ABSTRACT

We present the results from a high cadence, multi-wavelength observation campaign of AT 2016jbu, (aka Gaia16cfr) an interacting transient. This dataset complements the current literature by adding higher cadence as well as extended coverage of the light-curve evolution and late-time spectroscopic evolution. Photometric coverage reveals that AT 2016jbu underwent significant photometric variability followed by two luminous events, the latter of which reached an absolute magnitude of $M_V \sim -18.5$ mag. This is similar to the transient SN 2009ip whose nature is still debated. Spectra are dominated by narrow emission lines and show a blue continuum during the peak of the second event. AT 2016jbu shows signatures of a complex, non-homogeneous circumstellar material (CSM). We see slowly evolving asymmetric hydrogen line profiles, with velocities of $500 \text{ km s}^{-1}$ seen in narrow emission features from a slow moving CSM, and up to $10,000 \text{ km s}^{-1}$ seen in broad absorption from some high velocity material. Late-time spectra ($\sim +1$ year) show a lack of forbidden emission lines expected from a core-collapse supernova and are dominated by strong emission from H, He i and Ca ii. Strong asymmetric emission features, a bumpy light-curve, and continually evolving spectra suggest an inhibit nebular phase. We compare the evolution of Hα among SN 2009ip-like transients and find possible evidence for orientation angle effects. The light-curve evolution of AT 2016jbu suggests similar, but not identical, circumstellar environments to other SN 2009ip-like transients.

Key words: circumstellar matter – stars: massive – supernovae: individual: AT 2016jbu – supernovae: individual: Gaia16cfr – supernovae: individual: SN 2009ip

1 INTRODUCTION

Massive stars that eventually undergo core-collapse when surrounded by some dense circumstellar material (CSM) are known as Type II

¹ Contact e-mail: sean.brennan2@ucdconnect.ie
nova (SN) ejecta. Some events also show very broad emission or absorption features ($\sim 10,000$ km s$^{-1}$) arising from fast ejecta, typically associated with material ejected in a core-collapse explosion.

The existence of the dense CSM indicates that the Type IIn progenitors have high mass-loss rates shortly before their terminal explosion. This dense material at the end of a star’s life can come from several pathways (see reviews by Puls et al. 2008; Smith 2014; Fraser 2020, for further detail). Complicating this picture are a growing number of extra-galactic transients that show narrow emission lines in their spectra (indicating CSM) but have much fainter absolute magnitudes than most typical Type IIn SNe. These events are often termed SN Impostors (Van Dyk et al. 2000; Maund et al. 2006; Pastorello & Fraser 2019), and are believed in many cases to be extra-galactic Luminous Blue Variables (LBVs) experiencing giant eruptions (e.g. SN 2000ch; Wagner et al. 2004; Pastorello et al. 2010). These eruptions do not completely destroy their progenitors.

Perhaps the best studied exemplar of the confusion between LBVs, SN impostors, and genuine Type IIn SNe is SN 2009ip. SN 2009ip was found on 2009 August 26 at $\sim 17.9$ mag in NGC 7259 by CHASE project team members (Maza et al. 2009). This transient was originally classified as a Type IIn SN, and then re-classed as an impostor when it became clear that the progenitor had survived. SN 2009ip was characterized by a years-long phase of erratic variability that ended with two luminous outbursts a few weeks apart in 2012 (Li et al. 2009; Drake et al. 2010; Margutti et al. 2012; Pastorello et al. 2013; Fraser et al. 2013; Smith et al. 2014; Graham et al. 2014).

From pre-explosion images taken 10 years prior to the 2009 discovery, the progenitor star of SN 2009ip was suggested to be a LBV with a mass of $50–80$ M$_\odot$ (Smith et al. 2010; Folk et al. 2011). There is much debate on the fate of SN 2009ip. Some argue that SN 2009ip has finally exploded as a genuine Type IIn SN during the 2012 outburst (Prieto et al. 2013; Mauerhan et al. 2013). However, other authors remain agnostic as to SN 2009ip’s fate as a CCSN, pointing to the absence of any evidence for nuclosynthesised material in late-time spectra, as well as SN 2009ip not fading significantly below the progenitor magnitude (Fraser et al. 2013; Margutti et al. 2014; Fraser et al. 2015). Since the discovery of SN 2009ip, a number of remarkably similar transients have been found. The growing family of SN 2009ip-like transients share similar spectral and photometric evolution. SN 2009ip-like transients have the following observable traits.

1. History of variability lasting (at least) $\sim 10$ years with outbursts reaching $M_V \sim -11 \pm 3$ mag.
2. Two bright luminous events with the first peak reaching a magnitude of $M_V \sim -13 \pm 2$ mag followed by the second peak reaching $M_V \sim -18 \pm 1$ mag several weeks later.
3. Spectroscopically similar to a Type IIn SN i.e. narrow emission features and a blue continuum at early times.
4. Restrictive upper limits to the mass of any explosively synthesised $^{56}$Ni.

In this paper we focus on one such SN 2009ip-like transient. AT 2016jbu (also known as Gaia16crf; Bose et al. 2017) was discovered at RA. = 07:36:25.96, DEC. = $-69^h32^m55.25$ (J2000) by the Gaia satellite on 2016 December 1 with a magnitude of $G = 19.63$ (corresponding to an absolute magnitude of $\sim -11.97$ mag for our adopted distance modulus). The Public ESO Spectroscopic Survey for Transient Objects (PESSTO) collaboration (Smartt et al. 2015) classified AT 2016jbu as an SN 2009ip-like transient due to its spectral appearance and apparent slow rise (Fraser et al. 2017). Fraser et al. (2017) also finds that the progenitor of AT 2016jbu seen in archival Hubble Space Telescope (HST) images is consistent with a massive (< 30 M$_\odot$) progenitor. The transient was independently discovered by B. Monard in late December who reported the likely association of AT 2016jbu to its host, NGC 2442. AT 2016jbu is situated to the south-east of the spiral galaxy NGC 2442 nucleus and is indicated with a red cross reticle in the center of the image. This location lies on the outskirts of a Superbubble (Pancoast et al. 2010), with a high star formation rate. We also include the location of the Type Ia SN 2015F (blue circle, north west of image center; Cartier et al. 2017) and the Type II SN 1999ga (green square, south west of image center; Pastorello et al. 2009).

Figure 1. Finder chart for AT 2016jbu. Image is a 60s $r$-band exposure taken with the LCO 1-m. AT 2016jbu is situated to the south-east of the spiral galaxy NGC 2442 nucleus and is indicated with a red cross reticle in the center of the image. This location lies on the outskirts of a Superbubble (Pancoast et al. 2010), with a high star formation rate. We also include the location of the Type Ia SN 2015F (blue circle, north west of image center; Cartier et al. 2017) and the Type II SN 1999ga (green square, south west of image center; Pastorello et al. 2009).
environment. Ki18 model Hα using a multi-component line profile including a shifted blue emission feature that grows with time, with their final profile similar to that of the Type IIn SN 2015bh (Elias-Rosa et al. 2016; Thöne et al. 2017) at late times.

Using HST images, spanning 10 years prior to the 2016 transient, Ki18 reports that AT 2016jbu underwent a series of outbursts in the decade prior, similar to SN 2009ip, and finds the progenitor is consistent with a ~18 M⊙ progenitor star, with strong evidence of reddening by circumstellar (CS) dust (which would allow for a higher mass). Performing dust modelling using Spitzer photometry, Ki18 find the spectral energy distribution (SED) ~10 years prior is fitted well with a warm dust shell at 120 AU. They find that, given typical CSM velocities, it is unlikely that this dusty shell is in the immediate vicinity of the progenitor and is unlikely to be seen during the 2016 event. This means that the progenitor of AT 2016jbu was experiencing episodic mass loss within years to decades of its most recent explosion.

This paper focuses on photometry and spectra obtained for AT 2016jbu which is not covered by Ki18. In particular, this includes searching through historic observations of AT 2016jbu’s host, NGC 2442 for signs of variability, as is expected for SN 2009ip-like transients, as well as presenting high cadence data for Event A and the late time photometric and spectroscopic evolution.

We take the distance modulus for NGC 2442 to be 31.60 ± 0.06 mag, which is a weighted average of the values determined from HST observations of Cepheids (μ = 31.511 ± 0.053 mag; Riess et al. 2016) and from the SN Ia 2015F (μ = 31.6 ± 0.14 mag; Cartier et al. 2017). This corresponds to a metric distance of 20.9 ± 0.58 Mpc. We adopt a redshift of z=0.00489 from H I Parkes All Sky Survey (Wong et al. 2006). The foreground extinction towards NGC 2442 is taken to be AV = 0.556 mag, from Schlafly & Finkbeiner (2011) via the NASA Extragalactic Database (NED). We correct for foreground extinction using RV = 3.1 and the extinction law given by Cardelli et al. 1989. We do not correct for any possible host galaxy or circumstellar extinction, however we note that the blue colors seen in the spectra of AT 2016jbu do not point towards significant reddening by dust. We take the V-band maximum during the second, more luminous event in the lightcurve (as determined through a polynomial fit) as our reference epoch (MJD 57784.4 ± 0.5; 2017 Jan 31).

This is the first of two papers discussing AT 2016jbu. In this paper (Paper I), we report spectroscopic and photometric observations of AT 2016jbu. In Sect. 2 we present details of data reduction and calibration. In Sect. 3 and Sect. 4 we discuss the photometric and spectroscopic evolution of AT 2016jbu respectively. In Sect. 5 we compare AT 2016jbu to SN 2009ip-like transients, and also consider the observational evidence for core-collapse.

In Brennan et al. 2021 (hereafter Paper II) focuses on the progenitor of AT 2016jbu, its environment and using modelling to constrain the physical properties of this event.

2 OBSERVATIONAL DATA

The optical lightcurve evolution of AT 2016jbu has been previously discussed in Ki18. Their analysis covers Event B up to ~+140 days past maximum brightness. We present a higher cadence photometric dataset that covers both Event A, Event B, as well as late-time observations up to ~+575 d. This high cadence dataset allows for a more detailed photometric analysis of AT 2016jbu which will be discussed in Sect. 5. Ki18 discuss the spectral evolution of AT 2016jbu from ~27 days until +118 days. Our observational campaign presented here continues contains increased coverage during this period as well as observations up until +420 days allowing for late time spectral followup.

