catalysis in a controllable way.

Introduction

Metallomicellar systems, which exhibit similar structural and kinetic properties to natural enzymes, have been extensively investigated as effective biomimetic systems for asymmetric catalysis in water.1 The ability to carry out metallomicellar catalysis in a controllable way has profound importance in chemical synthesis, and this area has garnered intense interest. The key to achieving this controllable catalysis was developing a metallomicellar system in which the concentration and/or accessibility of catalytic sites in reaction media could be adjusted in a controlled manner.2 Stimuli-responsive metallomicelles were thus developed to control catalytic reactions via external signals.3 The metallomicelles often undergo instantaneous morphological and/or architectural changes upon exposure to an external stimulus, consequently altering their catalytic properties.4 Lately, we have reported thermo-responsive metallomicelles for enantioselective sulfoxidation at room temperature in water by using a chiral salen TiIV complex as the catalytic site and NIPAAm as the thermo-trigger.5,6 The metallomicelles underwent reversible switching between self-assembly and precipitation in aqueous system in response to local temperature. At room temperature which was its lower critical solution temperature (LCST), catalysts were amphiphilic and self-assembled to form metallomicelles, accelerating the aqueous sulfoxidation by “concentration effect”. Upon heating above their LCST, they switched to hydrophobic compounds, and thus precipitated from aqueous system for facile recovery. The switchable behavior turned the enantioselective sulfoxidation on or off at will by adjusting local temperature. Nevertheless, in the metallomicellar catalysis, chemical processes were typically limited to a fixed rate and/or selectivity once the catalyst and reaction condition are chosen, control of catalytic activity as the reaction proceeds was difficult to achieve. Logically, if the morphology and/or architecture of the metallomicelles can be adjusted in real-time by external stimuli, controlled catalysis of asymmetric sulfoxidation should be realized.

Light irradiation, a green and sustainable energy which could be precisely manipulated in a clean environment without pollution to reaction system, was considered as an ideal external stimulus for controllable catalysis. A variety of light-responsive moieties was introduced in catalysts to give the catalytic system response to light.7a-c Among them, azobenzene has received much attention in recent years due to its well-known reversible photoisomerization from trans- to cis-configuration. Amphiphilic catalysts containing azobenzene group often undergo conformational and electronic changes upon light irradiation.7 It offered an attractive alternative to modulate morphology and/or architecture of metallomicelles in real-time. With these points in mind, we decided to incorporate azobenzene as the hydrophobic block of amphiphilic chiral salen
TiIV catalyst to develop photo-controlled metallomicellar catalytic system of asymmetric sulfoxidation in water. We envisioned that in aqueous media, the azobenzene-containing amphiphilic catalyst should self-assemble through hydrophobic interaction and π–π stacking of azobenzene group, forming micelle having hydrophobic azobenzene core. Catalytically active Ti(salen) was grafted on azobenzene segment to ensure the effective shielding of catalytic sites in the hydrophobic compartment, mimetic of enzyme. The self-assembled metallomicelles would behave as biomimetic nanoreactor, accelerating asymmetric sulfoxidation in water. In particular, the salient feature of azobenzene, reversible structural changes in the photoisomerization (trans/cis), should be beneficial for temporal control of the metallomicelles morphology using light. This unique property allowed one to control the metallomicellar catalysis of aqueous asymmetric sulfoxidation by external light irradiation. Thermo-responsive NIPAAm, which underwent hydrophilic-to-hydrophobic transformation at its LCST, was selected as the “smart” hydrophilic block to control self-assembly and precipitation of Ti(salen)-containing metallomicelle in the aqueous system.

Herein, well-defined diblock copolymer of poly(NIPAAm-co-azo) (NIPAAm, N-isopropylacrylamide; azo, azobenzene) was synthesized by copolymerizing NIPAAm with N-azo-acrylamide via atom transfer radical polymerization (ATRP). Covalently appending chiral salen TiV complex on the azobenzene block provided an amphiphilic chiral salen TiV catalyst responsive to temperature and UV irradiation. At the reaction temperature (25 °C), the catalyst was amphiphilic and self-assembled into metallomicelles in water, accelerating the aqueous asymmetric sulfoxidation by “concentration effect”. UV irradiation provoked the morphological change of metallomicelles, which thus controlled the metallomicellar catalysis of asymmetric sulfoxidation in water. After reaction, the catalyst became hydrophobic upon heating above its LCST, and precipitated from aqueous system for recovery. The activity switching was repeatable even after seven cycles.

Results and discussion
Preparation of catalysts
Stimuli-responsive metallomicellar catalysis, in which intrinsic activity could be finely modulated in real-time by external stimuli, was highly desirable in biomimetic catalysis. Light was an attractive stimulus for this stimuli-responsive system, since it offered excellent temporal and spatial resolution, and could be precisely controlled with an appropriate source. The key to achieving the light-controlled catalysis was developing the metallomicelle whose morphology and/or architecture in reaction media could be instantaneously induced by light stimuli. Azobenzene with reversible E/Z photoisomerization was an ideal photosensitive group for constructing the light-responsive metallomicelle. With these points in mind, we decided to incorporate hydrophobic azobenzene into amphiphilic chiral salen TiV catalyst to fabricate a Ti(salen)-containing metallomicelle for photocontrollable catalysis of asymmetric sulfoxidation in water. PNIPAAm which underwent reversible switching between hydrophilicity and hydrophobicity at its LCST was incorporated as the “smart” hydrophilic block to ensure not only self-assembly of catalyst for metallomicellar catalysis, but also recovery of catalyst for efficient reuse in the aqueous system.

