Pulsar-driven Jets in Supernovae, Gamma-Ray Bursts, and the Universe

Abstract

The bipolarity of Supernova 1987A can be understood through its very early light curve observed from the CTIO 0.4-m telescope and IUE FES, and following speckle observations of the ‘Mystery Spot’ by two groups. These indicate a highly directional beam/jet of light/particles, with initial collimation factors in excess of $10^5$ and velocities in excess of 0.95 c, involving up to $10^{-5}$ M⊙ interacting with circumstellar material. These can be produced by a model proposed in 1972, by Bolotovskii and Ginzburg, which employs pulsar emission from polarization currents induced/(modulated faster than c) beyond the pulsar light cylinder by the periodic electromagnetic field, (supraluminally induced polarization currents – SLIP). SLIP accounts for the disruption of progenitors in supernova explosions and their anomalous dimming at cosmological distances, jets from Sco X-1 and SS 433, the lack/presence of intermittent pulsations from the high/low luminosity low mass X-ray binaries, long/short gamma-ray bursts and predicts that their afterglows are the pulsed optical/near infrared emission associated with these pulsars. SLIP may also account for the TeV $e^+/e^-$ results from PAMELA and ATIC, the WMAP ‘Haze’/Fermi ‘Bubbles’, and the r-process. SLIP jets from SNe of the first stars may allow galaxies to form without dark matter, and explain the peculiar, non-gravitational motions observed from pairs of distant galaxies by GALEX.

Keywords: acceleration of particles, plasmas, gamma rays: bursts, pulsars: general, stars: neutron, supernovae: general, supernovae: individual (SN 1987A), ISM: jets and outflows, dark matter, cosmology: observations, distance scale, early universe

1. Introduction

Supernova 1987A has provided astronomers with a wealth of data, some of which has not even now, a quarter century after the event, been satisfactorily accounted for by any model. One of the most remarkable features in the early study of SN 1987A was the ‘Mystery Spot’, with a thermal energy of $10^{54}$ erg, observed 50 days after the core-collapse event [1-3], and separated from the SN photosphere ‘proper’ by 0.060 ± 0.008 arc s at day 38 (Fig. 1), with about 3% of this energy eventually radiated in the optical band. The possibility that the enormous energy implied for the Mystery Spot might somehow link it to gamma-ray bursts (GRBs) attracted little serious consideration at the time, or even since, beyond a very astute few [4-6]. The Mystery Spot was also observed at separations of 0.045±0.008 arc s on day 30, and 0.074±0.008 arc s on day 50, but always at an angle of 194°, consistent with the southern (and approaching) extension of the bipolarity [7]. The Mystery Spot offsets from SN 1987A imply a minimum projected separation of ~10 light-days ($t_d$).

There is a also wealth of photometric and spectroscopic data from even earlier stages of SN 1987A, in particular photometry data from the Cerro Tololo Inter-American Observatory (CTIO) 0.4-m telescope [8], and the Fine Error Sensor (FES) of the International Ultraviolet Explorer (IUE – [9]), and spectroscopic data from [10] and [11], among others. Short timescale structure ($\leq 1$ d) in this data, following finite delays (~10 d) after SN 1987A core-collapse, implies at least one beam of light and jet particles which were initially highly collimated ($>10^4$), interacting with circumstellar material.

GRBs, particularly long, soft GRBs (sGRBs), appear to be the most luminous events in the Universe, occurring at the SN rate of one per second (assuming a collimation factor near $10^5$) yet we still know very little about them (see, e.g., [12], and references therein). A few GRBs have been found to be associated with SNe [13-15]. Others however, mostly those with slightly harder spectra and lasting only ~1 second, (sGRBs), usually produce no lingering evidence at all, and only rarely the ‘afterglows’ observed for a large proportion of tGRBs, sometimes extending down to radio wavelengths. A large number of models have been put forth to explain GRBs, including neutron star-neutron star mergers for sGRBs, and exotic objects such as ‘collapsars’ [16] for tGRBs. Part of the physical motivation for these, and the nearly universal use of their usually severe degrees of collimation, is the enormous energy of up to $10^{54}$ erg implied for an isotropic source. Indeed the data from SN 1987A presented herein, when interpreted through the model discussed in detail within this work, support a beam/jet collimation factor $>10^4$ in producing its early light curve by interaction with more-or-less stationary circumstellar material, but in addition predicts that GRB afterglows, and by extension of the principles of supraluminal excitations, even GRBs themselves, may dim only as distance$^{-1}$ (see [43], and thus easily removes the requirement for such a high energy.

Specifically this work argues that polarization currents, in-
duced beyond the light cylinders of, and by the rotating magnetic fields from, newly-formed pulsars embedded within their stellar remnants ([17][18]) can account for the bipolarity of SN 1987A [19-21]. This model of emission from supraluminally induced polarization currents (SLIP) provides a mechanism for generating a pulsed beam, rotating on the surface of a cone whose half angle (and angle from the pulsar axis of rotation) is given by,

$$\theta_v = \arcsin c/v,$$

(1)

for astronomical distances. Here $c$ is the speed of light, and $v > c$ is the speed at which the polarization currents are updated, i.e., $v = \omega R$, where $\omega$ is the pulsar rotation frequency, in radians $s^{-1}$. $R > R_{LC}$ is the distance of the polarization current from the pulsar, projected onto the rotational equatorial plane, and $R_{LC}$ is the light cylinder radius ($\omega R_{LC} = c$).

Emission from circularly supraluminous polarization currents is initially focused as a single point, which moves around the equator of the light cylinder at the angular pulsar rate, but which eventually travels outward on the two cones defined by Eq. (1). When the emission is observed for the conal directions the pulse profile will consist of only a single, sharp peak, and will have an intensity that decays only with the first power of distance ([22][23] (see [34]).

This emission mechanism, and its unusual distance law, will operate at any radius beyond the light cylinder where sufficient plasma exists. In principle this would render pulsations nearly always visible from neutron stars surrounded by plasma. However, pulsations are almost never observed from neutron stars which are born inside of SNe with $M_{\odot}$ of material yet to eject, and those in the non-transient (and more luminous) Low Mass X-ray Binaries (LMXBs). What happens is that emissions from smaller annuli must push out through the densest material of the stellar core or circumpulsar accretia, while emissions from larger annuli, although encountering more material on the way to the equatorial light cylinder, also bypass much of the core material while traveling toward the poles. This results in a greater beam concentration near the rotational poles, and thus the solid angle for which pulsed emissions are observable from SNe and LMXBs is tiny, and are almost never expected to be seen (a SN Ic, however, is worth observing – see §5). In the case of SNe, the beam accelerates (and transmutes) matter from the stellar interior, which includes H, He, C, O, and heavier elements for massive, solitary progenitor stars.

In the rest of this paper, §2 includes a quantitative discussion of the SN 1987A early luminosity history and motivations for why a later, quasi-steady, less collimated, as well as a prompt, highly collimated, injection event, is also needed. Then §3 estimates the kinematics and a working geometry for the 1987A beam/jet and Mystery Spot, and we explore the implications of these on the process which gave rise to SN 1987A, and observations during the following years. Section §4 relates the SN 1987A beam/jet process to GRBs, germinates the idea that their afterglows are highly pulsed, and introduces the possibility that 1987A itself was the result of a merger of two electron degenerate stellar cores within a common envelope – double degenerate, or DD – while Section §5 relates the process to Type Ia/c SNe. Section §6 includes Subsections §6.1-§6.5 extend the discussion of the implications of the DD process to the formation and luminosities of Type Ib and II SNe, the relation of plasma available to the SLIP process and transient signals §6.2, Sco X-1 and other Low Mass X-ray Binaries (LMXBs – §6.1), historic SNe, pulse profiles, and SNR bipolarity §6.3. Subsection §6.6 discusses how SLIP explains why PSR J0537 is predominantly an X-ray, but not an optical pulsar. Subsection §6.7 discusses the high kinetic energy of the particles in the SN 1987A jet(s), and its possible relation to the positron excess, WMAP ‘Haze’, and Fermi ‘Bubbles’, followed by a discussion of the unique SS 433 jets in §6.8: pulsar-driven jets in the early Universe in §6.9, and pulsar ‘recycling’ in §6.10. Section §7 concludes, and a short SLIP primer follows in the Appendix.

2. The Early Luminosity History of SN 1987A

Table 1 gives an event history for SN 1987A and its progenitor system. An approximate geometry for SN 1987A and a Mystery Spot located within circumstellar material (in this case, polar ejecta), is given in Fig. 2 while the early luminosity histories of SN 1987A from CTIO, and the Fine Error Sensor (FES) of the IUE, which we can use to refine the parameters

---

1Because not all pulsars show the characteristically sharply peaked pulse profiles which indicate that they are observable because they obey the distance-law, some pulsars are indeed observed from an angle, $\theta \neq \theta_v$.

2No observation of any GRB afterglow has yet been made in high time resolution, but they are expected to be highly pulsed because of the associated inverted distance law (see [24]). However, the afterglows of GRBs 990510, 990712, and 020405 were measured to be 1.7%, 2.9-1.2%, and 10% linearly polarized [25-28], which could be a signature of pulsed emission. The prompt emission of GRB 041219 was also found to be highly, and variably linearly polarized by INTEGRAL [29], though we don’t expect such emission to be pulsed.
that this figure postulates as reflecting reality, are both plotted in Fig. 3.

Table 1: SN 1987A Event Log

| Time   | Event                                     |
|--------|-------------------------------------------|
| -20,000 years | Rings formed                          |
| ∼(-2,000?) years | Polar, or near-polar ejection       |
| 0 (= UT 1987, Feb. 23.316) | Core-collapse of SN 1987A          |
| 0<t<2 days   | UV flash from SN 1987A                |
| 2<t<4 days   | Emergence of luminous jet            |
| 4<t<7 days   | Cooling/spreading of jet             |
| 7.8 days     | UV flash hits polar ejecta            |
| 8.26 days    | Jet impacts polar ejecta (PE)         |
| 19.8 days    | Pulsations clear through PE           |
| 20.8 days    | Jet particles clear through PE        |
| 30 days      | ‘Mystery spot’ at 45 mas              |
| 38 days      | ‘Mystery spot’ at 60 mas              |
| 50 days      | ‘Mystery spot’ at 74 mas              |

Following the drop from the initial flash, the luminosity rises again to a maximum (‘A’ in Fig. 3 and Fig. 4 top) of magnitude 4.35 at day 3.0, roughly corresponding to 2.7×10^{41} erg s^{-1} and interpretable as a luminous jet emerging from cooler, outer layers which initially shrouded it. This declines to magnitude 4.48 around day 7.0 (‘B’, Fig. 4 middle), interpretable as free-free cooling, or the loss of the ability to cool, as the jet becomes more diffuse. The next observable event should be the scattering/reprocessing of the initial UV flash in the polar ejecta at day ~8, and indeed ‘C’ (Fig. 4 bottom) shows ~2×10^{39} erg s^{-1} in the optical for a day at day 7.8, and a decline consistent with the flash after that, indicating that no significant smearing over time had occurred in this interaction. The 8 day delay to, and the rapid decline of, this first event implies a collimation factor >10^4 for this part of the UV flash. This can be seen if we let δ represent the radius of the illuminated area in the polar ejecta, d as in Fig. 2 the distance from the SN to this area, the collimation factor, Υ for the beam can be expressed as:

\[ Υ = \frac{2π}{\sqrt{d^2 - δ^2}}; \]  

or,

\[ Υ = 10^4 \left( \frac{d}{10 η t - d} \right)^2 \left( \frac{δ}{0.25 η t - d} \right)^2. \]  

A linear ramp in luminosity, visible by day 9.8 (‘D’ in Fig. 3 and Fig. 5 top), indicates particles from the jet penetrating into the polar ejecta, with the fastest traveling at >0.8 c, and, because of the sudden rise, a particle collimation factor >10^4. Back-extrapolation of the three CTIO points just after day 8 intersects the day 7 minimum near day 8.26, which would indicate that particles exist in this jet with velocities up to 0.95 c, and even higher if the true minimum flux is lower than the points at magnitude 4.48 (1.6×10^{41} erg s^{-1}) near day 7.