2.1 Optical imaging and reduction

Optical imaging of AT 2016jbu in BVRi filters was obtained with the 3.58m ESO New Technology Telescope (NTT) + EFOSC2, as part of the ePESSTO survey. All images were reduced in the standard fashion using the PESSTO pipeline (Smartt et al. 2015); in brief images were bias and overscan subtracted, flat fielded, before being cleaned of cosmic rays using a Laplacian filter (van Dokkum 2001). Further optical imaging was obtained from the Las Cumbres Observatory network of robotic 1-m telescopes as part of the Global Supernova Project. These data were reduced automatically by the banzai pipeline, which runs on all Las Cumbres Observatory (LCO) Global Telescope images (Brown et al. 2013). Images were also obtained from the Watcher telescope. Watcher is a 40 cm robotic telescope located at Boyden Observatory in South Africa (French et al. 2004). It is equipped with an Andor IXon EMCCD camera providing a field of view of 8×8 arcmin. The Watcher data were reduced using a custom made pipeline written in Python.

AT 2016jbu was monitored using the Gamma-Ray Burst Optical/Near-Infrared Detector (GROND; Greiner et al. 2008), a 7-channel imager that collects multi-color photometry simultaneously with Sloan-griz and JHK/ks bands, mounted at the 2.2 m MPG telescope at ESO La Silla Observatory in Chile. The images were reduced with the GROND pipeline (Krühler et al. 2008), which applies de-bias and flat-field corrections, stacks images and provides astrometry calibration. Due to the bright host galaxy we disabled line by line fitting of the sky subtraction for the GROND NIR data until +118 days. Our observational campaign presented here continues contains increased coverage during this period as well as observations up until +420 days allowing for late time spectral followup.

Unfiltered imaging of AT 2016jbu was also obtained by B. Monard. Observations of AT 2016jbu were taken at the KleinKaroo Observatory (KKO), Calitzdorp (Western Cape, South Africa) using a 30cm telescope Meade RCX400 f/8 and CCD camera SBIG ST8-XME in 2×2 binned mode. Unfiltered images were taken with 30s exposures, dark subtracted and flat fielded and calibrated against r-band sequence stars. Nightly images resulted from stacking (typically 5 to 8) individual images.

We also recovered a number of archival images covering the site of AT 2016jbu. Two epochs of g and r imaging from the Dark Energy Camera (DECam) (Flaugher et al. 2015)

1 https://ned.ipac.caltech.edu/
mounted on the 4 m Blanco Telescope at the Cerro Tololo Inter-American Observatory (CTIO) were obtained from the NOIRLab Astro Data Archive. The science-ready reduced “InstCal” images were used in our analysis. In addition to these, we downloaded deep imaging taken in 2005 with the MOSAIC-II imager (the previous camera on the 4 m Blanco Telescope). As for the DECam data, the “InstCal” reductions of MOSAIC-II images were used. We note that the filters used for the MOSAIC-II images (Harris V and R, Washington C Harris & Cantera 1979) are different from the rest of our archival dataset. The Harris filters were calibrated to Johnson-Cousins V and R. The Washington C filter data is more problematic, as this bandpass lies between Johnson-Cousins U and B. We calibrated our photometry for this, but this should be interpreted with appropriate caution.

Deep Very Large Telescope (VLT) + OmegaCAM images taken with i, g, and r filters in 2013, 2014, and 2015, respectively, were downloaded from the ESO archive. The Wide Field Imager (WFI) mounted on the 2.2-m MPG telescope at La Silla also observed NGC 2442 on a number of occasions between 1999 and 2010 in B, V, and R; these images are of particular interest as they are quite deep, and extend our monitoring of the progenitor as far back as −15 years. Both the OmegaCAM and WFI data were reduced using standard procedures in IRAF.

NED contains a number of historical images of NGC 2442, dating back to 1978. We examined each of these but found none that contained a credible source at the position of AT 2016jbu.

Several transient surveys also provided photometric measurements for AT 2016jbu. Gaia G-band photometry for AT 2016jbu was downloaded from the Gaia Science Alerts web pages. As this photometry was taken with a broad filter that covers approximately V and R, we did not attempt to calibrate it onto the standard system. V-band imaging was also taken as part of the All-Sky Automated Survey for Supernovae (ASAS-SN Shappee et al. 2014; Kochanek et al. 2017).

The OGLE IV Transient Detection System (Kozłowski et al. 2013; Wyrzykowski et al. 2014) also identified AT 2016jbu, and reported I-band photometry via the OGLE webpages.

The Panchromatic Robotic Optical Monitoring and Polarimetry Telescopes (PROMPT) (Reichart et al. 2005) obtained imaging of AT 2016jbu in BV RI filters; and as discussed in Sect. 5.1.1, unfiltered PROMPT observations of NGC 2442 were also used to constrain the activity of the progenitor of AT 2016jbu over the preceding decade. Images were taken with the PROMPT1, PROMPT3, PROMPT4, PROMPT6, PROMPT7 and PROMPT8 robotic telescopes (all located at the CTIO). PROMPT4 and PROMPT6 have a diameter of 40 cm while PROMPT1, PROMPT3 and PROMPT8 have a diameter of 60 cm and PROMPT7 has a diameter of 80 cm. All images collected with the PROMPT units were dark subtracted and flat-field corrected. In case multiple images were taken in consecutive exposures, the frames were registered and stacked to produce a single image.

NGC 2442 was also serendipitously observed with the FOcal Reducer/low dispersion Spectrograph 2 (FORS2) as part of the late-time follow-up campaign for SN 2015F (Cartier et al. 2017). Unfortunately, most of these data were taken with relatively long exposures, and AT 2016jbu was saturated. However, a number of pre-discovery images from the second half of 2016, as well as late time images from 2018 are of use. These data were reduced (bias subtraction and flat fielding) using standard iraf tasks.

2.2 UV Imaging

UV and optical imaging was obtained with the Neil Gehrels Swift Observatory (Swift) with the Ultra-Violet Optical Telescope (UVOT). The pipeline reduced data was downloaded from the Swift Data Center. The photometric reduction follows the same basic outline as Brown et al. (2009). In short, a 5′ radius aperture is used to measure the counts for the coincidence loss correction, a 3′ source aperture (based on the error) was used for the aperture photometry and applying an aperture correction as appropriate (based on the average PSF in the Swift HEASARC’s calibration database (CALDB) and zeropoints from Breiveld et al. (2011)).

Subsequent to the photometric reduction of our Swift data, there was an update to the Swift CALDB with time dependent zero-points which we have not accounted for. Given that our Swift observations occurred in early 2017, this would amount to a ∼3% shift in zero-point and would not lead to a significant change in our lightcurve.

2.3 NIR imaging

Near-infrared imaging was obtained with NTT+SOFI as part of the ePESSTO survey, and with GROND as mentioned previously. In both cases JHK/Ks filters were used. SOFI data were reduced using the PESSTO pipeline (Smartt et al. 2015). Data were corrected for flat-field and illumination, sky subtraction was performed using (in most instances) off-target dithers, before individual frames were co-added to make a science-ready image.

In addition to the follow-up data obtained for AT 2016jbu with SOFI, we examined pre-discovery SOFI images taken as part of the PESSTO follow-up campaign for SN 2015F. We downloaded reduced images from the ESO Phase 3 archive which covered the period up to April 2014. Two subsequent epochs of SOFI imaging from 2016 Oct were taken after PESSTO SSDR3 was released, and so we downloaded the raw data from the ESO archive, and reduced these using the PESSTO pipeline as for the rest of the SOFI follow-up imaging.

Fortuitously, the ESO VISTA telescope equipped with VIRCAM observed NGC 2442 as part of the VISTA Hemisphere Survey (VHS) in Dec. 2016. We downloaded the reduced images as part of the ESO Phase 3 data release from VHS via ESO Science Portal. Photometry was performed using AutoPhOT, see Sect. 2.6.
2.4 MIR imaging

We queried the WISE data archive at the NASA/IPAC Infrared science archive, and found that AT 2016jbu was observed in the course of the NEOWISE reactivation mission (Mainzer et al. 2014). As the spatial resolution of WISE is low compared to our other imaging, we were careful to select only sources that were spatially coincident with the position of AT 2016jbu. There were numerous detections of AT 2016jbu in the W1 and W2 bands over a one week period shortly before the maximum of Event B (MJD 57784.4 ± 0.5). The profile-fitted magnitudes measured for each single exposure (Lib frames) were averaged within a 1 day window.

We also examined the pre-explosion images covering the site of AT 2016jbu in the Spitzer archive, taken on 2003 Nov. 21 (MJD 52964.1). Some faint and apparently spatially extended flux can be seen at the location of AT 2016jbu in Ch1, although there is a more point-like source present in Ch2. No point source is seen in Ch3 and Ch4. Ki8 report values of 0.0111 ± 0.0032 mJy and 0.0117 ± 0.0027 mJy in Ch1 and Ch2 (corresponding to magnitude of 18.61 mag and 17.917 mag respectively) and similarly do not detect a source in Ch4 and Ch5 for the 2003 images.

2.5 X-ray Imaging

A target of opportunity observation (ObsID: 0794580101) was obtained with XMM-Newton (Jansen et al. 2001) on 2017 Jan 26 (MJD 57779) for a duration of ~ 57 ks. The data from EPIC-PN (Strüder et al. 2001) were analysed using the latest version of the Science Analysis Software, SASv18 including the most updated calibration files. The source and background were extracted from a 15′ region avoiding a bright nearby source. Standard filtering and screening criteria were then applied to create the final products.

X-ray imaging was also taken with the XRT on board Swift. These observations are much less sensitive than the XMM-Newton data, and so we do not expect a detection. Using the online XRT analysis tools (Evans et al. 2007, 2009) we co-added all XRT images covering the site of AT 2016jbu available in the Swift data archive. No source was detected coincident with AT 2016jbu in the resulting ~ 100 ks stacked image.

2.6 Photometry with the AutoPhOT pipeline

The dataset presented in this paper for AT 2016jbu comprises approximately ~ 3000 separate images from around 20 different telescopes. To expedite photometry on such large and heterogeneous datasets, we have developed a new photometric pipeline called AutoPhOT (AUTomated PHotometry Of Transients; Brennan & Fraser (2022)). AutoPhOT has been used to measure all photometry presented in this paper, with the exception of imaging from space telescopes (i.e. Swift, Gaia, WISE, Spitzer, XMM-Newton OM and HST), as well as from ground based surveys which have custom photometric pipelines (i.e. ASAS-SN and OGLE).

AutoPhOT is a Python3-based photometry pipeline built on a number of commonly used astronomy packages, mostly from astropy. AutoPhOT is able to handle heterogeneous data from different telescopes, and performs all steps necessary to produce a science-ready lightcurve with minimal user interaction.