The synthesis of thermo/photo-responsive chiral salen TiIV catalyst of PN427A10-C was illustrated in Scheme 1. First, well-defined diblock copolymer of poly(NIPAAm-co-azo) (denoted as PN427A10), featuring a terminated amino (–NH2) group on azobenzene block, was prepared via ATRP by using N,N-azobisisobutyronitrile (AIBN) as a radical initiator and 2-aminomethanethiol hydrochloride (AET) as the chain transfer agent. Successive N-alkylation of the terminal amino group (–NH2) with benzyl chloride group (–CH2Cl) at the 5-position of an reported asymmetric chiral salen ligand (CL) of (R,R)-N-(3,5-di-tert-butylsalicylidene)-N′-[3-tert-butyl-5-chloro-methysaliclylidene]-1,2-cyclohexane-diamine resulted in covalently appending chiral salen ligand on the hydrophobic segment of PN427A10, as shown in Scheme 1. The strategy ensured shielding of the catalytic motif in hydrophobic domain (protected by the hydrophilic corona) upon self-assembly in water, which was a salient feature of enzyme catalysis. The resultant PN427A10-modified chiral salen ligand was coordinated with Ti(O(iPr)4 and further treated with H2O, giving PN427A10-modified chiral salen TiIV complex. Excess Ti(O(iPr)4 was hydrolyzed into TiO2 and then was removed by filtration, affording the thermo/photo-responsive chiral salen TiIV catalyst of PN427A10-C (where 427 and 10 represented the repeated units number of NIPAAm and azobenzene in copolymer, which were determined by 1H NMR spectrum, as shown in ESI†).

Unlike traditional chiral ([R,R]-salen)TiIV(O(iPr)4) complex10 (denoted as neat complex, as shown in Chart 1) that was completely insoluble in water, the obtained PN427A10-C presented temperature-controlled water-solubility with the LCST of 26 °C. The LCST which was approximate to room temperature (25 °C) made PN427A10-C self-assemble at room temperature and separate also at mild temperature (slightly higher than room temperature) in the aqueous asymmetric sulfoxidation. Actually, to regulate the LCST close to room temperature, various rations of NIPAAm to azobenzene blocks have been modulated.
in the chiral salen TiIV-containing amphiphiles. The detail synthesis and identification of the controlled copolymers were available in the ESL†

Characterization of samples

LCST determination. Thermo-responsive behavior of PN427A10-C was investigated by monitoring the optical transmittance of typical PN427A10-C solution at 440 nm using UV-vis spectrophotometry (Fig. 1). Obviously, PN427A10-C was well soluble in water, giving clear aqueous solutions at temperature below 26 °C (Fig. 1A), although neat complex was practically insoluble in water. When the local temperature was raised to 26 °C, the aqueous solution became turbid, and transmittance decreased dramatically (Fig. 1A). It suggested a hydrophobic state of PN427A10-C at this temperature range. Therefore, the LCST of PN427A10-C was determined as ca. 26 °C. We noticed that the temperature was much lower than LCST of pure PNIPAAm microgel (32 °C). This difference confirmed the successful incorporation of hydrophobic azobenzene block and Ti(salen) unit into PNIPAAm, which changed the hydrophilicity-hydrophobicity balance in copolymer, and thus lower the LCST. It was the combined hydrophobic block that made PN427A10-C amphiphilic and ensured the self-assembly of the PN427A10-C in water. By continuous cooling to below 26 °C, the PN427A10-C aqueous solution reverted to the initial clear state, suggesting the returned amphiphilic state of PN427A10-C. Significantly, the water-solubility switch could be reversibly repeated for several times by controlling local temperature (Fig. 1B). The salient feature allowed for catalysis and separation of PN427A10-C in aqueous system in a mild temperature-controllable way.

UV-vis. Apart from thermo-responsivity, PN427A10-C also exhibited UV stimuli-responsive behavior due to the presence of photosensitive azobenzene moiety. The photoresponsive structural changes in PN427A10-C were then evaluated through spectral studies. The change in UV-vis absorption spectra of PN427A10-C upon UV irradiation (365 nm) were shown in Fig. 2. Before UV irradiation, a strong absorption band at 348 nm was observed which was ascribed to the π-π* transition of trans-azo (Fig. 2A). The absorption band gradually decreased with UV irradiation, and showed an obvious blue shift to 334 nm. Concomitantly, a new peak ascribed to n-π* band of cis-azo appeared at around 443 nm, and gradually increased with prolonged irradiation time (Fig. 2A). The observation suggested the progressive isomerization of azobenzene from tans to cis upon UV irradiation. After 220 s of UV light exposure, a photo-stationary state enriched by cis isomer was reached, and longer irradiation time caused no change in the UV-vis spectrum (Fig. 2A). The trans-azo could be obtained again when the irradiated sample was then kept in dark for 72 h (Fig. 2A). It indicated reversible photoisomerization of the azobenzene in PN427A10-C between the trans- and cis-forms. Notably, the trans-cis photoisomerization of azobenzene could be repeated many times without fatigue and decomposition of the component (Fig. 2B).

1H NMR. Photosensitivity of PN427A10-C was also investigated in detail by 1H NMR spectroscopy carried out in DMSO-d6. Dark-adapted sample was irradiated directly in the NMR tubes, by placing it 4 cm below 4 W 365 nm UV-lamp. After irradiation, the tube was put imminently into the NMR magnet, and the spectra were taken. As shown in 1H NMR spectra (Fig. 3A), discernible aromatic proton signals associated with azobenzene group underwent obvious changes upon UV irradiation. Before UV treatment, PN427A10-C exhibited only the proton signals in the 7.90–7.79 ppm range in 1H NMR spectrum, which was assigned as the 6- and 6'-position protons of trans-azo group (Fig. 3A(a)). Irradiation of UV light on the PN427A10-C solution induced a characteristic upfield shift of the typical signals (Fig. 3A(b–e)). Since overlapped protons in the bent cis-azo were shown at higher field than normal aromatic protons in the 1H NMR spectra owing to the shielding effect of the overlapping benzene ring, the observed upfield shift was attributed to photoisomerization of trans-azo in PN427A10-C to the cis-isomer which was overlapped at the 6- and 6'-positions. The trans to cis isomerization also reduced the intramolecular distance.