The ramp continues until after day 20, when a decrement of ~5×10^{39} erg s^{-1} appears in both data sets just after day 20 (‘F’ in Fig. 3 and Fig. 5 bottom). The CTIO point just before the decrement can be used as a rough upper limit for the Mystery Spot luminosity, and corresponds to an excess above the minimum (near day 7.0) of 5×10^{40} erg s^{-1}, or magnitude 5.8, the same as that observed in H\alpha for the Mystery Spot at days 30,
38, and 50, about 23% of the total optical flux of $2.1 \times 10^{41}$ erg s$^{-1}$ at that time.

This decrement is preceded by a spike (‘E’ in Fig. 3, Fig. 5 middle, and Fig. 6 day 19.8) of up to $10^{40}$ erg s$^{-1}$ in the CTIO data, with the unusual colors of B, R, and I, in ascending order, very close to the B and I bands speculated for the 2.14 ms signature observed from SN 1987A [31, 32] with an H$\alpha$ enhancement. Spectra taken by [32] around March 15 (the ‘Bochum event’), [10] on March 14.820 (day 19.504), and [11] on UT 1987, March 15.08 (day 19.76), support these flux enhancements, including the H$\alpha$ (and a Ca II triplet, $\lambda$849.8, 854.2, 866.2 nm, as well). The timing of this event, one day prior to the decrement, suggests that it is due to a photon stream, stripped of its UV component by absorption (the CTIO U point at day 19.8 was low, consistent with this interpretation), scattering into other directions, including the line of sight to the Earth, by what might have been a clumpy end to the circumstellar material. Optical pulsations were not detected at this early epoch (R. N. Manchester, private communication 2007), because of the oblique view, and the dimensions of the beam ($\sim 1$ t-d).

For the geometry derived in [3] below, the one day delay implies at least the same maximum jet velocity (0.95 c), supporting this interpretation of a beam and jet penetrating extrastellar material, and giving us a rough isotropic lower limit estimate of the strength of the pulsations. Spectra taken just before day 5, showing an enhancement for wavelengths below 5000 Å, explain the discrepancy between the CTIO and FES points at that time (Fig. 5).

In spite of the coincidence between the end magnitude of the linear ramp and that of the Mystery Spot, the two are probably not the same effect, as the offset of the Mystery Spot from SN 1987A was only 0.045 arc s even 10 days later at day 30 (Fig. 7), a location barely beyond where the ramp began, as is shown below, and there is no sign of elongation toward SN 1987A proper in Fig. 1 of [3] or Fig. 2 of [2]. The Mystery Spot may develop as a plume within the polar ejecta, pushed by a less collimated, 0.5 c pulsar wind, perhaps not unlike that observed from the Crab pulsar [33], many days after the passage of the initial, very fast, very collimated component of the jet. A beam only 1 t-d across at ~10 t-d translates via Eq. (1) into plasma at ~20 $R_{LC}$.

It is unlikely that the early light curve is due to shallow penetration of a precessing jet into a varying entry point of the polar ejecta, because the high density required to limit jet penetration comes with a higher opacity which would make the linear ramp hard to produce in this, the inner boundary of the approaching axial feature. The requirement for a 0.5 c mean motion of the Mystery Spot between days 30 and 38, slowing to 0.35 c between days 38 and 50 (ostensibly due to swept up matter), would also be difficult to fulfill in these circumstances. On the other hand, the polar ejecta density can not be so low as to allow more than 1 t-d penetration by the enhanced UV flash, or the drop in luminosity from day 7.8 to day 8.8 would not be as big. If the jet penetration is deep, precession and/or changes in the plasma density beyond the pulsar light cylinder (Eq. 1), may make its initial track, within the polar ejecta, a helical cone, and this may assist the ~0.5 c wind in the creation of the plume which forms the Mystery Spot within three weeks of the initial jet penetration.

We will assume that the optical flux from the interaction between jet particles and the polar ejecta will not be significantly occulted in the ejecta itself in the direction to the Earth, otherwise again, the linear ramp would be difficult to produce. As we will find below that the axis of the SN 1987A bipolarity is ~30° from the normal to the ring planes, the reason remaining a mystery even today, this is not necessarily a given. Proceeding nevertheless: by scaling homologously inward a factor of 10 from the equatorial ring density of $10^6$ cm$^{-3}$, we arrive at a polar ejecta density estimate of $\sim 10^7$ cm$^{-3}$ – sufficient to stop the UV flash from penetrating >1 t-d.

Assuming a polar ejecta depth, D, of ~10 t-d, or 2.6×10$^{16}$ cm, gives a total column of $2.6 \times 10^{23}$ cm$^{-2}$, sufficient to hopelessly disperse any pulsed radio signature, though enough to warrant some concern about continued particle penetration. However, only a fraction of the protons in the jet will scatter through the entire depth of the polar ejecta (the slight concave downward departure from linearity most apparent in the CTIO data, between days 9 and 20, may reflect this loss, and/or the density in the polar ejecta may decrease with distance). In addition, we will find that the angle, $\theta$, from our line of sight to the SN 1987A beam/jet, will be large in the self-consistent solution, justifying our assumption of visibility for the luminous column within the polar ejecta between days 9 and 20.

3. The Geometry and Kinematics of the Beam/Jet

Using the constraints shown in Figs. 1 and 2, we can solve for the three geometric variables, d, D, and $\theta$, diagrammed in Fig. 3, and the maximum velocity of the particles in the jet, $\beta$. First the UV flash hits the beginning of the polar ejecta at day 7.8:

$$d(1 - \cos \theta) = c t_0 = 7.8 \ t_d,$$

where $d$ is the distance to the beginning of the polar ejecta, $\theta$ is the angle from the beam/jet/polar ejecta direction to the line of sight to the Earth, and $c$ is the speed of light.

From Fig. 3 we also have the jet particles well into the polar ejecta by day 9.8. Extrapolating the three CTIO points (just after day 8) backward per above, we have the fastest beam particles hitting the polar ejecta at day 8.26:

$$d(1/\beta - \cos \theta) = c t_1 = 8.26 \ t_d.$$

Next, we have the projected offset of 0.060 arc s for the Mystery Spot, measured at day 29.8 by [2] and refined by [3]. This is more difficult to pin down relative to its position radially through the polar ejecta, so we assume it’s some fraction, $\alpha$, of the way through the polar ejecta depth, $D$, and derive a self-consistent solution:

$$(d + \alpha D) \sin \theta = c t_2 = 17.3 \ t_d,$$

using 50 kpc for the distance to SN 1987A. Finally, we have the decrement in the light curve at day 20, shown in Fig. 3 which
we will interpret as the fastest ‘substantial’ bunch of particles in the jet breaking through the end of the polar ejecta:

\[(d + D)(1/\beta - \cos \theta) = c t_3 = 20 \ell t - d.\]  

(7)

Figure 4: The geometry of the 1987A glowing beam/jet, initially opaque shroud, and UV flash (which may have an enhanced beam of its own in the jet direction – here 75°, down and to the right). The maximum velocity of the jet/shroud is 0.95/0.55 c. The dashed line to the upper scale flags the center of the emerging jet at day 3.3 (top – A), and day 6 (middle – B), and the UV flash hitting the polar ejecta at day 7.8 (bottom – C).

Figure 5: (Top – D) The intense center (~1°) of the jet begins to produce light as it penetrates into the polar ejecta, producing the jump in luminosity at day 9.8. (Middle – E) Particles in the jet continue to impact the polar ejecta (mostly hidden), extending the ramp in luminosity visible in Fig. 3 near day 20 (left dashed line to the top scale). (Right dashed line) Light from the filtered UV flash scatters in clumpy polar ejecta near its outer boundary. (Bottom – F) The fastest jet particles have cleared the end of the polar ejecta.

The solution to Eqs. (4-7) gives a constant ratio for \(D\) to \(d\), independent of \(\alpha\):

\[d = D t_1/(t_3 - t_1), \text{ or } (d + D) = d t_3/t_1.\]  

(8)
while θ is given by:

\[ \theta = 2 \tan^{-1}\left[ \frac{f_0}{f_2} \left( \frac{f_3}{f_1} - 1 \right) + 1 \right]. \]  

(9)

The parameters, \(d\), \(D + d\), and θ are plotted against β in Fig. 8 for 0.3 \(\leq \alpha \leq 0.7\), along with the maximum \(D + d\) implied by the three measurements of the Mystery Spot angular separation at days 30, 38, and 50. Figure 8 shows that the polar ejecta, at the very least, must start by 14 \(tt-d\) or closer, and extend to 22 \(tt-d\) or farther, consistent with our early 10 \(tt-d\) estimates for \(d\) and \(D\), as is the high value of θ (65° < θ < 85°), which also means that the axis of bipolarity is \(\sim 30°\) from the normal to the ring planes [34].

Given the similar magnitudes of the early lightcurve and the Mystery Spot (and indeed, the two are just phases of the same jet phenomenon, the first more penetrating and the second more energy-injecting), the energetics of the jet producing the early light curve and these are the same as that posited for the Mystery Spot in [1], except that the early lightcurve phase is shorter. For an interval of \(10^6\) s, at \(5 \times 10^{40}\) erg \(s^{-1}\), the optical output, from reprocessing of X-rays resulting from the jet particles scattering with electrons, which then add to it through free-free or later synchrotron radiation, is \(5 \times 10^{46}\) erg. Since only a fraction of the particles scatter in the polar ejecta, the overall efficiency, in the conversion of kinetic energy into optical luminosity, could still be as low as Meikle et al.’s estimated 0.001, which gives \(5 \times 10^{40}\) erg of kinetic energy in the initial jet. For 0.9 c protons, each with 0.002 erg of kinetic energy, this would mean \(2.5 \times 10^{42}\) protons or \(2 \times 10^{35} M_\odot\) initially each jet. Without the now visible counterjet, the ‘kick’ velocity to the neutron star would only be 10 km s\(^{-1}\), thus such jets are unlikely to produce the 100s of km s\(^{-1}\) velocities seen in few other pulsars.