In brief, AutoPhOT will build a model for the Point Spread Function (PSF) in an image from bright isolated sources in the field (if no suitable sources are present then AutoPhOT will fall back to aperture photometry). This PSF is then fitted to the transient to measure the instrumental magnitude. To calibrate the instrumental magnitude onto the standard system (either AB magnitudes for Sloan-like filters or Vega magnitudes for Johnson-Cousins filters) for this work on AT 2016jbu, the zeropoint for each image is found from catalogued standards in the field. For griz filters, the zero-point was calculated from magnitudes of sources in the field taken from the SkyMapper Southern Survey (Onken et al. 2019). For Johnson-Cousins filters, we used the stellar standards in NGC 2442 presented by Pastorello et al. (2009). In the case of the NIR data (JHK) we used sources taken from the Two Micron All Sky Survey (2MASS, Skrutskie et al. 2006). There is no u-band photometry covering this portion of the sky. We use U -band photometry from Cartier et al. (2017) and convert to u-band using Table 1 in Jester et al. (2005). We include Swope photometry from Ki8 in Fig. 2 to show that our u-band is consistent.

AutoPhOT utilises a local version of Astrometry.net (Barron et al. 2008) for astrometric calibration when image astrometric calibration meta-data is missing or incorrect. In instances where AT 2016jbu could not be clearly detected in an image, AutoPhOT performs template subtraction using hotpants (Becker 2015), before doing forced photometry at the location of AT 2016jbu. Based on the results of this, we report either a magnitude or a σ upper limit to the magnitude of AT 2016jbu. Artificial sources of comparable magnitude were injected and recovered to confirm these measurements and to determine realistic uncertainties, accounting for the local background and the presence of additional correlated noise resulting from the template subtraction.

Finally, in order to remove cases where a poor subtraction leads to spurious detections, we require that the FWHM of any detected source agrees with the FWHM measured for the image to within one pixel, as well as being above our calculated limiting magnitude. In practice we find these are good acceptance tests to avoid false positives, especially in the pre-discovery lightcurve of AT 2016jbu.

We present the observed lightcurve of AT 2016jbu in Fig. 2, and show a portion of the tables of calibrated photometry in Appendix B (the full tables are presented in the online supplementary materials).

2.7 Spectroscopic Observations

Most of our spectroscopic monitoring of AT 2016jbu was obtained with NTT+EFOSC2 through the ePESSTO collabo-

10 https://github.com/acbecker/hotpants
**Figure 2.** The complete multi-band observed photometry for AT 2016jbu. The upper panel covers the period from the start of Event A (First detection at ~91 d from VLT+FORS2) until the end of our monitoring campaign ~ 2 years after Event B peak. Offsets (listed in the legend) have been applied to each filter for clarity in the upper panels only. Note that there is a change in scale in the X-axis after 135 days. We indicate Event A and the rise and decline of the peak of Event B. Epochs where spectra were taken are marked with vertical ticks. We also include the published Swope photometry from Ki8 (given as filled circles) to demonstrate that our photometry is consistent. We include a horizontal magenta dotted line in all panels to demonstrate the early 2019 $F814W$ magnitudes (Paper II). We only plot error bars greater than 0.1 mag. The lower panel shows detections and upper limits over a period from ~ 18 years prior to Event A. No offsets are included in this panel; light points with arrows show upper limits, while solid points are detections.
ration. With the exception of the first classification spectrum reported by Fraser et al. (2017), observations were taken with grisms Gr#11 and Gr#16, which cover the range of 3345–7470 Å and 6000–9995 Å at resolutions of R ~ 390 and R ~ 595, respectively.

The EFOSC2 spectra were reduced using the PESSTO pipeline; in brief, two-dimensional spectra were trimmed, overscan and bias subtracted, and cleaned of cosmic rays. The spectra were flat-fielded using either lamp flats taken during daytime (Gr#11), or that were taken immediately after each science observation in order to remove fringing (in the case of Gr#16). An initial wavelength calibration using arc lamp spectra was then checked against sky lines, and in the final pass all spectra were shifted by ~ few Å, so that the [O i] ~ 6300 sky line was at its rest wavelength. This was done to ensure that all spectra were on a common wavelength scale in the critical region around Hα where Gr#11 and Gr#16 overlap.

Low-resolution spectra were obtained with the FLOYDS spectrograph, mounted on the 2-m Faulkes South telescope at Siding Spring Observatory, Australia. These spectra were reduced using the FLOYDS pipeline (Valenti et al. 2014). The automatic reduction pipeline splits the first and second order spectra into red and blue arms and rectifies them using a Legendre Polynomial. Data is then trimmed, flat-fielded using images taken during the observing block and cleaned of cosmic rays. Red and blue arms are then flux and wavelength calibrated and then merged into a 1D spectrum.

A single spectrum was obtained with the WiFeS IFU spectrograph, mounted on the ANU 2.3-m telescope. This spectrum was reduced with the PyWiFeS pipeline (Childress et al. 2014).

All optical spectra are listed in Table 1 and are shown in Fig. 7. For completeness, we also include the classification spectrum of AT 2016jbu in our analysis obtained with the du Pont 2.5-m telescope + WFCCD (and reported in Rose et al. 2017), as it is the earliest spectrum available of the transient, see also Fig. 3.

We present a single NIR spectrum taken in the low-dispersion and high-throughput prism mode with FIRE (Simcoe et al. 2013) mounted on one of the twin Magellan telescopes (Fig. 16). The spectrum was obtained using the ABBA “nod-along-the-slit” technique at the parallactic angle. Four sets of ABBA dithers totalling 16 individual frames and 2028.8s of on-target integration time were obtained. Details of the reduction and telluric correction process are outlined by Hsiao et al. (2019).

In addition, we present two spectra taken with Gemini South + Flamingos2 (Eikenberry et al. 2006) in long-slit mode. An ABBA dither pattern was used for observations of both AT 2016jbu and a telluric standard. These data were reduced using the gemini.f2 package within iraf. A preliminary flux calibration was made using the telluric standard on each night (in both cases a Vega analog was observed), and this was then adjusted slightly to match the J − H colour of AT 2016jbu from contemporaneous NIR imaging.

Swift+UVOT spectra were reduced using the uvtoty python package (Kuin 2014) and calibrations from Kuin et al. (2015).

3 PHOTOMETRIC EVOLUTION

3.1 Overall evolution

We present our complete lightcurve for AT 2016jbu in Fig. 2, spanning from ~ 10 years before maximum brightness (MJD 57784.4) to ~ 1.5 years after maximum light. Ki8 mainly focuses on the time around maximum light up until +118 days on AT 2016jbu. Our photometric coverage is much higher in cadence and covers a wider wavelength range.

For the purpose of discussion, we adopt the nomenclature for features seen in the lightcurve of SN 2009ip from Graham et al. (2014): rise, decline, knee, and ankle. We do not designate a “bump” phase as while SN 2009ip shows a clear bump at ~20 d, this is not seen in AT 2016jbu. The rise begins at ~ +22 days prior to V-band maximum. The decline phase begins at V-band maximum. The plateau begins at ~ +20 days, when the decline gradient flattens out initially. The knee stage is ~ +45 days past maximum when a sharp drop is seen in the lightcurve, and the ankle is the flattening of the lightcurve after ~65 days before the seasonal gap.

AT 2016jbu shows a clear double-peaked lightcurve which has been previously missed in literature. The first fainter peak (at MJD 57751.2, mainly seen in r-band) will be referred to as “Event A”, and the subsequent brighter peak is “Event B”. Event A is first detected around three months (phase: ~−91 d) before the Event B maximum in VLT+FORS2 imaging (Fraser et al. 2017). Phases presented in this paper for AT 2016jbu and other SN 2009ip-like transients will always be in reference to Event B maximum light (MJD 57784.4). The rise and decline of this first peak is clearly seen in r-band (mainly detected from the Prompt telescope array) and sparsely sampled by Gaia in g-band. Event A has a rise time to peak of ~60 days, reaching an apparent magnitude r ~ 18.12 mag (absolute magnitude ~ −13.96 mag). We then see a short decline in r-band for ~2 weeks until AT 2016jbu exhibits a second sharp rise seen in all photometric bands, starting on MJD 57764.

We regard the start of this rise as the beginning of Event B. The second event has a faster rise time of ~10 days, peaking at r ~13.8 mag (absolute magnitude ~−18.26 mag). Our high cadence data shows after ~20 days past the Event B maximum, a flattening is seen in Sloan-gri and Cousins BV that persists for ~2 weeks, with a decline rate ~0.04 mag d⁻¹. At ~50 days, a rapid drop is seen at optical wavelengths, with the drop being more pronounced in the redder bands and less in the bluer bands. After the drop there is a second flattening. After two months from the Event B peak, the optical bands flatten out with a decay of ~0.015 mag d⁻¹ and remain this way until the seasonal gap at ~120 days.

Our dataset includes late time coverage of AT 2016jbu not previously covered in the literature. A re-brightening event is seen after ~120 days and is seen clearly in BVGgr bands. We miss the initial rebrightening event in our ground-based data, so it is unclear if this is a plateau lasting across the seasonal gap or a re-brightening event. However, evidence for a rebrightening in the lightcurve is seen in Gaia-G (See Fig. 2). We can deduce that this event occurred between +160 and +195 days from our Gaia-G data, where we have G = 18.69 mag at +160 days, but an increase to 18.12 mag one month later. An additional bump is seen in Gaia-G at +345 days. We observe G = 18.95 mag at +316 d

11 https://github.com/LCOGT/floyds_pipeline
and $G = 18.88$ mag at +342 d before AT 2016jbu fades to $G = 19.72$ mag a month later.

Late time bumps and undulations in the lightcurves of SNe are commonly associated with late time CSM interaction, when SN ejecta collide with dense stratified and/or clumpy CSM far away from the progenitor, providing a source of late time energy (Fox et al. 2013; Martin et al. 2015; Arcavi et al. 2017; Nyholm et al. 2017; Andrews & Smith 2018; Moriya et al. 2020).