---

Fig. 1 Transmittance curves of the PN427A10-C aqueous solutions (concentration: 0.8 mg mL⁻¹, (A)), and optical transmittance at 440 nm of PN427A10-C solution observed upon several cycles under heating at 32 °C and then cooling to 25 °C (B).

Fig. 2 UV-vis spectra of PN427A10-C aqueous solution (concentration: 0.5 mg mL⁻¹) upon UV irradiation (365 nm) for different times (A), and optical absorbance at 443 nm of PN427A10-C aqueous solution observed upon several cycles under irradiation at 365 nm for 140 s and keeping in dark for 72 h (B).
between aromatic rings of azobenzene and slowed the rotation around C–N bonds, leading to better separation of the proton signals. Of course, multiple upfield signals at 6.75, 6.80, and 6.84 ppm progressively appeared when PN427A10-C was irradiated by UV light (Fig. 3A(b–e)). The composition of cis-isomer increased with the irradiation of UV light and reached the photostationary state after irradiation for 10 min (Fig. 3A(e)). Then, the 1H NMR spectra could revert to the initial state, after the UV-treated PN427A10-C was held in dark for 72 h (Fig. 3(f)). It demonstrated the reversible trans-cis photoisomerization of azobenzene moiety in PN427A10-C.

Interestingly, dark-adapted PN427A10-C in DMSO-d6 and D2O gave different 1H NMR spectra, as shown in Fig. 3B. 1H NMR spectrum of PN427A10-C in DMSO-d6 exhibited the distinct H signals of PNIPAAm moiety (δ = 3.84 ppm, O=C NhCH(CH3)2), azobenzene group (δ = 7.84 ppm, N=N–Ph–H), and Ti(salen) unit (δ = 1.24, cyclohexyl–H). It indicated the presence of hydrophilic PNIPAAm block, hydrophobic azobenzene block, and catalytically active Ti(salen) unit in PN427A10-C. Whereas, the H signals associated with azobenzene and Ti(salen) moieties almost disappeared when 1H NMR spectrum was carried out in D2O. The difference gave an evidence for the effective shielding of azobenzene and Ti(salen) groups from the aqueous environment upon self-assembly of PN427A10-C in water. Hydrophobic shielding of active site made the PN427A10-C an efficient enzyme-mimetic metalloelimicelle for asymmetric catalysis in water.

CMC determination. CMC determination provided strong evidence for the self-assembly behaviors of PN427A10-C, since amphiphiles would self-assemble in water when the concentration of solutions were above the CMC value. Surface tension measurements over a wide range of concentrations were used to determine the CMC value of PN427A10-C. Fig. 4 showed the plots of surface tension as a function of logarithm of concentration for PN427A10-C at dark-adapted state or under UV irradiation in water at 25 °C. Clearly, the surface tension decreased dramatically as the concentration of catalyst increased, and then it didn’t change substantially as a function of concentration of catalyst. The inflection point at characteristic concentration gave the information on CMC value of corresponding sample. The CMC value of PN427A10-C at dark-adapted state was thus determined to be 0.196 mmol L⁻¹ (Fig. 4A). Notably, the CMC value slightly increased to 0.210 mmol L⁻¹ when the dark-adapted PN427A10-C aqueous solution was exposed to UV irradiation for 5 min (Fig. 4B). Photoisomerization of azobenzene from trans-form to more hydrophilic cis-form should account for the increased CMC value. The results suggested the UV-controlled self-assembly behavior of PN427A10-C.

TEM. TEM images gave direct information of the self-assembly of PN427A10-C in water, as well as the morphological change induced by UV irradiation (Fig. 5). As expected, driven by hydrophobic interaction and the π–π stacking of azobenzene block, PN427A10-C self-assembled in water, forming metalmonicelles in a nanometer scale. Light-induced changes in azobenzene conformation adjusted the hydrophilic–hydrophobic balance of PN427A10-C. As a result, morphology and/or size of the metalmonicelles were controlled by UV irradiation. In the absence of UV irradiation, dark-adapted PN427A10-C self-assembled into spherical nanoparticulate (diameter of ca. 2 nm) in water exposing the hydrophilic NIPAAm to water, while the hydrophobic azobenzene and Ti(salen) units packed together to form a hydrophobic core (Fig. 5a). The nanoparticles presented a micelle to vesicle transition behavior upon UV treatment (Fig. 5b–d). Vesicles were observed when the sample was exposed to UV light for 10 s (Fig. 5b). The morphological transition accomplished after UV irradiation for 30 s, giving almost spherical nanoparticles (Fig. 5c).
uniform vesicles with size of ca. 6 nm (Fig. 5c). UV-induced isomerization of azo-moiety from trans- to cis-form was responsible for this morphological transition due to the differences in geometry and polarity between the two isomers. As we all know, the bend cis-azo occupied a larger volume than the rod-like trans-form.\textsuperscript{14,15,17} This implied that the UV-induced isomerization of azo-moiety increased the steric hindrance between azo-molecule in the hydrophobic core, which weakened their π-π stacking interaction. Furthermore, hydrophobicity of azo-molecule also decreased when trans-form were transformed into cis-form under UV light.\textsuperscript{23} The reduced π-π stacking and hydrophobic interactions made the azobenzene groups have no ability to accumulate tightly in the vesicular membrane, which brought a loose stacking formation in the vesicular membrane, or even disrupted the bilayer of vesicles. In addition, the surface area of vesicles should expand as a result of the transition from tight to loose packing, leading to an increase in instantaneous surface free energy. Therefore, fusion was the most likely pathway for the vesicles to become stable and reduce their surface free energy. Furthermore, fusion proceeded through a highly bent stalk intermediate, which was formed when hydrophobic tails from two apposing membranes came into contact via a fluctuation and made a hydrophobic bridge between them.\textsuperscript{23} The formation of the stalk structure required overcoming the free energy barriers. In fact, the change from tight to loose packing could increase the entropy without adversely affecting the enthalpy. It thus lowered the free energy barriers, which benefited the fusion process.\textsuperscript{23} In other words, the defects in loose packing state with more structural flexibility and plasticity may facilitate the restructuring of the PN\texttextsubscript{427}A\texttextsubscript{10}-C bilayer in the fusion process. Notably, the regions of defects were not large enough to cause the rupture of individual vesicle, since the rupture would overcome the entanglement of polymer chains and increase the surface free energy. The disruption extent of membranes gradually increased with continuous irradiation. When the vesicles with large disruption areas appeared, rupture of vesicular membrane took place. Subsequently, the disintegrated fragments rearranged to a majority of small vesicles by virtue of the hydrophobic interaction. Indeed, after the sample was irradiated for 60 s, those larger vesicles with damages and defects severely ruptured until almost complete disintegration occurred, and then rearranged to form a large number of very small vesicles (Fig. 5g vs. f). Similar observations of the photo-induced process including fusion, disintegration and rearrangement have also been reported in the literature.\textsuperscript{14} Upon keeping the UV-treated PN\texttextsubscript{427}A\texttextsubscript{10}-C in dark for 72 h, spherical nanoparticlar emerged again with a size close to 2.0 nm (Fig. 5h). Such morphological changes indicated the responsiveness of the metallomicelles towards UV light, which has the potential to adjust catalyst concentration and/or accessibility in real-time, allowing for fine control of the asymmetric sulfoxidation in water.