For a pulsar with an initial spin rate of 500 Hz this short phase alone would result in a drop of 10 Hz, corresponding to a mean spindown rate of \(10^{-5}\) Hz s\(^{-1}\), assuming a neutron star moment of inertia of \(5 \times 10^{41}\) g cm\(^2\). This may still be an underestimate.
as accelerating a square ft-d of the polar ejecta column, which amounts to ~0.002 M_⊙, to ~0.3 c, requires 1.6×10^{50} erg of kinetic energy, which amounts to 6.6% of the 2.5×10^{51} erg of rotational energy of a 500 Hz pulsar for each jet, or ~66 Hz of frequency drop from 500 Hz, still assuming 100% conversion of jet kinetic energy into Mystery Spot kinetic energy, unless the pulse has a smaller cross section than 1 ft-d, and/or the polar ejecta is less dense, on average, than 10^7 cm^{-3}. Since these numbers account only for the near polar SLIP beam(s), and not to the more equatorial beams, they must be considered to be lower limits. Observations of initial pulsar spindowns (see §3) would help greatly in resolving this uncertainty. Spinup from accretion may temper the spindown somewhat [35], but gravitational radiation reaction may counter it [36], though the high electromagnetic spindown will mask any effect of this latter on the pulse braking index, n, where \frac{df}{dt} \propto -f^n, and n = 5 for pure gravitational radiation.

In either case, the rotational energy required is too large to be supplied by a strongly magnetized pulsar over the required timescale, unless these are born spinning faster than the moderate rates generally believed to be typical (e.g., the ~12 ms initial period for the 16.1 ms PSR J0537-6910 [37] – see [38, 39]). There was certainly no evidence for a strongly magnetized pulsar within SN 1987A in its first few years (e.g., [38-40]) and most importantly, there is no evidence for such a pulsar in the last few years [41], whereas SN 1986J, at the same age, showed clear evidence of such a pulsar within it [42].

However, there may be a weakly magnetized pulsar within SN 1987A [30, 31], and at the very least this is supported by solid evidence for the at the very least this is supported by solid evidence for the may be a weakly magnetized pulsar within SN 1987A [30, 31], and at the very least this is supported by solid evidence for the formation of a neutron star [43, 44]. A binary merger of two electron-degenerate stellar cores (DD – in isolation these would be white dwarfs) has been proposed for SN 1987A [45], and the triple ring structure, particularly that of the outer rings, has recently been successfully calculated within this framework [46]. Other details of SN 1987A, including the mixing [47], the blue supergiant progenitor [48], the early polarization [49-51], and the possible 2.14 ms optical pulsations [30, 31], support this hypothesis.

The first clear evidence for DD-formed millisecond pulsars coincidentally came in the birth year of SN 1987A, with the discovery of the 3 ms pulsar, B1821-24 [52], in the non-core-collapsed globular cluster, M28. Subsequently many more were found over the next 20 years in such clusters (e.g., 47 Tuc – [53]), and attributing these to recycling through X-ray binaries has never really worked [54, 55], by a few orders of magnitude [56]. Thus the DD process in SN 1987A, albeit within a common envelope, would likely have formed a rapidly spinning, weakly magnetized pulsar.

Consequently, we also argue, as a corollary implication useful for understanding the SN process and its modern-day observation history, that the vast majority of core-collapse events are similar to SN 1987A, in that they are a result of the DD process, producing only weakly magnetized, rapidly-spinning, ms pulsars, the notable exceptions being SNe 1986J, and 2006gy and 2007bi, these latter which will be discussed further below. In spite of the rarity of recent SNe with solid evidence for a strongly magnetized neutron star remnant, many still currently hold that such a result is the more frequent result of stellar core-collapse events.

The above estimates for an early phase of drastic spindown are in line with the differences between the years-old spin period of the 2.14 ms (467 Hz) signature for SN 1987A of [50, 51] as a Population I pulsar [42] and the Population II pulsars with spin periods just over 2 ms, such as Ter 5 Y and V (2.05 & 2.07 ms invoke a short time interval with a very high spinup rate, ostensibly produced by a very high accretion rate in the X-ray binaries, to generate their ms pulsars. There are two problems with this hypothesis. The first is that relatively slowly rotating, recycled pulsars weighing 1.7 M_⊙, in the core-collapsed globular cluster, Ter 5 [54], have removed high accretion rate from contention as an alternative mechanism to produce the ms pulsars in the non-core-collapsed globular clusters without a long duration (and more obvious) X-ray source phase (see below regarding J1903+0327). The second problem is that we will see in §4.3 that because of SLIP the relation between accretion rate and spinup rate is often inverse. The three ms pulsars in Ter 5 O, P, and ad [57], and five other non-GC pulsars with periods < 2 ms, may have been recycled starting with periods near 2 ms.

6The 2.15 ms pulsar J1903+0327 [58] has a main sequence companion in a highly eccentric (e = 0.44), 95-day, > 105-ft/s orbit, from which it could never have accreted mass, but its high mass of 1.67 M_⊙ [59] indicates an extended era of accretion, ostensibly from a closer companion which has since been evaporated by the pulsar. Whether this accretion converted a strongly magnetized, only moderately rapidly spinning neutron star into J1903, at the same time drastically attenuating its magnetic field, rather than just converting a light J1903 into a heavier one, is still an unresolved question, given the effectiveness of weakly magnetized, rapidly spinning pulsars in driving jets, where jet-driven

![Figure 9: The distribution of pulsars from the ATNF pulsar database with spin rates greater than 100 Hz (http://www.atnf.csiro.au/).[61]).](http://www.atnf.csiro.au/)[61]
– 488 Hz & 482.5 Hz), and 47 Tuc F (2.10 ms – 476 Hz). The pulsar, J0034-0534, has the next highest spin rate, at 532.7 Hz, a gap of 44.5 Hz. There are seven in the same frequency range below Ter 5 Y (not counting SN 1987A), lending credibility to the commonality of 2 ms for the birth periods for pulsars produced by DD merger. This would also explain how ms pulsars could be recycled to spin rates faster than 500 Hz without requiring any decay of the magnetic field. The occurrence of pulsars with various spin frequencies shows an increased density for frequencies just under 500 Hz, consistent with this picture (see Fig. 2). After a (significant) gap from 378 to 346 Hz, where there is only PSR J0024-7204S at 353.3 Hz, the pulsars slower than 346 Hz, the steepest part of the curve, comprise the ‘5 ms pileup,’ i.e., those pulsars (in part) possibly the offspring of defunct LMXBs, are discussed further in §6.10. The pulsars between 378 and 500 Hz are not numerous enough to populate the pileup just by spinning down, without resorting to entities such as age and beaming differences.

| Process                                      | Timespan          |
|----------------------------------------------|-------------------|
| Bi-lobed to spheroidal CE                    | ~2,000? years     |
| Chandrasekhar-mass WD formed                 | ~2? seconds       |
| DD core-collapse to 2 ms pulsar              | ~0.5<t<0.5? s     |
| Gamma-ray burst (GRB)                        | ~0.5<t<~100? s    |
| Pulsed GRB afterglow                         | ~0.5 s<t<1 day    |
| Ejection spindown phase, θ_v ≪ 1            | 0<t<2 years       |
| Transition to θ_v ~ 1                        | 2<t<4 years       |
| GR-dominated spindown                        | 3<t<100? years    |
| Broadly beamed pulsations                    | 4<t<10 years      |
| Plasma depleted                              | 10<t<∞ years      |
| Cas A-type thermal X-ray source              | 10<t<400 years    |
| Magnetic dipole-dominated spindown           | 100<t<∞ years     |

Table 2 lists the anticipated emission and spindown phases of a SN/pulsar similar to 1987A. The epoch at which the common envelope transitions from bilobed to spheroidal is estimated at 2000 years prior to core-collapse, at which time the spindown is dominated by SLIP losses to mass ejection/disruption of the progenitor star, and thus very high. The time range at which the losses transition from SLIP to gravitational radiation is estimated to be 2 to 4 years, after which GR losses are estimated to dominate for a century. At ~2x10^-10 Hz s^-1, this amounts to a loss of ~0.6 Hz, which may be an overestimate, since the spindown may not sustain this rate over a century. Certainly the loss can not amount to several dozens of Hz, as the resulting tight grouping of pulsars with spin periods near 2 ms would not happen. When the pulsar is about a decade old, there is not enough plasma left (barring occasional clumps) to sustain optical pulsations. Thus the epoch of optical pulsations for SN 1987A started near 4 years of age, which is relatively late, due to the large angle between the spin axis inferred from the bipolarity, and the line of sight to the Earth, some 75°.

In this case, plasma initially available at many R_Lc resulted in axially driven pulsations. Precession and nutation may have further embellished the axial pattern [30]. A strongly magnetized pulsar, because it will be spinning more slowly than its weakly magnetized counterparts, will have a larger R_Lc and thus produce a much less collimated beam and jet than those of SN 1987A because plasma is available at far fewer R_Lc, but the larger progenitor counteracts this trend somewhat. As the 1987A circum-neutron star density declined, polarization currents were restricted to fewer R_Lc, resulting in pulsed emission along a cone of finite polar angle, which may have modified the resulting jet into the approaching and retreating conical features now easily visible in the HST ACS images [7].

Eventually, as the plasma continued to thin with time, its maximum density just outside of R_Lc, occurred between here and 2R_Lc, resulting because of Eq. (1), in pulsations driven close to the pulsar’s rotational equator, and according to our self-consistent solution, in the line of sight to the Earth. Such a beam can not possibly produce the observable excess luminosity that may have been seen by 1991 [63-65], as the amount of ^57Co required to otherwise account for the excess (m_y ~17.4 – 275 L⊙) was only barely consistent with hard X-ray and infrared spectral data [66,67]. If we were in the cusp of the pulsar within SN 1987A during this epoch, because of the distance^{-1} law associated with this direction, the implied luminosity would have dropped from 10 L⊙ (roughly magnitude 21), by half the distance modulus to the LMC, some 9.4 magnitudes, or a factor of ~5,000, to ~0.002 L⊙. Moving from 10 pc to ~12 tt-d (0.01 pc), the likely distance to the equatorial band (velocity ~2,500 km s^{-1}), the apparent luminosity falls by another factor of 1,000, far short of the required excess, and all possible other beams can not possibly make any difference. Because our geometrical solution puts the pulsar behind the equatorial torus visible in ACS images taken years later, the excess luminosity may have been due to an accretion-powered X-ray flux, reprocessed within ejecta thinning with time.

A few years earlier it is unlikely that the 2.14 ms signal would have been detectable in the broadband, as limits established in early 1988 [38] are comparable to levels of the 2.14 ms signal observed in the I band between 1992, Feb. and 1993, Feb. The 2.14 ms pulsar candidate was last detected in 1996, Feb. [31], and by 2002 there was no evidence of any such source in ACS images, which only really means that any pulsar within SN 1987A had entered the ‘Cas A’ phase [4] having exhausted its

---

1 Because there is initially always too much angular momentum, this rate is set by the branching of the Maclaurin and Jacoby solutions, leaving a near-Chandrasekhar mass white dwarf spinning with a period of 1.98 s.