### 3.2 Color Evolution

There exists a growing sample of SN 2009ip-like transients which evolve almost identically in terms of their photometry and spectroscopy, in the years prior to, and during their main luminous events. The color evolution of AT 2016jbu is discussed by Ki8. However, we include color information prior to Event B maximum. Additionally we show late-time color evolution of Ki8. In addition to AT 2016jbu, we focus on a small sample of objects that show common similarities to AT 2016jbu. For the purpose of a qualitative study, we will compare AT 2016jbu with SN 2009ip (Fraser et al. 2013; Graham et al. 2014), SN 2015bh (Elias-Rosa et al. 2016; Th one et al. 2017), LSQ13zm (Tartaglia et al. 2016), SN 2015gc (Reguitti et al. 2019) and SN 2016du (Pastorello et al. 2018). We will refer to these transients (including AT 2016jbu) as SN 2009ip-like transients. We also include SN 1996al (Benetti et al. 2016) in our SN 2009ip-like sample. Although no pre-explosion variability or an Event A/B lightcurve was detected, SN 1996al shows a similar bump decay from maximum and a similar spectral evolution as well as showing no sign of explosively nucleosynthesized material; e.g. [O i] $\lambda\lambda$ 6300, 6364 even after 15 years. A modest ejecta mass and restrictive constraint on the ejected $^{56}$Ni mass are similar to what is found for AT 2016jbu and other SN 2009ip-like transients, see Paper II. Benetti et al. (2016) suggest that this is consistent with a fallback supernova in a highly structured environment, and we discuss this possibility for AT 2016jbu in Paper II. We will also discuss SN 2018cnf (Pastorello et al. 2019); a previously classified Type IIInSN (Pren tice et al. 2018). Although Pastorello et al. (2019) argues that SN 2018cnf displays many of the characteristics of SN 2009ip, it does not show the degree of asymmetry in H$\alpha$ when compared to AT 2016jbu but does show pre-explosion variability and general spectral evolution similar to SN 2009ip-like transients. Fig. 4 shows that all these transients show a relatively slow color evolution, typically seen in Type IIIn SNe (Taddia et al. 2013; Nyholm et al. 2020). Where color information is available, SN 2009ip-like transients initially appear red $\sim 1$ month before maximum light, becoming bluer as they rise to maximum light. This is best seen in ($B - V$)$_B$ for AT 2016jbu, SN 2015bh and SN 2009ip. These three transients span colors from ($B - V$)$_B$ $\sim 0.5$ at $\sim 20$ d to $\sim 0.0$ at $\sim 10$ d. In general, after the peak of Event B the transients begin to cool and again evolve towards the red. For the first $\sim 20$ days after Event B, AT 2016jbu follows the trend of other transients, which is seen clearly in ($U - B$)$_o$, ($B - V$)$_o$, ($g - r$)$_o$, and ($r - i$)$_o$. At $\sim 20$ d AT 2016jbu flattens in ($U - B$)$_o$ and ($r - i$)$_o$, similar to SN 1996al and SN 2018cnf, whereas SN 2009ip flattens at $\sim 40$ d in ($U - B$)$_o$. This phase corresponds with the plateau stage in AT 2016jbu. This feature is also seen in ($r - i$)$_o$, and ($u - g$)$_o$, where AT 2016jbu plateaus at $\sim 20$ d and then slowly evolves to the blue. This behaviour is also seen in ($B - V$)$_B$ and ($g - r$)$_o$, where a color change is observed at $\sim 50$ d, followed by AT 2016jbu remaining at approximately constant color until the seasonal gap at $\sim 120$ d. SN 2018cnf follows the trend of AT 2016jbu quite closely in ($B - V$)$_B$, but this abrupt transition to the blue is seen at $\sim 30$ d in SN 2018cnf, and $\sim 60$ d in AT 2016jbu. AT 2016jbu and SN 2018cnf are distinct in their ($g - r$)$_o$ evolution, as they match SN 2009ip and SN 2016du closely until $\sim 50$ d, after which AT 2016jbu remains at an approximately constant color, while SN 2009ip and SN 2016du make an abrupt shift to the red. Filters that cover H$\alpha$ (viz. $r$, $V$) show an abrupt color change at $\sim 60$ d in AT 2016jbu (i.e. ($B - V$)$_B$, ($g - r$)$_o$, and ($r - i$)$_o$), whereas those that do not cover H$\alpha$.
show a similar feature at $\sim 30$ d i.e. $(U - B)_0$ and $(u - g)_0$. As noted by Ki8, at this time we see an increase in the relative strength of the Hβ blue shoulder emission component (see Sect. 4.1). $(B - V)_0$: $(g - i)_0$, and $(r - i)_0$ do not show this trend but rather a transition to the blue at $\sim 60$ d. At late times, > 120 days, AT 2016jb_u remains relatively blue and follows the trends of other SN 2009ip-like transients, especially in $(B - V)_0$.

### 3.3 Ground Based Pre-Explosion Detections

A trait of SN 2009ip-like transients is erratic photometric variability\(^\text{12}\) in the period leading up to Event A and Event B.

The lower panel of Fig. 2 shows all pre-Event A/B observations for AT 2016jb_u from ground based instruments. The majority of these observations are from the PROMPT telescope array, and have been host subtracted using late

\(^{12}\) referred to as “flickering” in Kilpatrick et al. 2018.
Figure 4. Intrinsic color evolution of AT 2016jbu and SN 2009ip-like transients. All transients have been corrected for extinction using the values from Table B2. X-axis gives days from Event B maximum light. We include a broken X-axis to exclude the seasonal gap for AT 2016jbu. Data shown for AT 2016jbu has been regrouped into 1 day bins and weighted averaged. Error bars are shown for all objects, and we do not plot any point with an uncertainty greater than 0.5 mag. The different stages of evolution of AT 2016jbu are marked with grey dashed vertical bands.

For AT 2016jbu, several significant detections are found with $r \sim 20$ mag in the years prior to Event A/B. For our adopted distance modulus and extinction parameters, these detections correspond to an absolute magnitude of $M_r \sim -11.8$ mag. Similar magnitudes were seen in SN 2009ip and SN 2015bh, see Fig. 17. SN 2009ip was observed with eruptions exceeding $R \sim -11.8$ mag, with even brighter detections for SN 2015bh.

Both SN 2009ip and SN 2015bh show a large increase in luminosity $\sim 450$ d days prior to their Event A/B. The AT 2016jbu progenitor is seen in HST images around $\sim 400$ d showing clear variations. A single DECam image in $r$ band gives a detection at $r \sim 22.28 \pm 0.26$ mag at $\sim 352$ d which roughly agrees with our F350LP lightcurve at this time (if we presume Hα is the dominant contributor to the flux). We present and further discuss HST detections in Paper II.

We note that we detect a point source at the site of AT 2016jbu in several PROMPT images but not in any of the LCO, WFI, NTT+EFOSC2/SOFI, OmegaCAM or VISTA+VIRCAM pre-explosion images. However, a clear detection is made with CTIO+DECam that is compatible with our HST observations (see Paper II for more discussion of this).

In Fig. 5 we show a selection of cutouts from our host subtracted PROMPT images, showing the region around AT 2016jbu. While some of the detections that AutoPhOT recovers are marginal, others are quite clearly detected, and so we are confident that the pre-discovery variability is real. If these are indeed genuine detections, then AT 2016jbu is possibly undergoing rapid variability similar to SN 2009ip and SN 2015bh in the years leading up to the ir Event A. The high cadence of our PROMPT imaging and the inclusion of Hα in
the $L_{\text{UM}}$ filter plausibly explain why we have not detected the progenitor in outburst data from any other instrument.

AT 2016jbu could be undergoing a slow rise up until the beginning of Event A similar to UGC 2773-OT (Smith et al. 2016) (Intriguingly this is also seen in Luminous Red Novae, Pastorello et al. 2021; Williams et al. 2015 - we return to this in Paper II). Fitting a linear rise to the PROMPT pre-explosion detections (i.e. excluding the HST and DECam detections) gives a slope of $-5.4 \pm 1 \times 10^{-4}$ mag d$^{-1}$ and intercept of 19.07 $\pm$ 0.19 mag. If we extrapolate this line fit to $-60$ d (roughly the beginning of the optical observation for Event A) we find a value of $r_{\text{extrapolate}}$ $\sim 19.11$ mag which is very similar to the detected magnitude at $-59$ d of $r \sim 19.09$ mag. However, this is speculative, and accounting for the sporadic detections in the preceding years, and the non-detections in deeper images e.g. from LCO see lower panel of Fig. 2, it is more likely that AT 2016jbu is undergoing rapid variability (similar to SN 2009ip) which is serendipitously detected in our PROMPT images due to their high cadence.

### 3.4 UV Observations

Fig. 6 shows Swift+UVOT observations around maximum light. All bands show a sharp increase at $\sim -18$ d, consistent with our optical lightcurve. The Swift+UVOT can constrain the initial Event B rise to some time between $\sim -18.6$ d and $\sim -16.2$ d.

The decline of the UV lightcurve is smooth and does not show any obvious features up to +45 d. UVW2 shows a possible bump beginning at $\sim 24$ d that spans a few days. This bump is also evident in $\text{UVM2}$ at the same time. This bump is consistent with the emergence of a blue shoulder emission in $\text{Hr}$ (See Sect. 4.1) and it is possible that we are seeing an interaction site between ejecta and CSM at this time.

### 3.5 X-ray Observations

No clear X-ray source was found consistent with the location of AT 2016jbu in the XMM data taken at $-5$ d. Using the srota tool on the data from the PN camera we obtain a $3\sigma$ upper limit of $< 3.2 \times 10^{-3}$ counts s$^{-1}$ for AT 2016jbu; while the summed MOS1+MOS2 data gives a limit of $< 2.1 \times 10^{-3}$ counts s$^{-1}$. Assuming a photon index of $2$, the upper limit to the observed flux in the 0.2–10 keV energy range is $1.2 \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$.

For comparison, SN 2009ip was detected in X-rays in the 0.3–10 keV energy band with a flux of $(1.9 \pm 0.2) \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$, as well as having an upper limit on its hard X-ray flux around optical maximum (Margutti et al. 2014).

X-ray observations can tell us about the ejecta-CSM interaction as well as the medium into which they are expanding into (Dwarkadas & Gruszko 2012). The non-detection for AT 2016jbu provides little information on the nature of Event A/B. Making a qualitative comparison to SN 2009ip we note that AT 2016jbu is not as X-ray bright, and this may reflect different explosion energetics, CSM environments or line-of-sight effects.

### 3.6 MIR evolution

We measure fluxes for AT 2016jbu in Spitzer IRAC $C1 = 0.123 \pm 0.003$ mJy and $C2 = 0.136 \pm 0.003$ mJy, which are roughly consistent with those found by Ki8. This corresponds to magnitudes of $16.00$ and $15.25$ for $C1$ and $C2$ respectively. Neither this work nor Ki8 finds evidence for emission from cool dust in $C3$ and $C4$ at the progenitor site of AT 2016jbu.