DLS. Size and morphological changes of PN\texttextsubscript{427}A\texttextsubscript{10}-C nanoassemblies under the influence of UV irradiation were also investigated by DLS. The hydrodynamic diameter and size distribution under different irradiation conditions were shown in Fig. 6. Before UV irradiation, PN\texttextsubscript{427}A\texttextsubscript{10}-C aqueous solution showed the aggregate with hydrodynamic diameter ($D_h$) of ca. 23.5 nm (polydispersity indexes, PDI = 0.143). When the PN\texttextsubscript{427}A\texttextsubscript{10}-C aqueous solution was exposed to UV light for 30 s, the size of the metallomicelles increased to 44.1 nm (PDI = 0.164). Great change in the metallomicelle size reflected a morphological transformation from micelle to vesicle, as confirmed by TEM. The $D_h$ increased continually to 58.3 nm (PDI = 0.179) when the UV irradiation time was prolonged to 60 s, due to photo-induced fusion of vesicles during the irradiation. After UV treatment for 90 s, the size of PN\texttextsubscript{427}A\texttextsubscript{10}-C metallomicelle decreased to 32.7 nm (PDI = 0.236) which indicated a disintegration and rearrangement of the larger vesicle. Relatively higher PDI value (0.236) was probably due to the relative inhomogeneity of rearranged vesicle.\textsuperscript{23} These observations were in complete agreement with the results obtained in TEM images.

**Catalytic performances**

Encouraged by the photo-induced change in morphology of PN\texttextsubscript{427}A\texttextsubscript{10}-C, the self-assembled Ti(salen)-containing metallomicelles was employed as the photo-sensitive bio-nanoreactor for controlled catalysis of asymmetric sulfoxidation in water. Phenyl methyl sulfide was used as a substrate to investigate the

![Fig. 6 Size distribution of self-assembled PN427A10-C in water at a concentration of 0.5 mg mL\textsuperscript{-1} under different UV irradiation time.](image-url)
photo-mediated catalytic performance of PN427A10-C. Before reaction, dark-adapted PN427A10-C in which all the azobenzene chromophores were in trans-state was exposed to UV light ($\lambda = 365$ nm) for a certain time, and then wrapped with aluminum foil to avoid the disturbance of natural light. The results are presented in Table 1. Traditional chiral salen TiIV complex (denoted as neat complex, Chart 1) was also employed for comparison.

As expected, PN427A10-C-based metallomicelles significantly accelerated the asymmetric oxidation of methyl aryl sulfides in water using H$_2$O$_2$ as oxygen source, giving high activity and remarkable selectivity (in terms of chemo- and enantioselectivity) (Table 1, entries 1–10). Only 0.1 mol% of PN427A10-C was sufficient for giving almost quantitative yield (>99%) of phenyl methyl sulfoxide with outstanding chiral induction (99%) when catalyst was treated with UV irradiation for 30, 60, or 90 s (Table 1, entries 4, 7, and 10). In contrast, extremely low activity (8%) with disappointing chemoselectivity (86%) and ee value (83%) was obtained under identical conditions when the reaction was catalyzed by neat complex (Table 1, entry 11). The results demonstrated the advantages of metallomicellar catalytic approach over self-assembled PN427A10-C. The formed metallomicelles not only showed good water-solubility, but also possessed a hydrophobic compartmentalized structure which allowed effectively shielding active sites from aqueous environment, reminiscent of enzyme.$^{21}$ Dense chiral salen TiIV complexes confined in the hydrophobic domain may enforce a cooperative reaction pathway favourable for the asymmetric sulfoxidation.$^{20,22}$ Substrates were also effectively sequestered by the hydrophobic compartment from the surrounding aqueous environment, creating a highly concentrated environment for efficient catalysis. Furthermore, synergistic effects between the metal-catalyzed center and the hydrophobic microenvironment in the metallomicelle led to high selectivity.$^{21}$