8 Calculations with the SLIP model involve a variation of Kepler’s equation, which relates the eccentric anomaly, E, to the mean anomaly, M, using the eccentricity, e, E = e sin E + M, but in this case e > 1. Such calculations are notoriously difficult, even for a compact star not surrounded by remnant plasma. Needless to say, no such calculations have been done to date, and
surrounding excess plasma and perhaps also because the Earth was no longer in the ‘cusp’ of its beam(s). Still, the central source should turn on when the pulsar encounters matter from time to time. Thus continued observations are warranted.

4. The SN 1987A Link to GRBs

Without (or perhaps even with) the H and He in the envelope of the progenitor of 1987A Sk -69°202, the collision of the jet with the 1987A polar ejecta (which produced the early light curve and Mystery Spot) might be indistinguishable from a full /GRB [6], otherwise it would just beg the question of what distant, on-axis such objects would look like. It is also the case that few or no /GRBs have been found in elliptical galaxies, and that the DD process must dominate (as always, through binary-binary collisions), by a large factor the neutron star-neutron star mergers in these populations, even when requiring enough white dwarf-white dwarf merged mass to produce core-collapse. All of these facts/realizations lead to the alternate conclusion that the DD process may produce sGRBs in the absence of common envelope and polar ejecta, the means by which they would otherwise become /GRBs. If the sGRBs in ellipticals are due to mergers of white dwarfs, we can conclude that: 1) the pre-common envelope/polar ejecta impact photon spectrum of /GRBs may be well characterized as those of sGRBs, 2) sGRBs are offset from the centers of their elliptical hosts possibly because they are white dwarf-white dwarf mergers to core-collapse in their hosts’ globular clusters (to produce most of their ms pulsars – [68]), and 3) neutron star-neutron star mergers may not make /GRBs as we know them, and/or be as common as previously thought. Thus sGRBs, which last a few seconds [69], may not flag neutron star-neutron star mergers, which may last only a few ms, the same timescale as the 30-Jy, DM=375 radio burst [70].

Supernova 1987A, with its beam and jet producing its early light curve and Mystery Spot, is therefore potentially the Rosetta Stone for three of the four types of GRBs: t, i, and s GRBs [71, 72], with both polar ejecta and common envelope, red supergiant common envelope and no polar ejecta, and neither polar ejecta nor common envelope, respectively [74].

In addition to axially driven pulsations, the SLIP model makes the very remarkable prediction that the component of pulsar intensity which obeys Eq. (1), diminishes only as distance\(^{-1}\) (see the Appendix), and verified experimentally [24,80] and has been dramatically confirmed [23] and noted by others [75], for pulsars in the Parkes Multibeam Survey (e.g., [80]) with single, narrow pulses (see Fig. 10 and [61]). There is also evidence that GRBs and their afterglows share this characteristic [83,84], which supports the SLIP prediction of axially driven pulsations when plasma is available at many \(R_{LC}\). The SLIP prediction also explains how GRBs and their afterglows can be visible across the Universe. As a consequence of this prediction, we initiated a campaign of high speed monitoring of GRB afterglows in 2008 and 2009 at the Lick Observatory Crossley 36-inch telescope (without success – ‘live’ bright afterglows occur about one night in 60), and will re-initiate it as soon as the opportunity presents itself.

If, as for SN 1987A, the vast majority of SNe are DD-initiated, then by measuring the pulse period, \(P\), of the optical/near infrared pulsations from an afterglow, and assuming the pulsars resulting from DD are all produced at a standard spin period, \(P_0\), first measured from SN 1987A near 2.14 ms, but corrected to near 2.00 ms because of material ejected, the

\[ \delta(\theta) = \frac{4\pi}{\theta^2} \]

thus no calculation through the core-collapse process, done so far, possibly including those of collapsars, can possibly be valid. One side effect of not properly accounting for the pulsar, and the large amount of 56Ni, when strongly-magnetized pulsars are produced, is a very low estimate for the mass, \(\sim 25 M_\odot\), above which the core collapse continues on to a black hole. SNe 2006gy and 2007bi, each with several \(M_\odot\) of 56Ni, argue for a much higher transition mass.

\[^9\text{All except Soft Gamma Repeater (SGR) GRBs, which are estimated to amount to less than 5% of sGRBs and 1.5% of the total [73].}\]

\[^8\text{With the high flux in Figure 10 neatly overlap when multiplied by their distances, confirming the distance\(^{-2}\) law, while those with low fluxes are detector-limited and thus are ordered according to their distance. The synthetic sample was generated with a distance\(^{-2}\) law, and are by contrast spread out according to their distance even for the parts with the highest fluxes/population fractions, well in excess of their detector-limited parts near the bottom at low fluxes.}\]

\[^7\text{The pulsars at high flux in Figure 10 neatly overlap when multiplied by their distances, confirming the distance\(^{-1}\) law, while those with low fluxes are detector-limited and thus are ordered according to their distance. The synthetic sample was generated with a distance\(^{-2}\) law, and are by contrast spread out according to their distance even for the parts with the highest fluxes/population fractions, well in excess of their detector-limited parts near the bottom at low fluxes.}\]

\[^6\text{Anyone who has noticed the wildly varying acoustic signature from helicopters has experienced this directly [77,78] and similar effects in other geometries are also well known in acoustics [79].}\]
Figure 11: Low frequency Fourier power from GRB 960216 (with ~18,000 events in 40 s) is contoured on the frequency-frequency derivative plane.

redshift is given by:

\[ z = \frac{P}{P_0} - 1, \tag{10} \]

and even a moderately precise \( P \) (by standards), may yield a very precise redshift.

SLIP predicts that the peak of the emission for slowest pulsars occurs in the gamma-ray band [85-87], and this is supported by recent gamma-ray detections of slow (~1 Hz) pulsars in supernova remnants by FERMI (e.g., [88]). Without this feature, one would naively question whether SLIP could produce pulsed GRB afterglows when the predicted post-core-collapse strength of the magnetic field at 100s of \( R_Lc \), whether from a several Teragauss 80 Hz pulsar, or a few Gigagauss 500 Hz pulsar, would be well below the few megagauss necessary to drive cyclotron radiation in the optical and near-infrared bands. SLIP is more complicated: the centripetal acceleration of the polarization currents leads to contributions for a wide range of high frequencies. The essential necessary ingredient is plasma (see [86,2]), and in this situation, there’s plenty.

There is no requirement in the SLIP model on the rotator being a neutron star – a white dwarf will do as long as it has a magnetic field and there is plasma outside of its light cylinder, whether this comes from pulsar-generated plasma sheets, or gravitationally attracted ISM or SNR plasma. If this is the case, strongly magnetized pulsars may not make GRBs, and it might even be possible for a pre-core-collapse, \(~1.4 \, M_\odot\) white dwarf, spinning at its minimum period of 1.98 s, to emit the prompt part of a GRB, and, as with the afterglow, the distance\(^{-1}\) law would likewise ameliorate the energy requirement, even with the large expected spinup. This also raises the intriguing possibility that a GRB could be produced without core-collapse, and a large spin-down may be present.

We tested for spinup/down in the GRB with the highest flu-
ence in the BATSE catalog, 960216 [89], by Fourier transforming the first 40 s of events and contouring power on the frequency vs. plane. Power appears, though not significant without further confirmation, at a mean frequency of 0.50 Hz, and derivative of \(+0.08 \, Hz \, s^{-1}\), and also for spinup/down about an order of magnitude smaller, in the 0.35 to 0.42 Hz region (the results for higher frequencies, assuming 0 \( f \), are also negative). Bursts with even better statistics (perhaps from FERMI) may be necessary to further test this hypothesis.

It is difficult for a GRB produced by pulsations during spinup to produce an inverted distance law because of the changing \( v \). Alternately, GRBs may be produced when gamma-ray photons from the initial, collimated SLIP photon flux scatters off of circumstellar material such as polar ejecta [90]. For material such as polar ejecta, in a plane perpendicular to a line of sight from the SN proper, the pattern of illuminated, scattering, concentric rings expands supraluminally, and thus this emission also exhibits a distance\(^{-1}\) law for certain directions. However, the initial gamma-rays from the compact remnant actually penetrate the polar ejecta considerably and thus the scattering produces a volume source. What will be observed as a GRB across the Universe will be whatever produces a supraluminal source with an inverted distance law.

The geometric model with small angle scattering of gamma-rays in distant polar ejecta can explain other details of \footnotesize{GRBs, such as their \(~100 \, s \, T_{90}^\prime\)\footnote{An offset of 0.5° at 10 \( t \)-d corresponds to a 33 s delay.} the negligible spectral lag for late \((~10-100 \, s)\) emission from ‘spikelike’ bursts [91], and why ‘precursor’ and ‘delayed’ contributions have similar temporal structure [92,74].

Moving a \(10^{40} \, erg \, s^{-1}\) source from 25 \( t \)-d to 8 billion light years \((z\sim1)\), assuming a distance\(^{-1}\) law, would only reduce the apparent magnitude to ~15. Optical flashes of visual magnitude 2, which reddened as they faded, were observed on two occasions by Howard Bond (private communication, 2008). No known triggers occurred at the noted times.

X-ray afterglows of GRBs are characterized by a power law index, \(\alpha\), for the decline of intensity with time, and another, \(\beta\), to characterize the power law decline of the X-ray spectrum. The temporal index is discontinuous at sudden changes in slope called ‘jet breaks’. The two indices can be related through the ‘closure relations’ for various circumstances affecting the jet, although with limited success for Swift GRBs [93]. In the SLIP model, breaks in the temporal slope of the optical afterglows, if they existed, would be caused by sudden changes in plasma density outside of the neutron star, through Eq. (1). Because the steep decline of the X-ray flux (\(\alpha \sim 3\)) matches that of the GRB, which is unlikely to be pulsed, we do not expect the X-ray afterglow to be pulsed either, and their jet breaks may be caused by changes in the scattering of high energy photons due to structure in the polar ejecta [90]. However, in order to be observable at all, the X-ray afterglows must have an inverted distance law similar to GRBs resulting from a supraluminal process of one sort or another. Whether or not these are pulsed at all remains to be determined.
SLIP has little difficulty explaining the unusually long duration of GRB 101225A ($T_{90} > 2000$ s) through a coalescence between a neutron star and another star (the NSNS merger), i.e., a ‘borrowed SN’. Initially the outer layers of the star will be ejected by SLIP; and this activity will become progressively more violent with the inspiral of the neutron star as plasma becomes available at increasing $R_{1,c}$, though the tilt of the rotation axis relative to the plane of the inspiral will matter. It is this progression that is unusual for the GRB, and is responsible for the longevity through gamma-rays scattering in previously ejected material. A magnetar or, again, the formation of a black hole is unnecessary to make the jets (and highly unlikely unless the star is extremely massive). This is yet another case where high time resolution observations are sorely needed.