We further discuss the evidence for a dust enshrouded progenitor in Paper II but here we briefly report the findings...
from K18. Coupled with pre-explosion HST observations, K18 finds that the progenitor of AT 2016jbu is consistent with the progenitor system having a significant IR excess from a relatively compact, dusty shell. The dust mass in the immediate environment of the progenitor system is small (a few $10^{-6} M_\odot$). However, the different epochs of the HST (taken in 2016) and Spitzer (taken in 2003) data suggest they may be at different phases of evolution. Fig. 2 shows that the site of AT 2016jbu underwent multiple outbursts between 2006 and 2013, and, as mentioned by K18, fitting a single SED to the HST and Spitzer datasets may be somewhat misleading.

4 SPECTROSCOPY

We present our high cadence spectral coverage of AT 2016jbu in Fig. 7. Our spectra begin at $\sim$31 days and show an initial appearance similar to a Type IIn SN, i.e. narrow emission features seen in H and a blue continuum. Our first spectra coincide with the approximate peak of Event A. After around a week, additional absorption and emission features emerge in the Balmer series, which we illustrate in Fig. 8 and plot the evolution of in Fig. 9. The spectrum does not vary significantly over the first month of evolution aside from the continuum becoming progressively bluer with time. Hα shows a P Cygni profile with an emission component with FWHM $\sim$1000 km s$^{-1}$ and a blue shifted absorption component with a minimum at $\sim$−600 km s$^{-1}$. The narrow emission lines likely arise from an unshocked CSM environment around the progenitor. Over time AT 2016jbu develops a multi-component emission profile seen clearly in Hα that persists until late times. We do not find any clear signs of explosively nucleosynthesised material at late times, and indeed the spectral evolution appears to be dominated by CSM interaction at all times. We discuss the evolution of the Balmer series in Sect. 4.1. In Sect. 4.2 we discuss the evolution of Ca ii features and model late time emission profiles. Sect. 4.3 discusses the evolution of several isolated, strong iron lines. Sect. 4.4 discusses the evolution of He i emission and makes qualitative comparisons between He i features and the optical lightcurve. We present UV and NIR spectra in Sect. 4.6 and Sect. 4.7 respectively.

4.1 Balmer Line Evolution

The most prominent spectral features are the Balmer lines, which show dramatic evolution over time. In particular the Hα profile, which shows a complex, multi-component evolution, provides insight to the CSM environment, mass-loss history and explosion sequence. Although SN 2009ip never displayed obvious multi-component emission features, a red-shoulder emission is seen at late times (Fraser et al. 2013). We present the evolution of Hα for AT 2016jbu at several epochs showing the major changes in Fig. 8.

K18 discuss the evolution of the Hα in detail out to $+118$ days. With our high cadence spectral evolution we perform a similar multi-component analysis while focusing on individual feature evolution. Similar to K18, we conducted spectral decomposition to understand line shape and the ejecta-CSM interaction. We used a Markov Chain Monte Carlo (MCMC) approach for fitting a multi-component spectral profile (Newville et al. 2014) using a custom python3 script. When fitting, absorption components are constrained to be blueward of the rest wavelength of each line to reflect a P Cygni absorption. All lines are fitted over a small wavelength window and we include a pseudo-continuum during our fitting, which is allowed to vary. Fitting the Hα evolution is performed on each spectrum consecutively, using the fitted parameters from the previous model as the starting guess for the next. This is reset after the observing gap at $+202$ days. Fig. 8 presents fitted models to the Hα profile at epochs where significant change are seen. The FWHM and peak wavelength for Hα are illustrated in Fig. 9.

Days $-31$ to $-25$: Similar to K18, our first spectrum coincides with the approximate peak of Event A (Fig. 2). Hα can be modelled by a P Cygni profile with an absorption minimum at $\sim$700 km s$^{-1}$ superimposed on a broad component at $\sim$+700 km s$^{-1}$ with a FWHM of $\sim$2600 km s$^{-1}$. This can be interpreted as a narrow P Cygni with extended, electron-scattering wings, as often seen in Type IIn SN spectra (see review by Filippenko 1997).

Days $-14$ to $+4$: We see a gradual decay in amplitude of the core broad emission until we find a best fit by a single intermediate width Lorentzian profile (FWHM $\sim$1000 km s$^{-1}$) and P Cygni absorption. Our Lorentzian profile has broad wings, possibly due to electron scattering along the line-of-sight (Chugai 2001). For further discussion, see K18.

At $-14$ days, a blue broad absorption component clearly emerges at $\sim$−5000 km s$^{-1}$ with an initial FWHM of $\sim$3800 km s$^{-1}$, with the fastest material is moving at $\sim$10,000 km s$^{-1}$. This feature was not seen in K18 due to a lack of observations at this phase. The trough of this absorption features slow to $\sim$3200 km s$^{-1}$ at $+3$ d. Panel B in Fig. 8, shows Hα at $-1$ days with a strong Lorentzian emission with the now obvious blue absorption. This feature indicates that there is fast moving material that was not seen in the initial spectra. Assuming free expansion, we set an upper limit on the distance travelled by this material to $\sim$2.5 $\times$ 10$^{16}$ cm.

Similar feature was also seen in SN 2009ip, (e.g. Fig. 2 of Fraser et al. 2013) around the Event B maximum. A persistent second absorption feature was also seen in SN 2015bh (Ellias-Rosa et al. 2016) which remained in absorption until several weeks after the Event B maximum, when it was replaced by an emission feature at approximately the same velocity.

Days $+7$ to $+34$: A persistent P Cygni profile is still seen but a dramatic change is seen in the overall Hα profile, now being dominated by a red-shifted broad Gaussian feature centered at $\sim$+2200 km s$^{-1}$ and FWHM $\sim$4000 km s$^{-1}$. The blue absorption component has now vanished and been replaced with an emission profile with a slightly lower velocity, $-2400$ km s$^{-1}$ at $+18$ d, seen in panel C of Fig. 8. Over the following month, this line moves towards slower velocities with a decreasing FWHM. The blue shoulder emission is clearly seen at $\sim$+18 d and remains roughly constant in amplitude (with respect to the core component) until $\sim$+34 d. At $+34$ d this line now has a FWHM $\sim$2700 km s$^{-1}$. By $+52$ d this blue emission line has grown considerably in amplitude with respect to the core component. During this period the relative strength of the red and blue component begins to change, indicating on-going interaction and/or changing opacities. We note that prior to $+52$ d, this Hα profile may.
Figure 7. Spectral evolution of AT 2016jbu. Wavelength given in rest frame. Flux given in log scale. Prominent spectral lines and strong absorption bands are labelled. Colors instruments used (see Table 1); black: NTT+EFOSC2, blue: FTS+FLOYDS, red: WiFeS, green: DuPont. Spectra marked with an asterisk have been smoothed using a Gaussian filter of FWHM 1 Å.

be fitted with a single, broad emission component with a P Cygni profile. However, during our fitting a significant blue excess was always present during +7 d to +34 d. Allowing for both a blue and red emission component during these times, allows each consistent component to evolve smoothly into later spectra, as is seen in Fig 8 and Fig. 9.

Days +52 to +120: As mentioned in by K18, Hα shows an almost symmetric double-peaked emission profile. The earliest profile of Hα at −31 d is reminiscent of some stages during an eruptive outburst from a massive star (for example Var C; Humphreys et al. 2014). We plot the profile of the +90 d profile in Fig. 10 with a blue-shifted Lorentzian profile removed.
The profiles are very similar in overall shape with a slightly broader red-core component in the +90 d spectrum. A possible interpretation is the P Cygni-like profile seen in our −31 d spectra is associated with the events during/causeing Event A (for example a stellar merger or eruptive outburst) and the blue side emission is associated with events during/causeing Event B (for example a core-collapse or CSM interaction).

Days +203 to +420: We present late-time spectra of AT 2016jbu not previously covered in the literature. The red and blue components of the Hα profile now have similar FWHM of ∼2100 km s$^{-1}$ and ∼1600 km s$^{-1}$ respectively. The overall Hα profile has retained its symmetric appearance (panel D of Fig. 8). After this time we no longer fit a P Cygni absorption profile, and our spectra can be fitted well using three emission components. We justify this as any opaque

---

**Figure 8.** Multi-component evolution of Hα over a period of ∼1 year. We use Lorentzian emission and Gaussian absorption profiles at early times (phase < +120 d), and Gaussian emission and absorption thereafter. Epochs are given in each panel, lines are coloured such that yellow = core emission, red = redshifted emission, green = P-Cygni absorption, cyan = high velocity absorption and blue is blueshifted emission. In panel A an additional emission component could be included to account for the blue excess shown, although this can simply be extended electron scattering wings.

**Figure 9.** Evolution of fitted parameters for Hα. The upper panel shows the absolute velocity evolution of each feature. We fit a power decay law with index 0.4 dex to the blue emission from when it first appears (∼+18d) until the seasonal gap (∼+125 d) indicated by the blue dashed line. The is also fitted for the red shoulder emission (with a different normalisation constant) as the red dashed line. We include a purple dotted line at 1200 km s$^{-1}$ that matches the late time red and blue emission components. The lower panel shows the FWHM evolution of each of the components. We do not plot the redshifted broad emission fitted during the first three epochs in either panel.

**Figure 10.** Hα profile at −31 d (red) and +90 d (green) for AT 2016jbu. The +90 d profile has had a strong blue emission profile (given by dotted blue line) subtracted and we plot the residual in green. Each spectra is normalised at 6563 Å. The profile at +90 d has been blue-shifted by 4 Å (∼−180 km s$^{-1}$) to match the peak at the Hα rest wavelength (6563 Å) of the profile at −31 d.
photometric and spectroscopic evolution of the interacting transient, AT 2016jbu

Figure 11. Calcium NIR triplet fit for +345 d. The individual components of the primary Ca ii NIR triplet is given by the blue dashed lines in both plots. The upper panel shows the emission profile with the inclusion of O i λ8466 (in green). The lower panel shows the model fit in blue (Region A) with the second region of Ca ii NIR triplet emission shown in purple (Region B). Both O i λ8466 and a second region of Ca emission give a similarly acceptable fit to the data.

material may have become optically thin after ∼ 7 months and the photospheric phase has ended.

Little evolution in Hα is seen for the remainder of our observations. The three emission profiles remain at the respective wavelengths and the approximate same width. The overall evolution of Hα suggests that AT 2016jbu underwent a large mass loss event (whether that be a SN or extreme mass loss episode) in a highly aspherical environment. Interaction with dense CSM forming a multi-component Hα profile as well as a bumpy lightcurve.