Photo-responsive behavior of the metallomicelles made catalytic efficiency of PN427A10-C sensitive to UV irradiation. Indeed, the catalytic activity of PN427A10-C was adjusted by UV irradiation in the aqueous asymmetric sulfoxidation. Before UV treatment, dark-adapted PN427A10-C gave 82% conversion of phenyl methyl sulfoxide in water within 75 min (Table 1, entry 1). UV irradiation mediated the catalytic performance of PN427A10-C in the aqueous asymmetric sulfoxidation (Table 1, entries 1–10). In particular, almost quantitative yield (>99%) of (R)-phenyl methyl sulfoxide was obtained when the dark-adapted PN427A10-C was exposed to UV light for 30 s (Table 1, entry 4). Enhanced activity should be related to the micelle to vesicle transition behavior of PN427A10-C upon UV treatment, as shown in TEM images. Despite both confined catalysis, vesicles represented bubble-like structures in which a water-containing interior was enclosed by a double-layer membrane. The bilayer membrane was a more conducive structure for sequestering substrates from the surrounding aqueous environment, creating a highly concentrated environment favorable for efficient sulfoxidation.$^{23}$ Varied UV irradiation time resulted in the variation of catalytic efficiency of PN427A10-C (Table 1, entries 5–10). Quantitative yield of (R)-phenyl methyl sulfoxide was also observed when PN427A10-C was treated by UV irradiation for 60 or 90 s.

$^a$Catalyst (0.1 mol% of substrate, based on titanium content), substrate (1.0 mmol), H$_2$O$_2$ (30 wt%, 1.2 mmol, slowly added within 15 min), H$_2$O (2.0 mL), 25 °C. $^b$Determined by GC. $^c$Chemoselectivity to sulfoxide (determined by GC). $^d$Determined by HPLC (Daicel Chiralpak AD column).
Various activities should be related to the photo-induced change in morphology of the metallomicelles. During the irradiation of UV light, the vesicles underwent photo-provoked disruption, fusion, disintegration and rearrangement in water. Relatively integrated double-layer membrane structure of the vesicles was observed when PN427A10-C was treated with UV light for 60 or 90 s, which was favourable for the metallomicellar catalysis. The UV-responsive catalytic efficiency of PN427A10-C made controlled catalysis of asymmetric sulfoxidation in water come true.

Kinetics was used to further investigate the advantages of the metallomicellar catalysis approach in aqueous reaction, as well as the photo-controlled catalytic performance of PN427A10-C-based metallamicelle. Corresponding kinetic curves and rate curves of asymmetric sulfoxidation of methyl phenyl sulfide over PN427A10-C in water (after 60 s of UV irradiation, after 40 s of UV irradiation, and at dark-adapted state) were shown in Fig. 7. Obviously, gradient increase in conversion of sulfide was observed over PN427A10-C either at dark-adapted state or upon UV treatment, when asymmetric sulfoxidations were performed in water (Fig. 7a-c). The corresponding rate constant ($k_{obs}$) initially rose rapidly due to the increasing concentration of substrate in hydrophobic microenvironment, went through a maximum, and then drastically decreased due to a dilution effect (Fig. 7a-c). The featured kinetics demonstrated confined catalysis of asymmetric sulfoxidation in water over PN427A10-C. To evaluate the advantages of metallamicelle, we carried out the reaction with dark-adapted PN427A10-C in ethanol, a solvent in which PN427A10-C, sulfide and $H_2O_2$ could be well dissolved. As expected, at the same catalyst concentration, dark-adapted PN427A10-C in ethanol was less efficient than that in water, although the ethanol-based system was homogeneous (Fig. 7d-c). Logically, in ethanol, PN427A10-C may gather together just via π–π stacking of azobenzene species from neighbouring catalyst, rather than packing to form the confined hydrophobic pocket. It thus couldn’t sequester organic substrate from surrounding environment through hydrophobic effect. Low local concentration of substrate in the ethanol system resulted in the unsatisfied activity. Interestingly, despite also homogeneous system, traditional neat complex in ethanol was far less efficient than PN427A10-C under identical conditions (Fig. 7e vs. d). Extremely low $k_{obs}$ value was observed over the traditional neat complex (Fig. 7b-e). It was reasonable that traditional neat complex without azobenzene moiety could not gather together in ethanol system to achieve concentrated catalytic sites and organic substrate. Low local concentration of catalytic species and sulfides were insufficient for the efficient sulfoxidation. The results were consistent with our hypothesis that the high local concentrations of catalytic species and substrate were crucial for this system to be active, and this was only achieved in the metallomicellar system in water. Notably, despite all metallomicellar catalysis, the $k_{obs}$ over PN427A10-C varied with the UV irradiation time, and highest efficiency was observed when PN427A10-C was treated with UV light for 60 s (Fig. 7a). The observations did agree with the ability to photo-modulate the activity of PN427A10-C in asymmetric sulfoxidation in water.

The UV-responsive catalytic efficiency over PN427A10-C was also noticeable for other aryl methyl sulfides, such as ethyl phenyl sulfide, methyl $p$-methoxyphenyl sulfide, and methyl o-methoxyphenyl sulfide. PN427A10-C after 60 s of UV irradiation always gave high activity than the dark-adapted PN427A10-C in corresponding sulfoxidations (Table 1, entry 13 vs. 12, entry 16 vs. 15, entry 19 vs. 18). All the aryl methyl sulfides get quantitatively oxidized to the corresponding sulfoxides with excellent chemo- (91–99%) and enantioselectivity (97–99%) within 105 min in water with the employment of UV-treated PN427A10-C (Table 1, entries 13, 16, and 19). Especially, almost quantitative chiral induction to (R)-sulfide (~99%) was observed for the methyl o-methoxyphenyl sulfide over the PN427A10-C after 60 s of UV irradiation (Table 1, entry 16). The results suggested the universality of PN427A10-C in green asymmetric sulfoxidation. Traditional neat complex was also inactive in the aqueous sulfoxidations systems due to water-incompatibility (Table 1, entries 14, 17, and 20).