5. Double-Degenerate in Type Ia/c SNe

Since 2007, Feb., it appeared unavoidable that Type Ia SNe were also DD-generated, one of the causes being the long list of reasons why Ia’s can’t be due to thermonuclear disruption [74,96-99]. Now, with two out of two SNe Ia (SNR 0509-675, SN 2011fe), leaving no symbiotic companion [100, 101], it is clear this ever happens in any progenitor, and empty SN remnants almost always contain a neutron star which is not visible, just as the one in Cas A is barely visible [102]. Further, this means that Ia’s and Ic’s (these latter have been regarded by many as DD-initiated, neutron star-producing since the invention of the classification), are both due to the DD process. Thus these must form a continuous class: Ia’s when viewed from the merger equator, with lines of Fe; and Ic’s when viewed from the merger poles, because this view reveals lines of the r-process elements characteristic of Ic’s part of the reason for the differing spectroscopic classification, and the high approaching velocity (e.g., ‘hypernovae’) due to the view looking down the axis of the approaching bipolarity.

In the application of Type Ia SN luminosities for cosmological purposes, the increase in blue magnitude from the light curve maximum, $\Delta M_S$ – essentially an inverse measure of the width of the light curve in time – in the first few weeks of SN Ia proper time, is used to correct the Ia luminosity for the variable amount of $^{56}$Ni produced [103]. However, the direct relation, between the $\Delta M_S$ of the width-luminosity relation and the fractional SiII polarization in Ia’s, pointed out by [104], is more meaningfully interpreted as an inverse relation between the SiII polarization and luminosity (unlike the Fe lines, SiII lines must also exist in the axial features because they are also observed in Ic’s, and their polarization in Ia’s is a result of the more rapid axial extension when viewed close to the merger equator).

This inverse relation would be expected in Ia’s if the luminosity of the (very extended and productive of polarization) axial features were fixed, while the luminosity of the (less extended and less productive of polarization) toroidal component is driven by the amount of encapsulated $^{56}$Ni positron annihilation gamma-rays, which can be very high. As with 1987A-like events, it would again beg the question of “What else they could possibly be?,” and ‘delayed detonation’ [105], or ‘gravitationally confined detonation’ [106], may not produce polarization which would be inversely proportional to luminosity. And unless the view is very near polar, this geometry can produce split emission line(s) on rare occasions, as was seen in SN 2003jd [107], and thus again there is no need to invoke exotic, or an entire population (III) to account for GRBs [108, 109].

Because there is a spectroscopic difference between Ia’s and Ic’s, the SLIP-driven polar jets are either deficient in $^{56}$Ni, or are too diffuse to encapsulate their gamma-rays, or both. No observation of any recent SN other than SN 1986J, 2006gy, and 2007bi, and including all ever made of Type Ia SNe, is inconsistent with the bipolar geometry of 1987A.

All this raises serious concerns about the use of SNe Ia in cosmology, because many Ia’s/c’s in actively star-forming galaxies belong to the continuous class, and some of these, and most Ia’s in ellipticals, may not encapsulate a sufficient fraction of their gamma-rays to be bolometric, especially given the toroidal geometry, lying as much as two whole magnitudes (or more for nearly naked core collapse) below the width-luminosity relation (the faint SNe Ia of [110]). Thus the log of the systematics (2+ magnitudes) can be an order of magnitude bigger than the log of I plus the small effect (0.25 magnitude) from which dark energy was inferred, in the same sense, an effect which could easily swamp Malmquist bias, the largest systematic working in the opposite sense.

In the SLIP model the pulsar eviscerates its stellar remnant as long as there is remnant remaining, the SN can not ‘close in’ to a spherical configuration until much later when it will essentially become a shell source. This enforces a toroidal geometry of ejecta near its rotation equator, which may not conform to the width-luminosity relation because of unencapsulated positron annihilation gamma-rays from the toroid, an assertion supported by the early detection of hard X-rays and gamma-rays [111-114]. However, the local sample was selected on the basis of conforming to the width-luminosity (W-L) relation, which is by definition [115] the high end of the luminosity function. Thus the unavoidable inclusion of faint Ia’s in the distant sample leads to a bias which makes it appear to be anomalously dim, assuming a distance$^{-2}$ law, which seems appropriate for these objects. Supernovae which do not conform to the W-L relation have also been noted in 2005, by [116], for high redshift ESSENCE SNe.

6. Sco X-1 & LMXB’s, SS 433, and other details

6.1. DD and SN Luminosities

The double-degenerate mechanism ensures that many SNe are born from the core-collapse of a post-merger white dwarf with a rotation period near 2 s. In this circumstance the amount of $^{56}$Ni produced depends on how much and what type of material is left in the common envelope in excess of the ~1.4 $M_\odot$ lost to the neutron star (and emitted neutrinos), which can exceed this. The paltry amounts of $^{56}$Ni associated with Ib’s and

---

13]If sufficient matter exists, in excess of that lost to core-collapse, to screen the Ia thermonuclear products – a rare circumstance in elliptical galaxies, the reason why Ic’s are absent from these.

14]These velocities, near 0.4 c, match those of the Mystery Spot.
at least 90% of IIs are likely the result of dilution of their thermonuclear fuel with He and/or H due to the DD merger process. Thus SNe 2006gy and 2007bi do not have to be pair-instability SNe [119, 122], or the former a collision of two massive stars [123], only massive FeSNe of up to 75 M☉, which may actually have produced 3 and 6 M☉ of 56Ni respectively, and a strongly magnetized neutron star remnant, a prediction which, in the case of SN 2006gy, can be tested soon. Alternatively, if the progenitor of SN 2007bi was stripped of its H and He by some mechanism, it could have been a DD (Type Ia/c) SN with a high luminosity due to a high mass (C and O) in its common envelope.

6.2. SLIP, plasma, and intermittent pulsations

The presence of plasma makes a huge difference to rapidly rotating, weakly magnetized neutron stars. Strong transient pulsations have occurred during observations of SN remnants or X-ray binaries which have never been subsequently confirmed, and yet have no explanation other than as a real, astrophysical signal (e.g., the Cygnus Loop – see [126]). Judging from the high fraction of empty SN remnants, the population of ‘quiet’ neutron stars must exceed all other ‘loud’ populations combined [127]. All Galactic pulsars have the interstellar medium from which to draw plasma with their intense gravitational field, but frequently this is not enough, then only when such a neutron star encounters a cloud of matter will it become sufficiently luminous to be detected. It is for this reason that observations of SN 1987A should continue, as has already been suggested in §3 in spite of conclusions drawn from recent ‘snapshot’ null results [41, 128].

SLIP also makes no assumptions about the carrier wave – a physical process such as cyclotron radiation/strong plasma turbulence is necessary for the pulsar to radiate at shorter/longer wavelengths, but centripetal acceleration of the emitting region further modifies this spectrum by adding emission to shorter wavelengths. Thus, whether or not emission is observed in a band where SLIP predicts it should exist, as, for example, the few GeV cutoff of the Fermi pulsars [129], if real, would indicate something about the physical conditions of, and/or near, the pulsar.

In the context of the SLIP model, emission from rotation powered pulsars is not haphazard – radiation from the known pulsars may very well be detected from Earth because we are ‘in the cusp’, i.e., we are in the part of the pulsar’s beam that decays inversely only as the first power of distance (Eq. 1), which may be one of the reasons why repeated attempts to detect pulsations from extragalactic SNe have failed (e.g., [130] – another reason might be that all except SN 1987A were too distant).

6.3. Low Mass X-ray Binary (and other) Rotation Rates

Although SLIP makes the detection of pulsations from the luminous LMXBs unlikely (see the Introduction), there may still be a few ways to tell how fast their neutron star components are spinning. Because neutron stars are the accreting compact members of most, if not all LMXB’s [131], thermonuclear (Type I) X-ray bursts are common, as are the oscillations which occur during them [132, 133]. Some of the oscillation frequencies are quite high, with 1122 Hz for XTE J1739-285 topping the list [134]. Many of these frequencies are thought to reveal the actual rotation period of the neutron star. Many, including the first observed burst oscillations in the optical, in 4U1254-69 [135], show oscillations with only modest frequencies (in this case, 36.4 Hz) [9] which also might be the neutron star rotation rates. These modest spin rates are consistent with the LMXB rotation rates settling to a rate where spindown from SLIP, which may increase more than linearly with mass transfer rate, can exceed by several orders of magnitude any spinup due to accretion, which is subject to the Eddington limit. The association with rotation periods might be made when these are observed to remain the same (or very close) in repeated bursts. Pulsations from LMXB rotation frequencies may be observed in those for which the restrictive beaming (θ 1 ≪ 1) occasionally relaxes, i.e., for which plasma is restricted to fewer RLC (θ 1 ≅ 1 – see §6.10).

There is also a small group of about a dozen transient accreting millisecond X-ray pulsars, most of which also only show oscillations during Type I bursts (e.g., [137]). Many of these have accretion rates that are not persistently high, and also have very high spin rates, such as 400 Hz for SAX J1808.4-3658. In addition, of the three fastest pulsars, two, J1748-2446ad and J1959+2048, are currently evaporating their extremely low mass companions, and one, B1937+21, already has. All this is consistent with an inverse relation, at some point, between the rates of mass transfer and net rates of spinning up.

6.4. Sco X-1

The dual radio lobes of Sco X-1 [138], which expand at ~0.3-0.57c, and to which energy must be transported at speeds of 0.95 c or greater, are a nearly exact match to the derived kinetics of the Mystery Spot of SN 1987A, and might have actually been observed and detected from 1987A in the radio band, given a sufficiently large and sensitive radio array in the Southern Hemisphere, which did not exist at the time. Wright et al. [139] have noted that the <19-hour orbital period constrains the companion to a very faint M dwarf, or a white dwarf stellar core. This would imply that the accretia would be rich in metals as is the case with SN 1987A, though the 0.95 c transport of energy in its jets also argues for some hydrogen, or at least spall protons (see §5.7), which are then accelerated by the usual SN ‘boost’ mechanism of heavier elements hitting lighter

---

15 Helium has been found where it was not expected in almost all well-studied Type II SNe.
16 Such amounts of 56Ni can lift a lot of stellar material, thus 40 M☉ in a SN remnant is no longer a reason to invoke ‘milisecond magnetars’ as the dispersal mechanism [124, 128].

---

This may have happened with 4U1728-24, which showed strong 104 Hz optical pulsations for a short interval (B. A. Peterson & J. E. Nelson, private communication, 1977 – if this is the rotation rate, then the ~111 s periodicity is due to some other mechanism, see, e.g., [130]). This result was never published because of its high implied energetics and it was never reproduced. However there is no other good explanation given the single-photon-counting detector used, and SLIP can explain the energetics (an image of the source at the same time should also have confirmed this), and further development of survey telescopes could also detect such events.
ones. If so, then considering that the elements of the accretia may not be stratified, as they may have been at least partially so within the newly-born remnant of SN 1987A, it is amazing that this mechanism works at all, and this, plus the relative dearth of H, may explain the relative weakness of Sco X-1’s very fast jet component.