4.2 Calcium Evolution

Sect. 4.1 indicates that AT 2016jbu has a highly non-spherical environment. We investigate similar trends in other emission profiles. Ki18 suggest that the [Ca ii] and Ca ii NIR triplet may be coming from separated regions. Motivated by this, we explore the Ca ii NIR triplet λλλ 8498, 8542, 8662 using the same method in Sect. 4.1. The Ca ii NIR triplet appears in emission at approximately the same time as blue-shifted emission in Hα (∼ +18 d) and at early times shows P Cygni absorption minima at velocities similar to Hα. For profile fitting, the wavelength separation between the three components of the NIR triplet was held fixed, while the three components were also constrained to have the same FWHM. Amplitude ratios between the three lines were constrained to physically plausible values between the optically thin and optically thick regimes (Herbig & Soderblom 1980).

The early evolution of the Ca ii NIR triplet is detailed in Ki18. We explore two scenarios for the Ca ii NIR triplet evolution after −200 d. In the first, we assume that the Ca ii emission comes from the same regions as Hα (as suggested in Sect. 4.1) i.e two spatially separated emitting regions. We allow the first region to be fitted with the above restrictions (fixed line separation, single common FWHM), we refer to this as Region A. A second, kinematically distinct, multiplet is added (we refer to this as Region B) and simultaneously fitted with additional constraints; the lines have the same FWHM as the region A and the amplitude ratio of the Ca ii NIR triplet being emitted from region B is some multiple of the region A. Region B represents this blue-shifted material seen in Hα. The second scenario has an additional Gaussian representing O i λ8446 fitted independently to a single Ca ii emitting region.

As shown in Fig. 11, both scenarios give an acceptable fit to spectrum at +345 d. Fitting a single Gaussian emission line representing O i λ8446 gives a reasonable fit with FWHM∼ 4000 km s⁻¹ redshifted by ∼ 800 km s⁻¹. Alternatively, adding an additional Ca ii emission profile we find a good fit at FWHM∼ 2000 km s⁻¹ and blue-shifted by ∼ −2800 km s⁻¹. Although the scenarios are inconclusive, this does not exclude a complex asymmetrical CSM structure producing these multiple emitting regions along the line-of-sight.

Although both scenarios give reasonable fits, the FWHM and velocities deduced for both scenarios are not seen elsewhere in the spectrum at +345 d. It is possible that the region(s) producing the Ca ii NIR triplet is separated from Hα emitting areas as although detailed modelling is needed to confirm. We note however one should expect a similar flux from O i λ7774 when assuming the presence of O i λ8446 which is not the case here. If both lines are produced by recombination, we expect similar relative intensities (Kramida et al. 2020). Interestingly, this is also trend is also seen in SN 2009ip (Graham et al. 2014).

Our final spectra on +385 d and +420 d show the Ca ii NIR triplet and [Ca ii] having a broadened appearance compared to earlier spectra. This may indicate an increase in the velocity of the region where these lines form, similar to what is seen in Hα in Sect. 4.1.

4.3 Iron Lines

As temperatures and opacities drop the spectra of many CCSNe become dominated by iron lines, as well as Na i and Ca ii. We notice persistent permitted Fe ii group transitions throughout the evolution of AT 2016jbu which is likely pre-existing iron in the progenitor envelope. Our initial spectra display the Fe ii λλλ 4924, 5018, 5169 (multiplet 42) as P Cygni profiles, see Fig. 3. At −31 d we measure the absorption minimum of Fe ii multiplet 42 at −750 km s⁻¹. This is the same velocity as the fitted absorption profile from Hα/Hβ see Fig. 8A. We can assume that this lines originate in similar regions.

The Fe ii multiplet 42 appears in our late time spectra, see Fig. 12. Fe ii lines in general appear with P Cygni profiles at late times. It is difficult to measure the absorption minimum of the Fe ii profile due to severe blending. However, using several relatively isolated Fe ii lines at +345 d we measure an absorption minimum of ∼ −1300 km s⁻¹. The values is similar to the velocity offset for the red and blue emission components seen in Hα. This suggest that these lines are originating in the same region.
4.4 Helium Evolution

None of the He i lines display the degree of asymmetry seen in hydrogen. Transients exist displaying double-peaked helium lines, such as the Type Ibn SN 2006jc; (Foley et al. 2007; Pastorello et al. 2008), as well as some displaying asymmetric He i and symmetric H emission e.g. the Type Ibn/IIb SN 2018gjx (Prentice et al. 2020).

We show the evolution of He i λ65876 (black line) and He iλ7065 (green line) in Fig. 13. He iλ7065 first appears in emission on −14 d with a boxy profile that is poorly fit with a single Lorentzian emission line. He iλ7065 then becomes more symmetric by +18 d. Note the blue absorption feature in Hα is also first seen at this time. The line begins to broaden over the next month, peaking at FWHM~3400 km s⁻¹ at ~ +28 d. After +51 d, He iλ7065 is no longer detected with any reasonable S/N.

Interestingly, He iλ7065 then re-emerges at +200 d, the emission feature has FWHM ~ 1100 km s⁻¹ centered at rest wavelength. We see this same FWHM in the red and blue shoulders in Hα (Sect. 4.1). We find that a single emission profile matches the He iλ7065 line well after +200 d. However, motivated by the multi-component profile of Hα we also find that He iλ7065 after +200 d can be fitted equally well with two emission components. In this case, both components are offset by ~ ±400 km s⁻¹ from their rest wavelength, and each has a FWHM of ~ 1000 km s⁻¹. Unlike Hα, no third core emission component is needed.

For He iλ5876, in our −31 d spectrum there is a clear P Cygni profile centered at 5898 Å. The emission is likely caused by Na I D with the possibility of some absorption contamination from He iλ5876. We measure a velocity offset of ~ −450 km s⁻¹ with respect to 5890 Å. At −13 d, He iλ5876 emerges and has a complicated, multi-component profile with contamination from Na I D. Emission centered on 5876 Å persists until +20 d, after which the emission returns to being dominated by Na I D.

Low resolution spectra preclude further investigation, but if He iλ7065 is composed of two emission profiles, these two emission regions are at significantly lower velocity when com-
compared to the similar components in Hα. An increase in the strength of He i was also seen in the Type II SN 1996al and was interpreted as a signature of strengthening CSM interaction (Benetti et al. 2016).

He i λ6678 evolves in a similar manner to He i λ7065, but shows a clear P Cygni profile as early as −14 d with an absorption trough at ~ −500 km s⁻¹, similar to Hα. After the seasonal gap He i λ5876 is not clearly seen. At +345 d we measure a Gaussian emission profile centered at 5897 Å with a FWHM ~ 1800 km s⁻¹. This is likely dominated by Na I D with minor contamination from He i λ5876. The

FWHM value for this line suggests that it is coming from the site of AT 2016jbu and not due to host contamination.

We plot the evolution of the pseudo-Equivalent Width (pEW) (a pseudo-continuum is fitted over a small wavelength window) of the two seemingly isolated He i λ 6678, 7065 emission lines in Fig. 14. We note that there is little change in pEW for the first ~ 120 days. After the seasonal gap, both emission lines increase dramatically in pEW, until ~ +300 d after which the pEW declines. A similar jump in He i was seen in SN 1996al (Benetti et al. 2016). This decline coincides with the narrowing and increase in amplitude of the blue, red, and core emission components of Hα.

He i emission is expected to be formed in the de-excitation/recombination region of the shock wave (Chevalier & Kirshner 1978; Gillet & Fokin 2014). As mentioned in Sect. 4.1, after ~ 2 months, the blue shifted emission in Hα grows in amplitude and narrows considerably, likely due to changing opacities. This jump in pEW may represent a time when shocked material is no longer obscured and photons can escape freely from the interaction sites. We reach a similar conclusion for He i. If the trend in both He i lines is linked to the Hα emitting regions, then it is likely that the late time He i might also be double-peaked.

Fig. 2 shows a rebrightening/flattening after the seasonal gap. This is seen best in Gaia-G. The trend seen in He i λ 6678 and λ 7065 pEW may follow the interaction of the shock front with some clumpy dense material far away from the progenitor site. This would reflect a stratified CSM profile possibly produced by the historic eruptions, or possibly a variable wind, in AT 2016jbu.

4.5 Forbidden Emission Lines

A clear sign of a terminal explosion is forbidden emission lines from material formed during explosive nucleosynthesis/late-time stellar evolution. All CCSNe will eventually cool down.
sufficiently for the photosphere to recede to the innermost layers of the explosion. We expect to see the signatures of material synthesised in the explosion as well as material produced in the late-stages of stellar evolution such as [O i] $\lambda\lambda 6300, 6364$ or Mg i] $\lambda 4571$ (Jerkstrand 2017). Fig. 12 shows the late time spectra of AT 2016jbu highlighting prominent emission lines. Tenuous detections are made of [O i] and Mg i], although these lines are much weaker than are typically seen during the nebular phase of CCSNe. Late time spectra show that there is on-going CSM interaction for AT 2016jbu, as is clear for the double-peaked Hα emission. The spectra are still relatively blue (i.e. Fig. 12, $\lambda \lambda 5600 \AA$) even after 1 year, again indicating interaction in the CS environment.

It is a common conclusion for SN 2009ip-like transients that there are only tenuous signs of core-collapse (Fraser et al. 2013; Benetti et al. 2016). Fraser et al. (2013) find no clear signs of any such material during the late nebular phase of SN 2009ip. SN 2009ip showed little indication of a nebular phase and in 2012 showed spectral features similar to its 2009 appearance. Benetti et al. (2016) finds no evidence of nebular emission features in SN 1996al even after 15 yrs of observations. For AT 2016jbu one may posit that if the transient is indeed a CCSNe, on-going interaction has led to densities too high for forbidden lines to form. Alternatively, fallback onto a compact remnant could result in an apparently small mass of synthesized heavy elements, and hence an absence of nebular CCSN features. We will expand further on the nature of AT 2016jbu and SN 2009ip-like transients, their powering mechanism and the possibility that the progenitor survived, in Paper II.

4.6 UV spectrum

We present a single UV spectrum in Fig. 15 taken with Swift+UVOT on 2017 January 22. The spectrum has quite low S/N towards the red with a very tenuous detection of the Balmer series. It is likely that $\lambda > 4000$ Å is affected by second order contamination. The continuum of AT 2016jbu deviates significantly from a blackbody at short wavelengths ($\lambda < 2400$ Å) mainly due to blends of lines of singly ionized iron-peak elements.