Apart from photo-responsive catalytic activity, PN427A10-C also exhibited the reversibility of thermal-driven water-
solubility switching, as shown in Fig. 1. The salient features allowed for the facile recovery of PN_{427:A10}^\circ C from the aqueous phase by thermo-controlled separation. Especially, the LCST close to room temperature made the recovery of catalyst for reuse under mild local temperature (at 32 °C). Fig. 8 showed the reusability of PN_{427:A10}^\circ C after 60 s of UV treatment or in dark-adapted state in asymmetric oxidation of methyl phenyl sulfoxide in water.

To our delight, the catalyst either at dark-adapted state or upon UV treatment could be reused up to seven times without significant loss in activity and selectivity. Leaching test of catalyst revealed negligible leaching loss of titanium species (less than 0.1 ppm by ICP) to reaction medium during the oxidation. Chemical analysis of the recovered PN_{427:A10}^\circ C gave the titanium content (0.0172 mmol g^{-1}) almost identical to that of the fresh one (0.018 mmol g^{-1}). Furthermore, oxidative decomposition of PN_{427:A10}^\circ C, a main reason for the deactivation of chiral salen Ti^IV catalyst in H_2O_2-based oxidation, also did not occur during the reaction. The excellent stability of catalyst should arise from the shielding of the chiral salen Ti^IV complex in a hydrophobic pocket, which protected the catalytic site from oxidative decomposition by excluding excess H_2O_2 from the hydrophobic compartment.

Conclusions

In conclusion, controllable metallomicellar catalysis of aqueous asymmetric sulfoxidation has been realized by using photo-responsive self-assembled metallomicelle which contained azobenzene and chiral salen Ti^IV complexes in the hydrophobic compartment. Catalytic activity of the metallomicelle could be precisely controlled by UV irradiation time, due to the UV-induced change in morphology which adjusted catalyst concentration and/or accessibility in real-time. Furthermore, the catalysts could be facilely recovered from the aqueous system for efficient reuse by adjusting the local temperature. The photo-controlled catalytic efficiency, as well as outstanding reusability, made the metallomicelle highly promising for controllable catalysis of various organic reactions in water. And also, the responsive self-assembly approach inspired researchers to develop other controllable metallomicellar catalysis system for a much wider range of application.

Experimental section

Materials and reagents

Tetra-isopropyl titanate, aminoazobenzene and methyl aryl sulfides were obtained by J&K. N,N-Azobis(isobutyronitrile) (AIBN), NIPAAm, 2-aminoethanethiol hydrochloride, and l(+)- tartaric acid were purchased from Acros. 2-tert-Butyl phenol was purchased from Alfa Aesar. Other commercially available chemicals were laboratory grade reagents from local suppliers. All solvents were purified by standard procedures. NIPAAm was purified by recrystallization from n-hexane and dried in vacuo before use.

Methods

UV-vis spectroscopy was carried out on a UV-vis Agilent 8453 spectrophotometer. Molecular weight of the synthesized copolymers were obtained by gel permeation chromatography (GPC) on an Alliance Instrument (Alltech, America) equipped with an Alltech ELSD 800 detector. NMR spectrum of samples was recorded on a BRUKER AVANCE-500 spectrometer with TMS as an internal standard. The measurements were repeated for at least three times to ensure good reproducibility. The critical micellization concentration (CMC) was investigated using the surface tension method. The surface tension of an aqueous solution of catalyst was measured as a function of catalyst concentration (10 × 10^{-3} to 1.0 mmol L^{-1}) on a Krüss K12 tensiometer using the Wilhelmy plate method at 25 °C. The surface tension vs. catalyst concentration plot gave information on the CMC. Morphologies of the self-assembled aggregates were observed by TEM on a Microscope JEM-2100F at an accelerating voltage of 200 kV. Samples were prepared by depositing aqueous solution (0.5 mg mL^{-1}) onto a carbon-coated copper grid, followed by removal of excess solution by blotting the grid with filter paper. The samples were dried for 72 h at room temperature in a desiccator containing dried silica gel. After that, the samples were negatively stained by phosphotungstic acid and dried for another 72 h before examination. Dynamic light scattering (DLS) was performed using a MS2000 Laser Particle Size Analyzer (Malvern, UK). The sample solutions for measurements were prepared for concentrations of 0.5 mg mL^{-1} followed by filtering through a 0.45 lm disposable polyamide (PA) membrane to free it from dust particles. Light transmittance was fixed at 633 nm with the scattering angle of 90°. The mean diameters of self-assemblies were obtained from the number distribution curves produced by the particle analyzer. The titanium content in samples was determined by inductively coupled plasma mass spectrometry (ICP-MS) on a NexION 30X analyzer (Perkin-Elmer Corp.). Optical rotation of samples was measured in dichloromethane on a WZZ-2A Automatic Polarimeter. The dark-adapted PN_{427:A10}^\circ C was obtained by the irradiation of visible light (λ = 410 nm) for 30 min, and then being kept in the dark for 72 h to ensure that all the azobenzene chromophores were in trans-state.

Preparation of PN_{427:A10}^\circ C

Synthesis of N-azo-acrylamide. Aminoazobenzene (3.0 mmol, 0.592 g), triethylamine (3.0 mmol, 0.303 g) and benzenediol (0.1 mmol, 0.011 g) were dissolved in 10 mL mixed solvents of acetonitrile and dichloromethane (1:1, v/v) at room temperature. Acryloyl chloride (4.5 mmol, 0.410 g) in acetonitrile (5 mL) was then dropwise added into the solution. The mixture was stirred at 55 °C for 4 h, and the amidation progress was monitored by thin-layer chromatography. After cooling to room temperature, the reaction mixture was filtered through a 0.2 μm PTFE filter. The orange residue was washed with water and purified by recrystallization in ethanol to get N-azo-acrylamide. FT-IR (KBr): \( \gamma_{\text{max}} \text{cm}^{-1} \) 3280, 3199, 3134, 3068, 1670, 1600, 1560. \(^{1}\)H NMR (CDCl_3, 500 MHz) δ (ppm): 7.94–7.89
(s, 4H, N=N–Ph–H), 7.76 (s, 2H, O=C–NH–Ph–H), 7.52–7.44 (s, 3H, aromatic), 6.50–5.81 (s, 3H, O=C–CH–CH=CH3).