### 6.5. Historic remnants and pulse profiles

If we are not ‘in the cusp’, for any annulus of plasma beyond the pulsar light cylinder, whose induced radiation is free to propagate to infinity, spinning neutron stars may only appear as thermal sources, such as the one in Cas A [102]. A century older, as is the case with Tycho 1572, and not even the thermal sources are detectable. However, the extinction of $A_V = 3.47, +0.13, -0.29$ mag. to the Kepler 1604 remnant [140], though a revision up from 2.2 [141], is still much less than the 6.2$\pm$0.6 mag. to Cas A [142], with the distances nearly equal at 3.2 and 3.4 kpc. Thus assuming that extinction traces H column and all SNe produce compact remnants, the pulsar in this remnant should be visible as a thermal source, so perhaps the neutron star in Cas A is visible because of SLIP beaming. Evidence does linger, however, even in the outwardly very spherical remnant of SN 1006, as bipolar high energy emission in XMM and VLA images [143], the high velocity chimneys seen in Cas A [144] being long gone. For many pulsars, such as the Crab, which were discovered because of a SN remnant association, we may not be in the ‘in the cusp,’ and thus the isotropic optical luminosity of the pulsar may currently still be $\sim 3 \times 10^{37}$ erg s$^{-1}$. However, for those pulsars that are in the cusp, the SLIP model predicts that the pulse profile will consist of two very close peaks [39] which would seem to exclude the Crab (e.g., [145] and [146]) and ascribing the interpulse to some other mechanism – [147] – see the Appendix), but the solitary pulse of the 16.1 ms pulsar, J0537-6910, will split, if allowed by the fitting process (see immediately below).

### 6.6. The pulsar, J0537-6910, and the SLIP model

SLIP predicts that pulsed emission arises outside of the light cylinder, either from current sheets, originating close to the pulsar, or from ISM plasma which has been concentrated by gravitational forces, J0537 can not, and does not produce strong optical pulsations – the centripetal acceleration of the polarization currents is not sufficient to alleviate this. However, assuming that the frequency 2nd derivative persists at $-0.95 \times 10^{-21}$ Hz s$^{-2}$, J0537 will spin at 31 Hz in $\sim 3,800$ years, and may be a strong optical pulsar by that time.

As mentioned above, the single, narrow peak of the pulse profile of J0537 is likely an indication that we observe its X-ray pulsations at least partially (the pulse width is $\sim 10\%$ of the period) as a result of the distance$^{-1}$ law, and its 2-10 keV pulsed X-ray luminosity could be lower than $2\times 10^{38}$ erg s$^{-1}$ as estimated by [149].

### 6.7. The positron excess, WMAP ‘Haze’, and Fermi ‘Bubbles’

A beam of protons, with kinetic energies of up to 2.2 GeV or greater, will eventually produce electrons with similar energies. Electrons/positrons with even higher energies may result from photon scattering because the cross section varies inversely as the square of the particle mass, and/or the leptons may, in turn, be further accelerated by magnetic reconnection, in wound-up magnetic fields near the Galactic center, or other mechanisms [150], possibly to TeV energies, to produce the WMAP ‘Haze’/FERMI ‘Bubbles’ observed in that direction [151, 152]. In addition, the SNR loss/relativistic injection of $^{36}$Ni positrons into the pulsar jet, which occurs because of the bipolarity of SNe, and which also makes them unfit for easy cosmological interpretation, may show up as an excess in cosmic ray data [153-155]. This may offer a satisfying resolution for the apparent anomalous dimming of distant SNe explained in terms of local cosmic ray abundances, without invoking the creation of electron-positron pairs near pulsars and their acceleration along ‘open’ field lines which do not exist if one believes in the validity of the Sommerfeld equations [17, 18]. TeV fermions generated by SNe and/or pulsars would alleviate the short lifetime problem ($\sim 10^6$ yr) associated with the Galactic center as a potential direct source. SLIP does not require pulsars to generate positrons in order for them to emit radiation, so the 10-100 GeV positron flux may not be dominated by contributions from local pulsars, but may be provided instead by the supernovae that gave birth to them recently. The main difficulties lie in accounting for how and why the excess rises at energies above 10 GeV and below 100 GeV.

Positrons at multiple GeV energies will destroy the (relatively stationary) heavy nuclei they collide with, resulting in the release of free neutrons which can drive the r-process in supernovae. A density of $10^{24}$ cm$^{-3}$ in free neutrons has been invoked to drive this process, but SLIP can provide this near the center of the newly-formed remnant. SLIP clearly also drives the r-process, visible in early Ic spectra, at the poles of SNe Ia/c, as described in the Introduction, where the influence of annulli well outside of the stellar core bypasses that same core to produce focused beams at the two poles, where C and O are both available. Detailed calculations are deferred for future efforts (see, e.g., [156]).
6.8. The SS 433 Jets

The extreme collimation of the initial beam and jet in SN 1987A, and even the strong Hα seen in its spectrum near day 19.6 are suggestive of a similar situation in SS 433 (e.g., [157]), and a rapidly spinning pulsar has been proposed for the underlying central engine (e.g., [158]), although mass estimates for the compact object vary from 0.8 to 16 M☉ [159-162]. The big problem with SS 433 is accounting for the mechanical power necessary to produce 10^{38} erg s^{-1} of Hα from recombination in two jets with velocities of 0.26 c, which could amount to 10^{42} erg s^{-1} if each atom has only one recombination. Because of the few minute variability of the Hα [163, 164] with no variability of its velocity >1%, the standard method of its solution is to invoke a clumpiness of 10^5 in the jets titled ‘bullets,’ (e.g., [165]), so that each atom recombines many times (∼10^{2-3}).

Although [166] constrained the parameter space for the bullets, assuming the Hα production mechanism was an interaction of the jets with a B-star wind, the possibility of many excitations per atom, due to beamed radiation, was an admitted exception to the requirement for bullets. Of course this is exactly what SLIP does, in the process easily producing the kinematic and collimation properties of the SS 433 jets from a ms pulsar buried in hydrogen-dominated accretia, where L∞ at the source is redshifted to Lα in the mature jets (this is exact for β=0.28, but the actual β is lower [0.26,] consistent with the finite band-width necessary for the jet acceleration mechanism to work), the usual SN boost mechanism being unavailable because of the lack of high Z accretia.

If SLIP turns out to be a necessary mechanism to produce the jets and their Hα flux, then the rarity of SS 433 may be less due to the wind from a Population I B star, than to its association with a weakly magnetized ms pulsar, which clearly did not originate from a massive, solitary star similar to what we think describes the primary. The best chance to detect a pulsar in SS 433 may be during a low state, should that ever happen, there having been no sign of any pulsar (e.g., [167]) in the high state it has occupied since the discovery of its bizarre behavior in 1978. A 2 ms pulsar could power the jets for 10^4 years if each atom produces ∼20 Hα photons, not even accounting for any spinup due to accretion. It is more likely, however, that the spin period of SS 433 is larger because a 2 ms period is associated with the eversion of SN progenitors by SLIP, and, in the presence of plasma at many R_{LC}, as happens in both SS 433 and SNe, will have a very large spindown, whereas the actual spin of SS 433 will settle to a rate where spinup from accretion is balanced by spindown due SLIP. This rate will likely be a bit higher than what is typical for the luminous LMXBs, perhaps closer to a period of 5 ms, because of the lack of heavy elements loading SLIP (see 6.10).

6.9. Star Formation Avalanche in the Early Universe

Computer simulations of clustering in the Early Universe fail without the addition of some extra agent to increase the rate at which clusters form (see, e.g., [168]). The problem is that the agents which can be easily inserted into the codes, such as dark matter or dark energy, almost always involve controversial physics which may not be valid. Aside from such agents, the only known mechanism which is frequent and violent enough to possibly play the same role are the pulsar-driven jets resulting from the supernovae of the first stars.

Although high velocity material will suppress star formation locally (M.-M. Mac Low, 2011, private communication), even the early Universe (z~7) is vast, and this same material will initiate star formation [169-172] at some distance from the pulsar in the two initially polar jets. Without spreading, the Mystery Spot column, σ_{MS} of 0.5 cm^{-2} will penetrate even the early Universe at z=7, with 4% of the present day critical density in baryonic mass. Assuming, for the sake of simplicity, a linear (conical) spreading scale of ℓ_0 = 3 ×10^{16} cm in an interstellar medium of density of σ_{B}=1.9×10^{-28} g cm^{-3} (4% of critical density at z~ 500^{1/3} − 1 ~7), and solving for the pathlength, ℓ, whereby a column of mass equal to the spread-diluted Mystery Spot column has been swept up in its last 10%, we get:

\[
ℓ \sim 200 \text{ pc} \left( \frac{ℓ_0}{3 \times 10^{16}} \right)^{2/3} \left( \frac{σ_{MS}}{0.5} \right)^{1/3} \left( \frac{σ_{B}}{1.9 \times 10^{-28}} \right)^{-1/3}
\] (11)

The collimation of the Mystery Spot is not exactly known, but it can’t be as extreme as the 10^{4-5} of the initial beam/jet. However, it could easily amount to a few square light days at a distance of 10 light days. In that case, the plume would be about a few light years across at 100 pc. Along the way, shearing vortices may initiate star formation, with higher velocities at the larger distances from the endpoint.

The actual situation may be much more complicated, as the decline of the jet collimation with time will impact the previously formed vortices. The stars formed by this process may also initiate another round of star formation as they move through the primordial ISM, and so on, with each cluster retaining a tiny, though important fraction of the initial jet velocity. Infant clusters in close proximity with nearly matched velocities may merge due to their sustained mutual gravitational attraction. In this way, the SLIP jets may initiate a star formation avalanche, possibly leading to mini-cluster and/or stream formation in a few million years, with no requirement for dark matter. The recent discovery by GALEX [173, 174] of velocities, between close pairs of distant galaxies, which do not reflect their mutual gravitational attraction, may be the result of the separation velocities of pulsar-driven jets in their formation of star clusters. Again, detailed calculations are deferred for future efforts.

6.10. Pulsar ‘recycling’

Pulsars with rapid spins and weak magnetic fields are commonly referred to as having been ‘recycled,’ wherein these attributes are a result of a (usually) long dead pulsar undergoing an extensive interval of accretion from a binary companion which it acquired or already had, that as a result has increased its spin rate from the few second period typical of a very old strongly magnetized pulsar, to the ms period range, and as a side effect either of the accretion, or slow decay of the effective magnetic dipole by some other mechanism because of advanced age, or both, reduced its original several Teragauss magnetic field by 2 to 4 orders of magnitude.
Here, however, we have seen evidence that the spindown due to SLIP can greatly exceed any spinup due to accretion. Thus, the only way to tell if a pulsar has been recycled is by a mass substantially in excess of 1.3 M⊙ (as is the case for J1903+0327) but even then, there’s no guarantee that the pulsar has suffered any net spinup, the result depending on accretion rate and history, spin rate, and magnetic field strength and configuration.