A broad (FWHM $\sim 5000$ km s$^{-1}$) emission line is the strongest feature seen. It is centered at $\sim 2630$ Å and is well fitted with a single Gaussian. We are unsure of the identification of this emission line, however there is a strong Fe ii line at $\sim 2631$ Å (Kramida et al. 2020; Nave et al. 1994).

It is curious that there is a strong Fe ii line here and no other emission features at comparable strength. Swift observations of SN 2009ip do show this emission line but it is much weaker than that seen in AT 2016jbu (Margutti et al. 2014). This particular emission line has been seen in several Type IIP SNe with UV coverage such as SN 1999em and SN 2005cs (see Gal-Yam et al. 2008, and references therein). However, the Type IIP SNe discussed by Gal-Yam et al. (2008) also show strong emission from Mg ii $\lambda 2800$. AT 2016jbu shows a weaker P Cygni feature centered at 2800 Å with an absorption at $\sim 12000$ km s$^{-1}$ which is likely due to Mg ii $\lambda 2800$. Detailed spectral modelling is needed to secure this line identification.

4.7 NIR spectra

We present our NIR spectra in Fig. 16 covering the peak of Event A as well as the rise and peak of Event B. Paβ $\lambda 12822$ follows the same evolution as Hα, with a strong blue absorption profile that is not present in the $\sim 31$ d FIRE spectrum but which appears in the FLAMINGOS-2 $\sim 12$ d spectra. At this phase the blue absorption is already seen in Hα and Hβ. Paβ is also broader at $\sim 31$ d and narrows at $\sim 12$ d, similar to the Hα evolution shown in Fig. 8 at $\sim 31$ d and $\sim 1$ d.

There is a strong He i $\lambda 10830$ line blended with Paβ. At $\sim 31$ d this line appears in absorption at rest wavelength, while by $\sim 12$ d the line is in emission. This helium feature may be thermally excited and this is supported by the blackbody temperature seen peaking at this time (see Paper II). We see an absorption trough bluewards of $\lambda 10830$ which may be associated with Paβ $\lambda 10941$ (as a similar absorption is seen in Paβ). There appears to be a flux excess beyond 2.1 μm in the FIRE spectrum at $\sim 31$ d. This may represent emission from a CO bandhead, possibly signifying some pre-existing dust during Event A. However, the S/N is extremely low in this region of the spectrum (see the grey shaded region in Fig. 16), and it is likely that the apparent "excess" is due to bright K-band sky contamination rather than CO emission.

5 DISCUSSION

We will discuss AT 2016jbu and their relation to SN 2009ip-like objects, mainly their photometric similarities in Sect. 5.1.1 and their spectroscopic appearance in Sect. 5.1.2, in particular the appearance of their Hα emission profiles is varies times during their evolution (Sect. 5.1.3).

5.1 AT 2016jbu and other SN 2009ip-like transients

For this paper we focus the discussion on the photometric and spectral comparison between AT 2016jbu and similar transients. In Paper II we discuss topics including the progenitor of AT 2016jbu using pre-explosion images, the environment around the progenitor and a non-terminal explosion scenario.

5.1.1 Photometric Comparison

We compare the $R/r$-band lightcurves of a sample of SN 2009ip-like transients events in Fig. 17. In cases where $r$-band photometry was not available, Johnson-Cousin $R$-band is shown. The adopted extinction and distance moduli are given in Table B2. The photometric evolution for SN 2009ip-like transients is undoubtedly similar. Our sample of transients all show a series of outbursts in the years prior to Event A, as seen in Fig. 17. This has been described as historic "flickering" by K18. AT 2016jbu shows several clear detections within $\sim 10$ years before the peak of Event B. Similar outbursts are seen in other SN 2009ip-like transients (see Fig. 17).

The duration of Event A varies between each transient. For SN 2009ip, Event A lasts for $\sim 1.5$ months (Fraser et al. 2013) and rises to $\sim 15$ mag. LSO13zm shows a rise to $\sim 14.8$ mag and has a time frame of a few weeks (Tartaglia et al. 2016). All transients show a fast rise of $\sim 17$ days to maximum in Event B to $\sim 18 \pm 0.5$ mag followed by a
Figure 15. *Swift* + UVOT spectrum for AT 2016jbu taken on 2017 January 22 (MJD: 57775, Phase: $-18 \, d$). Wavelength in given in rest frame and the spectrum is corrected for Galactic extinction ($A_V = 0.556 \, \text{mag}$). The spectrum is given in black with the grey shaded region showing the uncertainty. The trough around 2000 Å is likely noise which is likely exacerbated by our extinction correction.

Figure 16. NIR spectra of AT 2016jbu, covering the peak of Event A as well as the rise and peak of Event B. H and He i are clearly seen in all spectra. The FIRE spectrum (blue) has been smoothed for presentation and shows what appears to be an excess redwards of 2.05 μm. This excess is likely due to spectra being saturated by the bright K-band sky.

Figure 17. Pre-explosion outbursts and the main luminous event for the sample of SN 2009ip-like transients. SN 2009ip (Sloan r) is taken from Fraser et al. (2013); Graham et al. (2014), SN 2015bh (R) from Thöne et al. (2017), SN 2016bdu (r) from Pastorello et al. (2018), SN 2013gc (R) from Reguiiti et al. (2019), SN 1996al (R) from Benetti et al. (2016), SN 2018cnf (r) from Pastorello et al. (2019), and LSQ13zm (R) is taken from Tartaglia et al. (2016). All data given in Vega magnitudes (Blanton & Roweis 2007). We do not show limiting magnitudes in this figure for clarity. All events show an initial rise to a magnitude of $\sim 14$ (if coverage available) followed by a second rise to $\sim -18$ roughly 30 days later. Our sample of SN 2009ip-like transients all show outbursts in the months/years prior to their luminous events.
rapid/bumpy decay. Kiewe et al. (2012) found that a magnitude of $-18.4$ is typical for Type II In SNe. Using a larger sample size, Nyholm et al. (2020) find a larger value for the mean value although Event A peak is still within a standard deviation of this.

Curiously, several of the transients in our sample show their first initial bump around the same time, approximately 20 days post maximum; see Fig. 18. AT 2016jbu shows no major bumps in its lightcurve, but instead flattens slightly, whereas SN 2009ip and SN 2018cnf show a clear and prominent bump at $\sim 20$ d.

From $\sim 60 - 120$ d, AT 2016jbu appears to follow the extrapolated decline of SN 2009ip (see Fig. 18). However, when AT 2016jbu emerged from behind the Sun at $+200$ d, it shows a large increase in magnitude in all bands. No other SN 2009ip-like transient shows a comparable behaviour. At $\sim 200$ d, AT 2016jbu is almost $1$ mag brighter than SN 2009ip. We see a change in He i pEW (see Sect. 4.4) which is not clearly seen in H$\alpha$ at this time and may reflect enhanced interaction with a complex CSM environment.

5.1.2 Spectroscopic Comparison

The spectra of SN 2009ip-like transients remain remarkably similar as they evolve. Fig. 12 shows our sample of extinction corrected SN 2009ip-like transients at several phases during their evolution. All objects initially similar to Type II In SNe, with $T_{BB} \sim 10,000$ K and prominent narrow lines seen in the Balmer series.

In Fig. 19 we compare the appearance of SN 2009ip, AT 2016jbu, and SN 2015bh around the time of their Event A maxima. We also include the apparent pre-explosion outburst of SN 2015bh (Thöne et al. 2017) seen in 2013 ($\sim 1.5$ years before the possible SN). This spectrum of SN 2015bh shows a very narrow H$\alpha$ profile that is fitted well with a single P-Cygni profile, and is reminiscent of a LBV in quiescence (Thöne et al. 2017). All four transients show a blue continuum with narrow emission features seen mainly in the Balmer series and Re. Where they differ is in the presence or absence of a broad component in H$\alpha$. SN 2009ip is dominated by a $\sim 13000$ km s$^{-1}$ absorption feature and strong narrow emission line. AT 2016jbu shows a broader emission component ($FWHM \sim 2600$ km s$^{-1}$) with a P-Cygni absorption feature at $\sim 700$ km s$^{-1}$. Similarly SN 2015bh shows a broad emission profile like AT 2016jbu and also lacks any broad absorption at this time. Although these transients evolve similarly (see below), our earliest Event A spectra suggest that the explosion mechanism for these transients may be quite diverse. This argument is strengthened by the variety among Event A lightcurves (inset in Fig. 18). It is a puzzle why these transients appear to evolve similarly during and after Event B but show such diversity during Event A. In particular, the presence of fast material during Event A of SN 2009ip was suggested to be evidence that the progenitor has undergone core-collapse (Mauerhan et al. 2013). If this is true, then the absence of high velocity features in the other transients must be explained by different CSM configuration or viewing angle effects. If geometry is a strong contributor to the appearance of these transients, then one can not ignore the possibility that Event A for each transient is a result of a similar explosion mechanism e.g. a low luminosity Type II SN (Elias-Rosa et al. 2016; Mauerhan et al. 2013; Margutti et al. 2014).
5.1.3 Ha comparison

We show a zoom in on Ha in Fig. 20, where the spectra are plotted in order of “double-peaked”-ness i.e. according to the level of double-peaked nature of the Ha line profile. We arbitrarily define double-peaked -ness as the strength and separation between the two emission peaks (if any) seen in Ha. All objects also appear to show an additional high velocity blue absorption in their Balmer lines (panel B of Fig. 20)\(^\text{13}\). At intermediate times, \(\sim 3\) months after maximum, all transients (excluding SN 2009ip) show clear evidence of strong multi-component profiles. AT 2016jbu shows the strongest appearance of a double-peaked profile, whereas SN 2009ip show the least, with weak evidence of some blue excess.

After \(\sim 10\) months, all transients show multi-component profiles in Ha. Each transient displays different velocity and FWHM values for their red and blue components. For SN 2009ip, Fraser et al. (2015) notes a red component at +500 km s\(^{-1}\) at late times, this shoulder is also seen in H\(\beta\). We measure the same component at +625 km s\(^{-1}\) while fitting for an additional blue component at -510 km s\(^{-1}\). Our fit is illustrated in Fig. 21. In the case of SN 2009ip, this red shoulder only appeared at \(\sim 5.5\) months after maximum light, whereas there is evidence of this red shoulder as early as a week after maximum for AT 2016jbu. This is likely due to geometric inclination effects along the line-of-sight, with SN 2009ip being the most edge on and AT 2016jbu being the more face on. Ejecta-disk models by Kurfürst et al. (2020) show this profile shape versus line-of-sight effect.