**Synthesis of PN427A10.** Monomers of NIPAAm (24.5 mmol, 2.774 g) and N-azo-acrylamide (0.49 mmol, 0.123 g) were dissolved in THF in a Schlenk tube. AIBN (0.125 mmol, 0.021 g) and 2-aminoethanethiol hydrochloride (0.25 mmol, 0.028 g) were then added into the solution. The reaction mixture was degassed by bubbling with nitrogen gas at room temperature for 30 min. Polymerization was carried out at 60 °C for 24 h with nitrogen protection. After being cooled to room temperature, the mixture was treated with solid KOH to liberate the terminal amino group. The obtained solution was concentrated under vacuum. Crude product was purified by repeated precipitating from diethyl ether and followed from THF to remove unreacted monomers. After being dried under vacuum for 6 h at 40 °C, the copolymer of poly(NIPAAm-co-azo) was obtained as yellow powder, which was denoted as PN427A10 (where the repeated units number of NIPAAm and azobenzene in copolymer was 427 and 10, which were determined by 1H NMR spectrum).<ref>1H NMR (500 MHz, DMSO-d6) δ (ppm): 7.84 (m, 40H, -N=N–Ph–H), 7.57–7.56 (m, 20H, O=C–NH–Ph–H), 7.52 (m, 30H, N=N–Ph–H), 7.30–7.19 (m, 437H, O=C–NH–CH and O=C–NH–Ph), 3.83 (m, 427H, CH3–CH–CH2 in NIPAAm), 2.93 (m, 2H, S–CH2–CH2–NH2), 2.63 (m, 2H, S–CH2–CH2–NH2), 2.36 (m, 2H, S–CH2–CH2–NH2), 1.96 (m, 437H, CH3–CH– in NIPAAm and N-azo-acrylamide), 1.44 (m, 847H, CH3–CH–CH2– in NIPAAm and N-azo-acrylamide), 1.03 (s, 2562H, CH3–CH–CH2–), The Mn of PN427A10 is about 30 825 g mol⁻¹ based on GPC.

**Synthesis of PN427A10-C.** The obtained PN427A10 (0.18 mmol, 5.54 g), (R,R)-N-(3,5-di-tert-butylsalicylidene)-N′-(3-tert-butyl-5-chloromethyl-salicylidene)-1,2-cyclohexanediamine (0.25 mmol, 0.137 g) and triethylamine (0.2 mmol, 0.02 g) were mixed in dry toluene (30 mL) under room temperature. The mixture was refluxed for 48 h under nitrogen protection. After removal of solvent, the residue was dissolved in THF to remove the formed triethylamine hydrochloride through filtration. Filtrate was concentrated in vacuo, and was then treated with Ti(OiPr)4 (0.25 mmol, 0.07 g) in dichloromethane (30 mL) for 12 h at room temperature. The mixture was concentrated under vacuum. Crude product was purified by repeatedly precipitating from tetrahydrofuran using diethyl ether as precipitant. The resulting orange solid was dissolved in chloroform (20 mL), and the mixture was treated with water (2 mL) to remove any traces of TiO2 by filtration. Filtrate was concentrated in vacuum and further dried in vacuum at 40 °C overnight, giving orange powder of PN427A10-C modified chiral salen Ti IV catalyst, denoted as PN427A10-C. 1H NMR (500 MHz, DMSO-d6) δ (ppm): 9.97 (s, 2H, Ph–HC=N–), 7.90 (s, 2H, Ph–H in Ti[salen]), 7.84 (m, 42H, N=N–Ph–H), 7.60–7.56 (m, 20H, O=C–NH–Ph–H), 7.52 (m, 30H, N=N–Ph–H), 7.29–7.20 (m, 437H, O=C–NH–CH and O=C–NH–Ph), 3.83 (m, 427H, CH3–CH–CH2 in NIPAAm), 3.17–3.16 (m, 2H, cyclohexyl-H), 2.92–2.90 (m, 2H, NH–CH2–Ti[salen]), 2.63 (m, 2H, S–CH2–CH2–NH), 2.36 (m, 2H, S–CH2–CH2–NH), 2.17 (m, 2H, CH3–CH–CH3 of 1PrO in Ti[salen]), 1.95 (m, 437H, CH3–CH– in NIPAAm and N-azo-acrylamide), 1.44 (s, 847H, –CH2–CH2– in NIPAAm and N-azo-acrylamide), 1.22 (m, 8H, cyclohexyl-H), 1.17 (m, 39H, –CH2 of t-Bu and 1PrO in Ti[salen]), 1.03 (s, 2562H, CH3–CH–CH2–), [α]D20 = −16.0 (C = 0.005 g mL⁻¹ in CH2Cl2). Titanium content: 0.018 mmol g⁻¹. The LCST of PN427A10-C is 26 °C based on transmittance measurement.