To gain further understanding of this process, 1723 pulsars are located on the log period-period derivative plane in Figure 12. On this plot, the connection between the ‘ordinary’ pulsars in the upper right to the ‘recycled’ pulsars in the lower left is a two-lane, one-way highway. The top lane (higher period derivative) contains all six of the globular cluster pulsars, and nine Population I pulsars, for the period range from 10 to 100 ms, while the bottom lane contains just Population I pulsars for that range. Metallicity and gravitational contamination are unlikely contributors to this pattern. The lanes have numerical slopes of about 1.5, meaning if pulsars migrate to the right and slightly up in the lanes, the period derivatives gain 3 parts for every 2 parts gain in period. By contrast the same ratio is 3 to 1 for the young (4,000-year old), 16.1 ms PSR J0537-6910 (see §6.6), twice the slope of the two lanes (its effective magnetic dipole increases by 0.02% per year), so perhaps the pulsars in these lanes actually do migrate right and up along their respective, sloped paths.

Unfortunately, none of the six globular cluster pulsars in the upper lane within that period range have measured second frequency derivatives (which should be negative for this migration but which will also suffer extremely from gravitational contamination), so we can’t test the hypothesis that these pulsars are migrating on the slightly upward path. Of the 32 non-globular pulsars in the lanes within this period range, 2 have negative and 2 have positive frequency second derivatives, so half of these four pulsars are not migrating within the lanes. With a period derivative of 1.88e-20, J1903+0327 lies on the low boundary of the short period end of the upper lane. The offset between the two lanes corresponds to nearly two orders of magnitude in period derivative, but only one order of magnitude in field strength.

Still, this offset between the two lanes is likely to be due to different accretion histories, provided accretion does in fact reduce pulsar effective dipoles, as postulated by [182] and [183]. The simplest interpretation is that pulsars in the upper lane, containing about ten of eleven globular cluster pulsars with periods >8 ms, have never suffered accretion and were born fast and weakly magnetized.

---

30Given that the best estimate for the mass of Her X-1 is 1.30 M⊙ [173,176], and the likelihood that it has been accreting 10^-9 M⊙ from HZ Her for several hundred million years (with gaps ~177), the best estimate for the standard, initially strongly magnetized neutron star mass is likely closer to 1.25 M⊙, which is supported by the masses of the strongly magnetized pulsars, J0737-3039B at 1.2498(7) [175], and J1906+0746 at 1.248(18) Me [175,180], respectively (see also [183] and references therein). This could mean that the standard Chandrasekhar mass is closer to 1.35 M⊙, unless it is actually higher for weakly magnetized progenitors, or that 0.05 M⊙ is typically excluded from the core-collapse for strongly magnetized neutron stars.

31This assumes that the accretion cycle from these to the lower left is always hidden, i.e., the accretion is never interrupted until the pulsars arrive near the pileup near 5 ms, nor the ‘normal’ population with higher period derivatives. We reject the hypothesis that this does happen during the accreting phase but a large fraction somehow fall neatly into this well focused lane once their accretion ceases.

21As well as the 104 Hz optical signal observed from the LMXB 4U1728+24.

---

Figure 12: A plot of 1723 pulsars from the ATNF Pulsar Database in the log period-period derivative plane. Non-binary, non-globular cluster pulsars are marked by ‘+’ signs, non-globular binary pulsars by x’s, non-binary globular cluster pulsars by circles, globular binary pulsars by squares, four strongly magnetized, young pulsars by pentagons, and the 2.14 ms signal from SN 1987A by an hourglass.

It is even difficult to argue in favor of a strongly magnetized origin for those pulsars in the lower lane, as it would seem strange that this population starts only from those ‘ordinary’ pulsars with the smallest period derivatives, and neither from the much larger population of ‘dead’ pulsars with even lower period derivatives. It may be more likely that this (lower) lane is from faster pulsars which accreted from binary companions to become LMXB’s that have ceased to accrete, and are left there. Similarly, the upper lane may populate the main group just above its lowest point.

So on average these pulsars slowed during their phase of high accretion, which is in line with the modest QPO frequencies seen in many LMXB’s [3] and the high frequencies seen from most of the accreting millisecond X-ray pulsars, which have very low accretion rates.

As the accretion rate diminishes when the binary companion begins to withdraw from its Roche limit, for whatever reason, as long as this is a gradual process, the pulsar will have an era of spin-up, possibly resulting in the pileup at 3-5 ms periods. Here however, pulsars are found with period derivatives still lower than those of the lower path, thus requiring a population of neutron stars which were born only weakly magnetized, and likely spinning in the millisecond range.

Thus these two discrete lanes connecting the “normal” pulsar group in the upper right to the ms pulsars in the lower left...
require a source of pulsars whose spin rates are faster than 200 Hz. Again, the most likely source to populate these paths is the source of born-fast 2 ms pulsars from the DD process. Since there are orders of magnitude more neutron stars generated by the DD mechanism than by Fe catastrophe, there should be a much larger reservoir of ‘dead’ weakly magnetized pulsars than their ‘dead’ strongly magnetized cousins. A study of the high space velocities of solitary neutron stars as compared to the masses and low eccentricities of double neutron star binaries has also reached the conclusion of the necessity of two mechanisms to produce neutron stars [184], the DD process being the second (though overwhelmingly predominant) mechanism.

7. Conclusion

We have derived a self-consistent solution for the onset (~11 ft-d), and depth (~13 ft-d), of the polar ejecta of the progenitor of SN 1987A, the energetics of its beam/enhanced UV flash (>10^{40} \text{ erg s}^{-1}), the kinetics of its jet (β ∼ 0.95 for −10^{-6} M_☉), and angle from the line of sight to the Earth (~75°). There is plenty of evidence for the absence of any strongly magnetized pulsar within SN 1987A, and such a pulsar may not have the rotational energy to account for the kinetics derived anyway. Thus, we have argued, through the paradigm of a model of pulsar emission (SLIP) from polarization currents updated supraluminally beyond the pulsar light cylinder [20], that SN 1987A, its beam/jet, ‘Mystery Spot,’ and possible 2.14 ms pulsar remnant, are intimately related to SS 433, Sco X-1 and as many as 99% of LMXBs, GRBs, ms pulsars, and other SNe, including all Type Ia SNe. The SLIP model explains, in a natural way (Eq. 1), the changes over time observed in the collimation of the SN 1987A beam and jet.

The time lags, energetics, and collimation of GRBs are consistent with those of 1987A’s initial beam, jet, and the inferred polar ejecta. When the bipolarity of SN 1987A is interpreted through this model, its polar jet cannot have rested out of its poles at speeds up to 0.95 c or greater, and enforcing a toroidal geometry on the remaining equatorial ejecta. Since there is no reason to suggest that this is not universally applicable to all SNe, this geometry has grave implications for the use of Type Ia SNe as standard candles in cosmology (see, e.g., [185], and [5]).

Lines observed from Type Ic SNe provide proof that SLIP beams drive the r-process at the rotational poles, in or near the progenitor photosphere (§§ 8.5 & 8.7). No other model of SNe can explain why such lines are only observed in SNe Ic (which are actually SNe Ia when observed away from the poles, and also when the r-process lines can not be observed), the reason being that C and O are only available at the surface of SNe Ia/c.

Because even weakly magnetized neutron stars buried within plasma can spin down at a rate which exceeds their ability to spin up from accretion by orders of magnitude, pulsars interacting with the rest of the remnant progenitor (if this rest exists), clearly can not be ignored – they are the driving force behind the disruption of their progenitor stars in supernova explosions, in spite of the difficulty of detecting them within the remnant, now explained by the associated beaming. This has observable consequences: the start of the associated UV flash will show up within minutes, or even seconds, of the core-collapse and neutrino flux, and the timetable of many SN 1987A events needs to be revised accordingly. In addition, the existence of a robust mechanism for disrupting progenitor stars means that the stellar mass at which core-collapse continues on to create a black hole is much larger than previously thought – perhaps closer to 75 M☉ or even higher.

There appears to be no need to invent exoticia to explain GRBs – the SLIP model provides the young pulsar (or even a near-Chandrasekhar-mass white dwarf) with an initially tightly collimated beam as the central engine, and makes the very specific and testable prediction that GRB afterglows are, in fact, pulsars, usually spinning at 500 Hz in the proper frame.

Beaming has always been a wild card for pulsars, and for the SLIP model, the beaming is effectively infinite – part of the radiation decays only as the first power of the distance, and the two cones of this beam (which subtend a solid angle of measure 0) will change in polar angle as plasma conditions change outside of the pulsar light cylinder. Beams and jets which are less than maximally collimated (those which originated from annuli of less than maximal radii) may not have enough concentrated energy to break through extensive surrounding material, and rather help to lift it away from the neutron star. Rotating objects for which pulsations are not detected may simply be beamed in other directions. Thus the disappearance, or persistent absence, of pulsations from rotating compact objects, such as those which might lie within the Cygnus Loop (§§ 6.2, SN 1987A (§§ 6.3), SS 433 (§§ 6.8), and Sco X-1 (§§ 6.4) and other LMXBs (§§ 6.3), does not automatically imply that there never was a pulsar, and/or that the compact object is a black hole, the energy requirement for a pulsar being negligible because of the distance^{-1} law. Finally, it may be that all transient events observed in the very distant Universe, including the outbursts of QSOs, are seen because they have a similar inverted distance law, which is a result of a supraluminial excitation of one sort or another.

Such restrictive beaming (θv ≪ 1 and plasma at many R_L) explains, in a natural way, the non-detections of pulse frequencies from the luminous LMXB’s, and less restrictive beaming (θv ≈ 1 and plasma at few R_L) the intermittent detections of oscillations from the less luminous LMXB’s – the accreting millisecond X-ray pulsars. The neutron star components of the LMXB’s will settle to a spin rate where spin up from accretion (or that the compact object is a black hole, the energy requirement for a pulsar being negligible because of the distance^{-1} law). Finally, it may be that all transient events observed in the very distant Universe, including the outbursts of QSOs, are seen because they have a similar inverted distance law, which is a result of a supraluminial excitation of one sort or another.

As is the case for many other things, the Devil in this Universe may lie in the details. Thus while the most extensive simulations of the early Universe still require dark matter to form galaxies (see e.g., [185] and [187]), the jets driven by the pulsars resulting from the SNe of the first stars may provide the perturbations necessary to initiate the next generation of star formation in such a way as to include much of this generation in rapidly growing star clusters and/or streams (see §6.9).
Thus, although it may take longer to form the first stars without dark matter, the formation of clusters via pulsar-driven jets may make up this time. The peculiar motions observed from distant galaxy pairs \[173, 174\] which would otherwise be expected to show motions reflecting their mutual gravitational attraction, may be due to the pulsar jet-star-formation process.

In addition, because of the large systematic effects involved in measuring Type Ia (and all other) SN luminosities due to the unsuitability of their geometries (see \[\S 110\] and \[116\]), we simply can not tell if they suffer any anomalous dimming with cosmological distances, without further understanding of the SN process and the ability to apply this understanding to carefully select the distant sample. This was the only really direct evidence that the expansion of the Universe is accelerating, and now the scientific community must again question the existence of dark energy. Without it, in addition to the possible lack of need for dark matter in the formation of star clusters, there may be no longer any numerical coincidence to support the role of dark matter in Concordance Cosmology. Recent observations of solitary ring galaxies have also cast significant doubt on the existence of dark matter \[188, 189\].