We include a close up of the Ha profile of \(\eta\) Car in Fig. 20, based on VLT+MUSE observations taken on 2014 Nov. 13. This spectrum was extracted from spaxels with a 14“ radius of \(\eta\) Car after masking nearby stars. \(\eta\) Car displays a multi-peaked Ha profile similar to what we see in our SN 2009ip-like transients events, albeit at a lower velocity. A similarly shaped profile is also seen in spectra obtained from light echoes of the Great Eruption (GE) (Smith et al. 2018). This resemblance raises the tantalising possibility that \(\eta\) Car and SN 2009ip-like transients share similar progenitors or progenitor systems. To date, it is still uncertain what caused the GE in \(\eta\) Car, although commonly discussed scenarios include a major eruption triggered by a merging event in a triple stellar system (Smith et al. 2018), mass transfer from a secondary star during periastron passages (Kashi & Soker 2010) or even a pulsational pair-instability explosion (Woosley et al. 2007).

Despite the asymmetric Ha emission lines, curiously no other lines show such asymmetry, in particular He i. However, we cannot exclude that this is simply due to lower S/N in these other lines, or that their lower velocities mean that any signs of asymmetry are masked by our moderate instrumental resolution.

6 CONCLUSION

In this paper, we have presented the results of our follow-up campaign for AT 2016jbu consisting of high cadence photometry up to \(\sim 1.5\) years after maximum light, together with spectra spanning \(-31\) to \(+420\) days covering the UV, optical and NIR. We also present historical observations over the preceding decade from ground based observations. In summary, the salient points of this work are:

- AT 2016jbu displays variability in the years prior to maximum light, with outbursts reaching \(M_r \sim -11.5\) mag, and a double-peaked lightcurve. The first peak reaches \(M_r \sim -13.5\) mag and the second reaches a SN-like magnitude of \(M_r \sim -18.26\) mag, with both peaks separated by \(\sim 1\) month.
- AT 2016jbu shows a smooth lightcurve with a major re-brightening event occurring after the seasonal gap (\(\sim 200\) days). An increase in He i emission is seen during this time, which may be a sign of increased interaction.
- AT 2016jbu appears spectroscopically and photometrically alike to SN 2009ip, SN 2015hj, SN 2016du, SN 1996al, SN 2013gc and SN 2018cnf. However, the increase in brightness at \(\sim +200\) d is unique to AT 2016jbu with respect to our sample of SN 2009ip-like transients. The color evolution is similar amongst all SN 2009ip-like transients. Color changes can be linked with the appearance of the red and blue emission components seen in Ha.
- The Ha profiles of each transient show an apparent continuum of asymmetry and we deduce that this may be caused by an geometric inclination effect.
- AT 2016jbu and other SN 2009ip-like transients do not exhibit signs of explosive nucleosynthesis at late times such as [O i] \(\lambda\) 6300, 6364 or [Mg i] \(\lambda\) 4571. On-going CSM interaction may be inhibiting these features and/or obscuring their emitting regions.

AT 2016jbu and the SN 2009ip-like transients are peculiar objects. If they are indeed SNe then their progenitors undergo an unusual and poorly-understood series of eruptions in the years prior to core-collapse. If these events are non-terminal and the progenitor star will be revealed in the future, it begs the question what sort of mechanism can produce such an energetic explosion.

In Paper II we continue the discussion of AT 2016jbu and SN 2009ip-like transients using the data presented here, focusing on the local environment, the progenitor and modeling of the light-curve.

N.E.R. acknowledges support from MIUR, PRIN 2017 (grant 20179ZF5KS). L.G. acknowledges financial support from the Spanish Ministry of Science, Innovation and Universities (MICIU) under the 2019 Ramón y Cajal program PID2020-115253GA-I00. Support for TW-SH was provided by NASA through the NASA Hubble Fellowship grant HST-HF2-51458.001-A awarded by the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., for NASA, under contract NAS5-26555. Support for JLP is provided in part by ANID through the Fondecyt regular grant 1910938 and through the Millennium Science Initiative grant ICN12-009, awarded to The Millennium Institute of Astrophysics, MAS. D.A.H and D.H are supported by AST-1911151, AST19-11225, and NASA Swift grant 80NSSC19K1639. G.P acknowledges support by the Ministry of Economy, Development, and Tourism’s Millennium Science Initiative through grant IC120009, awarded to The Millennium Institute of Astrophysics, MAS. L.T. acknowledges support from MIUR (PRIN 2017 grant 20179ZF5KS). H.K. was funded by the Academy of Finland projects 324504 and 328898.

This research made use of Astropy14, a community-developed core Python package for Astronomy (Astropy Collaboration et al. 2013; Price-Whelan et al. 2018). This research made use of data provided by Astrometry.net15. This research has made use of the NASA/IPAC Extragalactic Database (NED), which is operated by the Jet Propulsion

Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration. We acknowledge the use of public data from the Swift data archive. This work made use of data supplied by the UK Swift Science Data Centre at the University of Leicester. We acknowledge Telescope Access Program (TAP) funded by the NAOC, CAS, and the Special Fund for Astronomy from the Ministry of Finance. This work was partially supported from Polish NCN grants: Harmonia No. 2018/30/M/ST9/00311 and Daina No. 2017/27/L/ST9/03221. Parts of this research were supported by the Australian Research Council Centre of Excellence for All Sky Astrophysics in 3 Dimensions (ASTRO 3D), through project number CE170100013. This work is based in part on observations made with the Spitzer Space Telescope, which was operated by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA. Support for this work was provided by NASA through an award issued by JPL/Caltech. This work made use of v2.2.1 of the Binary Population and Spectral Synthesis (BPASS) models as described in Eldridge et al. (2017) and Stanway & Eldridge (2018).

This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. This paper includes data gathered with the 6.5-meter Magellan telescopes located at Las Campanas Observatory, Chile. This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration. This research is based on observations made with the NASA/ESA Hubble Space Telescope obtained from the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. These observations are associated with program 15645. Observations were also obtained from the Hubble Legacy Archive, which is a collaboration between the Space Telescope Science Institute (STScI/NASA), the Space Telescope European Coordinating Facility (ST-ECF/ESAC/ESA) and the Canadian Astronomy Data Centre (CADC/NRC/CSA). This work made use of data from the Las Cumbres Observatory network. We thank the Las Cumbres Observatory and its staff for its continuing support of the ASAS-SN project. ASAS-SN is supported by the Gordon and Betty Moore Foundation through grant GBMF5490 to the Ohio State University, and NSF grants AST-1515927 and AST-1908570. Development of ASAS-SN has been supported by NSF grant AST-0908816, the Mt. Cuba Astronomical Foundation, the Center for Cosmology and Astroparticle Physics at the Ohio State University, the Chinese Academy of Sciences South America Center for Astronomy (CAS–SACA), and the Villoum Foundation. This research has made use of the SVO Filter Profile Service supported from the Spanish MINECO through grant AYA2017-84089. We acknowledge ESA Gaia, DPAC and the Photometric Science Alerts Team. This project used data obtained with the Dark Energy Camera (DECam), which was constructed by the Dark Energy Survey (DES) collaborating institutions: Argonne National Lab, University of California Santa Cruz, University of Cambridge, Centro de Investigaciones Energéticas, Medioambientales y Tecnológicas-Madrid, University of Chicago, University College London, DES-Brazil consortium, University of Edinburgh, ETH-Zurich, University of Illinois at Urbana-Champaign, Institut de Ciencias de l’Espai, Institut de Física d’Altes Energies, Lawrence Berkeley National Lab, Ludwig-Maximilians Universität, University of Michigan, National Optical Astronomy Observatory, University of Nottingham, Ohio State University, University of Pennsylvania, University of Portsmouth, SLAC National Lab, Stanford University, University of Sussex, and Texas A&M University. Funding for DES, including DECam, has been provided by the U.S. Department of Energy, National Science Foundation, Ministry of Education and Science (Spain), Science and Technology Facilities Council (UK), Higher Education Funding Council (England), National Center for Supercomputing Applications, Kavli Institute for Cosmological Physics, Financiadora de Estudos e Projetos, Fundação Carlos Chagas Filho de Amparo à Pesquisa, Conselho Nacional de Desenvolvimento Científico e Tecnológico, and the Ministério da Ciência e Tecnologia (Brazil), the German Research Foundation-sponsored cluster of excellence “Origin and Structure of the Universe” and the DES collaborating institutions. Based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA. Based on observations obtained at the international Gemini Observatory (GS-2016B-Q-22), a program of NSF’s NOIRLab, which is managed by the Association of Universities for Research in Astronomy (AURA) under a cooperative agreement with the National Science Foundation, on behalf of the Gemini Observatory partnership: the National Science Foundation (United States), National Research Council (Canada), Agencia Nacional de Investigación y Desarrollo (Chile), Ministerio de Ciencia, Tecnología e Innovación (Argentina), Ministério da Ciência, Tecnologia, Inovação e Comunicação (Brazil), and Korea Astronomy and Space Science Institute (Republic of Korea). This paper includes data gathered with the Nordic Optical Telescope (PI Stritzinger) at the Observatorio del Roque de los Muchachos, La Palma, Spain. We thank Norbert Scharf for rapid approval and scheduling of ToO observations (Obsd IDs 0794580101). Based on observations collected at the European Organisation for Astronomical Research in the Southern Hemisphere under ESO programmes 1103.D-0328, 1103.D-0328, 199.D-0143, 197.D-1075, 191.D-0935 (PESTO), ePESTO and ePESTO+). In addition, data taken under ESO programmes 098.A-0909, 0104.A-0999, 0100.D-0865, 098.D-0692, 100.D-0341, and 0103.D-0139(A) are presented here. Based in part on data acquired at the ANU 2.3m Telescope at Siding Spring Observatory. We acknowledge the traditional owners of the land on which the telescope stands, the Gamilaraay people, and pay our respects to elders past, present, and emerging. Part of the funding for GROND (both hardware as well as personnel) was generously

1 Galactic Extinction only. If \(A_V\) not mentioned in reference, we take values from NED.

2 With respect to Event B maximum light in V-band.

### APPENDIX B: PHOTOMETRY TABLES

Table B1: Sample of full photometry table for AT 2016jbu. All measurements were carried out using AutoPhoT. Phase is with respect to V-band maximum of Event B. Limiting magnitudes listed where AT 2016jbu could not be detected, and 1\(\sigma\) errors are given in parentheses. UBVIJHK filters are in Vegamags, ugriz are in AB magnitudes. Full photometry table available online.