**Catalyst testing.** Before reaction, PN427A10-C was irradiated by visible light (λ = 410 nm) for 30 min, and then kept in the dark for 72 h to ensure that all the azobenzene chromophores were in trans-state. The dark-adapted PN427A10-C (0.1 mol% substrate, based on the titanium content in catalyst) and methyl aryl sulfides (1.0 mmol) were added to H2O (2 mL) under stirring at 25 °C. The mixture was exposed to UV light (λ = 365 nm) for a certain time, and then wrapped with aluminum foil. H2O2 (30 wt%, 1.2 mmol) was dropwise added into the solution within 15 min. The resulting mixture was stirred at room temperature until the reaction was judged to be complete based on GC analysis. Then, the reaction mixture was heated to 32 °C. Catalyst was recharged with fresh substrate and oxidant for the next catalytic cycle. The supernatants separated from reaction system were extracted with dichloromethane thrice. Combined organic phase was concentrated in vacuum. Further purification of the residue by chromatography on silica gel (petroleum ether/ethyl acetate, 1.5/1) afforded pure chiral sulfoxides. The products have been identified by 1H NMR and 13C NMR spectra. The conversion and chemoselectivity of chiral sulfoxides were measured by a 6890N gas chromatograph (Agilent Co.) equipped with a capillary column (HP19091G-B213, 30 m × 0.32 mm × 0.25 μm) and a FID detector. Ee values of corresponding chiral sulfoxides were determined by HPLC analysis using the Daicel Chiralpak AD columns. Detailed NMR spectra and HPLC analysis for the chiral sulfoxides were available in ESI.†

**Methyl phenyl sulfoxide.** Chemoselectivity: 99% determined by GC, nitrogen was used as the carrier gas with a flow of 30 mL min⁻¹, the injector temperature and the detector temperature were 250 °C, the column temperature was programmed from 80 to 180 °C with 6 °C min⁻¹. t1/2 methyl phenyl sulfoxide = 6.9 min; ee value: 99% determined by HPLC ([i-PrOH/h-hexane = 5:5 (v/v)]; flow rate = 1.0 mL min⁻¹; 25 °C; λ = 254 nm; major enantiomer tR = 4.4 min, minor enantiomer tS = 5.2 min; 1H NMR (CDCl3, 500 MHz) δ (ppm): 2.49 (s, 3H, Me), 7.27–7.29 (m, 3H, ArH), 7.42–7.44 (m, 2H, ArH); 13C NMR (CDCl3, 125 MHz) δ (ppm): 43.1 (SCH3), 122.8, 128.6, 130.3, 144.9 (ArC).

**Ethyl phenyl sulfoxide.** Chemoselectivity: 91% determined by GC, nitrogen was used as the carrier gas with a flow of 30 mL min⁻¹, the injector temperature and the detector temperature were 250 °C, the column temperature was 180 °C, t1/2 ethyl phenyl sulfoxide = 2.5 min; ee value: 97%, determined by HPLC ([i-PrOH/h-hexane = 2:8 (v/v)]; flow rate = 1.0 mL min⁻¹; 25 °C; λ = 254 nm; major enantiomer tR = 6.4 min and minor enantiomer tS = 8.2 min; 1H NMR (CDCl3, 500 MHz) δ (ppm): 7.59–7.53 (m, 2H, ArH), 7.52–7.47 (m, 3H, ArH), 2.92–2.72 (m, 2H, –CH2–), 1.19–1.16 (m, 3H, Me); 13C NMR (CDCl3, 125 MHz) δ (ppm): 5.91 (CH3), 50.24 (SCH3), 124.13, 129.09, 130.88, 143.25 (ArC).
Methyl p-methoxyphenyl sulfoxide. Chemoselectivity: 92% determined by GC, nitrogen was used as the carrier gas with a flow of 30 mL min⁻¹, injector temperature and detector temperature were 250 °C, the column temperature was programmed from 80 to 180 °C with 6 °C min⁻¹. t_{methyl p-methoxyphenyl sulfoxide} = 11.7 min; ee value: 97%, determined by HPLC (i-PrOH/n-hexane = 4 : 6 (v/v)); flow rate = 1.0 mL min⁻¹; 25 °C; λ = 254 nm; major enantiomer t_R = 5.3 min and minor enantiomer t_S = 6.6 min; 1H NMR (CDCl₃, 500 MHz) δ (ppm): 7.60–7.57 (d, 2H, ArH), 7.03–7.01 (d, 2H, ArH), 3.84 (s, 3H, OCH₃), 2.69 (s, 3H, SCH₃); 13C NMR (CDCl₃, 125 MHz) δ (ppm): 43.9 (SCH₃), 55.5 (OCH₃), 114.8, 125.4, 136.6, 162.0 [ArC].

Methyl o-methoxyphenyl sulfoxide. Chemoselectivity: 99% nitrogen was used as the carrier gas with a flow of 30 mL min⁻¹, injector temperature and detector temperature were 250 °C, the column temperature was 180 °C. t_{methyl o-methoxyphenyl sulfoxide} = 9.8 min; ee value: 99% determined by HPLC (i-PrOH/n-hexane = 5 : 5 (v/v)); flow rate = 1.0 mL min⁻¹; 25 °C; λ = 254 nm; major enantiomer t_R = 4.8 min and minor enantiomer t_S = 5.1 min; 1H NMR (CDCl₃, 500 MHz) δ (ppm): 7.82–7.80 (m, 1H, ArH), 7.46–7.42 (m, 1H, ArH), 7.19–7.16 (m, 1H, ArH), 6.92–6.90 (m, 1H, ArH), 3.87 (s, 3H, OCH₃), 2.76 (s, 3H, SCH₃); 13C NMR (CDCl₃, 125 MHz) δ (ppm): 41.16 (SCH₃), 55.64 (OCH₃), 110.53, 121.65, 124.58, 131.89, 133.07, 154.76 [ArC].

Sulfoxidation reaction for kinetic measurement

Chiral salen Ti⁣IV catalyst (0.1 mol% of substrate, based on titanium ion content) was stirred with methyl phenyl sulfides (1.0 mmol) in solvent (2 mL) at 25 °C. H₂O₂ (30 wt%, 1.2 mmol) was then added into the stirred solution in one portion. To determine the rate of sulfoxidation, aliquots at an interval of 10 min were drawn from the reaction mixture, filtered through silica gel with ethyl acetate as an eluent and analyzed by GC.