Thus, aside from bizarre entities such as quantum entanglement currents, there is not much evidence for any dark “stuff” present in the recent Universe \(z \leq 1\) having any observable effect, and this has been due in significant part to a new understanding of the role of pulsar-driven jets. Still, the evidence is strong that \(\Omega_{\text{total}} = 1\) at the era of recombination \(z \sim 1000 \) e.g., \[190\]). However, in addition to kinematic redshift, gravitational redshift becomes important when looking back that far, and our knowledge of gravity is incomplete at best. Perhaps the best assessment of this apparent factor of \(\sim 20-25\) difference in \(\Omega_{\text{total}}\) between the era of recombination and the more recent Universe is that it remains a deeper mystery.

The path to the intimate and productive study of the SN and GRB processes is now clear: with high time resolution observations of GRB afterglows, through the selection effect of the inverted distance law operating across billions of light years, we let the Universe reveal the behavior of the pulsars responsible. It might appear that a Universe without the need for dark matter or energy, collapsars, hypernovae, pair instability SNe, super-Chandrasekhar mass white dwarfs, frequent collisions of massive stars, and neutron star-neutron star mergers which make sGRBs, is much less ‘exotic’ than previously thought. However pulsars, i.e., clocks and minutes-old neutron stars to boot, which can be seen across almost all of this same Universe (which is never in equilibrium), including even core-collapse remnants of the first stars, and which may yield practically instant redshifts just from their pulse frequencies alone, may well suffice in explaining all of the issues which gave rise to the previously mentioned entities, are more in line with Occam’s Razor, and are also, of themselves, extremely worthy of study.

I would like to thank Dr. John Singleton for supporting this work through the Los Alamos National Laboratory LDRD grant 20080085DR, “Construction and Use of Superluminal Emission Technology Demonstrators with Applications in Radar, Astrophysics and Secure Communications,” and grant 201100320ER, “Novel Broadband Terahertz Sources for Remote Sensing, Security and Spectroscopic Applications,” as well as Drs. Joe Fasel, Todd Graves, Bill Junor, and Andrea Schmidt. I am also grateful to Larry Earley of Los Alamos, Jim Johnson and Carl Pennypacker of Lawrence Berkeley Laboratory, and John Saarloos for loans of equipment for use at Lick Observatory, as well as Keith Baker, Costas Chloros, Ellen Gates, Bryant Grigsby, Rem Stone, and the rest of the entire staff of of Lick Observatory for their assistance, and M. T. “Brook” Sanford of Los Alamos for programming assistance. I would also like to thank Joel Roop and Andy Toth of Keithley Instruments for the loan of an engineering unit of the KUSB 3116 for testing at home while far away from Lick Observatory. This work was performed under the auspices of the Department of Energy.
Models of pulsar emission usually involve the motion of charged particles between the neutron star and the light cylinder. The Outer Gap model \[191\] produces the emission by particle acceleration in the gap just outside of the last closed magnetic field line within the light cylinder and the null surface \((\Omega \cdot \mathbf{B} = 0)\). The Polar Cap models involve pair production, electron acceleration, and production of secondaries close to the magnetic poles of the neutron star \[192\]. Other models produce emission via inverse Compton upscattering of lower energy photons (see, e.g., \[193\], and references therein). In the SLIP model radiation from polarization currents induced beyond the light cylinder initially focuses on the light cylinder and drives a particle wind along with a beam. SLIP is indifferent to material within the light cylinder, and for isolated pulsars relies on material from the ISM concentrated by the gravitational field of the neutron star (see, e.g., \[87\]).

Electromagnetic radiation can be generated by a time-dependent polarization, \(\mathbf{P}(t)\), just as it can from currents of free charges, \(\mathbf{j}\), displacement, \(\mathbf{D}\), and electric field, \(\mathbf{E}\) \[194\]:

\[
\nabla \times \mathbf{H} = \frac{4\pi}{c} \mathbf{j} + \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t} = \frac{4\pi}{c} (\mathbf{j} + \frac{\partial \mathbf{P}}{\partial t}) + \frac{1}{c} \frac{\partial \mathbf{E}}{\partial t},
\]

(12)

where \(\mathbf{H}\) is the magnetic field and \(c\) is the speed of light in vacuo. Although the motion of the charged particles in the polarization currents is, in general, slow, there is no limit to the speed at which they can be modified, similar to a wave produced by fans in a stadium at a sports event. In particular, the action of a rotating dipole, such as a neutron star with a non-aligned magnetic field, can change polarization currents much faster than the speed of light at many light cylinder radii, \(R_{\text{LC}}\).

As the (mostly dipole) magnetic field of the neutron star rotates, much of the polarization current field beyond \(R_{\text{LC}}\) will be instantaneously parallel because the magnetic field in opposite directions with respect to the axis of rotation is also opposite. Thus the polarization currents can be thought of as a single vector function of radius, which is rotating rigidly with with the pulsar rotation frequency, \(\omega\).

The influence of currents from an annulus of a given radius, on a point on the light cylinder and in the same plane perpendicular to the axis of rotation, will then consist of the magnetic field produced by such currents, and the influence of the cyclotron radiation and strong plasma turbulence induced by the currents. However, the influence of the currents is affected, in a non-trivial way, by their centripetal acceleration in the supraluminally rotating frame of reference (see, e.g., \[85\]), a complication which we will ignore in this discussion. The net influence on the point can at least be understood by the influence of a progression of a series of Huygens’ wavelets, as shown in Fig.13 which shows many wavelets intersecting a point tangent to the light cylinder. Ultimately the wavelets from nearly a third of a whole revolution will intersect at such a point still further clockwise around the light cylinder. More than this would be unproductive, both because directions of further contributions to \(\mathbf{H}\) at the point would be more than 60° away from the mean.

Figure 13: (Bottom to top) A progression of Huygens’ wavelets for a supraluminal source moving at 5 times the speed of light, with 36 wavelets in a full circle. The light cylinder footprint is marked by the small, black circle.
phase, and, of course, the induced time-varying cyclotron radiation or strong plasma turbulence would also suffer out-of-phase contributions.

As time progresses further, this focus point, or ‘cusp’, will split as it moves out of the plane, spiralling out on two cones of polar half angle given by Eq. (1) (see, e.g., $\theta_v$ of Eq. (13) of [22]). The dependence of observer time on source time for three different $\theta_v$, and the three different resulting pulse profiles, are shown in Fig. 14. The singly-peaked pulse profile (repeated once) for the direction corresponding to the ‘cusp’, for this $v = 5c$ case (polar angle of $\sim 11.5^\circ$) is shown in the lower part of the right frame. Almost exactly half of the $\sim 1,000$ pulsars in the Parkes Multibeam Survey have a single pulse peak with a full width at half maximum less than 3% of the pulse period (see e.g., [61], and [34], and SLIP predicts that all of these will be very closely spaced doubles (see [65]).

For larger polar angles the pulse profiles are obviously double, and less sharp (right frame, middle), and for smaller polar angles (right frame, top), the pulse profiles are again single, but still smaller, and eventually not sharp at all. The advantage in intensity of one pulse profile over another will depend on how many points are used in plotting the curves – the more points, the greater the advantage, until the limiting case of the distance$^{-1}$ law is reached. The point of inflection in the lowest curve of Fig. 14 is the circular analog of a shockwave, and it is this that results in the distance$^{-1}$ law.

If the rotation-powered pulsars which radiate from just beyond the light cylinder (see [6,6]), produce the characteristic singly-peak pulse profile, and a beam which, according to Eq. (1), is very nearly equatorial, how is it that pulsars with doubly-peaked profiles find the phase space in greater polar angle to generate those profiles?

One possible production mechanism for complex pulse profiles is a multipole component of the neutron star magnetic field. Barring that, the Crab pulsar may offer a clue to this conundrum. Its inter-pulse, which alone is similar to the small polar angle top pulse profile of Fig. 14 shows the emission bands in the 2-10 GHz range predicted by SLIP, while its main pulse does not [147]. The possibility that the main pulse is a result of a less homogeneous environment and the bands are smeared out to uniformity seems to be excluded by these observations. Thus the Crab’s main pulse may arise from a different location, i.e., a different radius, which would also imply emission from a radius greater than just outside the light cylinder, which in turn could mean plasma sheets generated closer to the pulsar travelling outward through $R_{LC}$. Still, the equal $180^\circ$ swing in polarization across both the main and interpulse supports a SLIP process for both.

The movie of the Crab [33] in Chandra X-rays appears to show at least one nearly equatorial fan of pulsations and 0.5 $c$ wind, as predicted by SLIP through Eq. (1) for material just outside the light cylinder, with our line of sight between the lower rotation axis and the lower near-equatorial wind component. Weisskopf et al. [195] interpret this as a single circular feature projected onto the plane of the sky, and offset from the plane of the sky containing the pulsar as a fan beam of some 4.5 degrees off the equatorial plane of the pulsar, which would indicate that the location of the SLIP emission occurs at 1.003 times the light cylinder radius. It is not clear if there is another fan, as predicted by SLIP, which does not appear because its aspect produces less back-scattering. The width of the bottom lip of the ‘bell’ supports a two-fan interpretation of some sort, and may imply that plasma around the Crab pulsar does not extend a large fraction beyond $R_{LC}$ ($\sim 1,600$ km), although it has to exist more densely at great distance to reveal the very distant dominant ring.

Because our line of sight to the pulsar is much closer to the pole than the fan in the opposite hemisphere from that which produces the circular arc, the Crab’s interpulse may be a small polar angle feature similar to the pulse profile in the upper right of Fig. 14. There is the possibility that plasma is trapped at a few $R_{LC}$ and leads to an emission fan that is more nearly polar, but just not easily visible in the movie, and could be associated with a second arc visible to the right (west) of the innermost arc. The fan in the opposite hemisphere to the one that produces this second arc may actually lie at, or closer, to the pole than our line of sight, and this would ease the angular requirement for producing sharp and double pulses, and may, in some way, reveal the production mechanism of the Crab’s main pulse.

The movie also shows the Crab has polar jets, and there are two possible sources of supraluminal excitations of the same concentric feature which reveals the fan of wind and pulsations. The first supraluminal excitation may be due to the discrete waves of particles, made famous by the movie, impacting the concentric features. Although the timing of the particle wave arrivals at all azimuths will not be exact, it may be close enough to drive substantial polar jets. The second supraluminal excitation is due to the actual $\sim 30$ Hz pulsations themselves, and for
these the timing will be exact because there will frequently be enough material in the features to trace the path of each individual pulse over a wide range of azimuth, in spite of the fact that they are of order 100s of millions of light-pulse periods away (a few light-months).

If pulsars on the ‘cusp’ have to be very close to satisfying Eq. (1), it may not take a lot of range in polar angle closer to 90° to populate the doubly- or multiply-peaked sample. Those pulsars with smaller polar angle may be relatively suppressed due to the poor detectability of their bland, singly peaked pulse profiles (the top right curve in Fig. [4]). Further studies of artificial pulsar populations may yield a definitive answer to this question about the distribution of types of pulse profile.
