Linear-superelastic Ti-Nb nanocomposite alloys with ultralow modulus via high-throughput phase-field design and machine learning

Yuquan Zhu1, Tao Xu2, Qinghua Wei1, Jiawei Mai1, Hongxin Yang2, Huiran Zhang3, Takahiro Shimada4, Takayuki Kitamura4 and Tong-Yi Zhang1

The optimal design of shape memory alloys (SMAs) with specific properties is crucial for the innovative application in advanced technologies. Herein, inspired by the recently proposed design concept of concentration modulation, we explore martensitic transformation (MT) in and design the mechanical properties of Ti-Nb nanocomposites by combining high-throughput phase-field simulations and machine learning (ML) approaches. Systematic phase-field simulations generate data of the mechanical properties for various nanocomposites constructed by four macroscopic degrees of freedom. An ML-assisted strategy is adopted to perform multiobjective optimization of the mechanical properties, through which promising nanocomposite configurations are prescreened for the next set of phase-field simulations. The ML-guided simulations discover an optimized nanocomposite, composed of Nb-rich matrix and Nb-lean nanofillers, that exhibits a combination of mechanical properties, including ultralow modulus, linear superelasticity, and near-hysteresis-free in a loading-unloading cycle. The exceptional mechanical properties in the nanocomposite originate from optimized continuous MT rather than a sharp first-order transition, which is common in typical SMAs. This work demonstrates the great potential of ML-guided phase-field simulations in the design of advanced materials with extraordinary properties.

npj Computational Materials (2021) 7:205; https://doi.org/10.1038/s41524-021-00674-7

INTRODUCTION

Titanium-based shape memory alloys (SMAs), such as Ti-Nb alloys, are an important class of smart materials that possess shape memory effect (SME) and pseudoelasticity (PE), as well as high specific strength, excellent corrosion resistance, superior biocompatibility, etc. These fascinating merits are widely exploited for industrial and biomedicine applications. In general, the SME and PE originate from temperature- or stress-induced reversible first-order martensitic transformation (MT). The common PE stress-strain curve during loading consists of an initial true elasticity stage with a high Young’s modulus (>80 GPa) of austenite phase until MT occurring, followed by the stress-plateau associated with the structural transition, and final true elastic deformation of martensitic phase, while during unloading the stress lever causing the reverse MT is lower than that causing MT during loading, thereby exhibiting a large stress-strain hysteresis. Due to the stress-strain hysteresis, low efficiency and poor position control of the SMA actuators are generally observed due to the large hysteresis and strong nonlinearity. Moreover, as potential metallic biomaterials, a low Young’s modulus comparable with those of natural human bones (~20 GPa) is essential for Ti-Nb alloys to avoid the “stress-shielding effect” and the resulting bone degradation. Although several efforts have been made to optimize the mechanical responses of metallic alloys, e.g., concentration of the components and concentrations of defect engineering, introduction of elastic-inelastic strain matching, and grain refinement, the deliberate design and control of MTs for a combination of specific properties, such as low modulus, linear superelasticity, and free-hysteresis is still highly desired for various advanced biomedical and engineering applications.

Recently, Zhu et al. have conducted comprehensive investigations via phase-field simulations on the design of how to make apparently linear-superelastic alloys with ultralow modulus and high strength in SMAs. The pioneer works illustrate that concentration modulation, which can be obtained by spinodal decomposition, multilayer deposition, and precipitation of nanoprecipitates, is able to convert the first-order MT to pseudo-high-order MT and result in purely apparent elastic deformation with low Young’s modulus and high strength. From the perspective of the Landau thermodynamic theory, such manipulation of the mechan properties essentially derive from the flattening the average thermodynamic energy density profile of the structures, since many physical quantities of ferroic materials are associated with free-energy derivatives with respect to certain thermodynamic variables. More specifically, elastic constants of ferroelastics such as SMAs are determined by second derivatives of the Gibbs free-energy density with respect to strain, i.e., the curvature of the thermodynamic energy profile. This design concept has also been widely used in ferroelectrics to optimize corresponding properties, such as ultrahigh piezoelectricity and ultrahigh energy density dielectrics achieved by deliberately introducing nanoscale structural heterogeneity or nanodomain.

On the other hand, the rational design of these concentration modulations or nanoscale structural heterogeneity usually requires synergistic control of various structural attributes (such as concentration gradient, distribution, and morphology, etc) and
chemical features, which poses a great challenge for the conventional time-consuming experimental or computational searches by the trial-and-error process. The emerging data-driven material design approach through the combination of high-throughput (HTP) calculations and machine learning (ML) has been recognized as a powerful tool in the search for new materials or structures with tailored properties and novel functionalities. There have been many inspirational HTP first-principles works, from which direct links between atomic-scale information and macroscopic functionalities are established. These approaches have shown many successes in the discovery of new piezoelectric and dielectric materials, thermoelectric materials, magnetic materials, and so on. Nevertheless, the origin of material properties resides in not only chemical constituent itself but also mesoscale morphological and microstructure evolutions. The development of HTP mesoscale calculations is not only indispensable for the accelerated characterization of microstructure evolutions but also a boost for data- and modeling-driven discovery of new materials and structures.

In this work, we propose an alternative concentration modulation approach, i.e., nanocomposite engineering, meanwhile developing an integrated framework of HTP phase-field simulations and ML, to achieve the extraordinary mechanical properties in the Ti-Nb SMAs. A HTP phase-field simulations procedure is designed to optimize the mechanical response of various Ti-Nb SMA nanocomposites constructed by four structural feature variables and to seek the optimal microstructure with desired properties. Guided by the ML, a nanocomposite with a perfect combination of ultralow $E_t$, giant $\sigma_t$, and tiny $A_t$ is screened out, which shows great potential for biomedical material applications. The developed computational approach is also applicable to the design of a wide range of advanced materials.

### RESULTS

#### Workflow of high-throughput phase-field simulations

We design a series of Ti-Nb square-array nanocomposite structures consisting of different Nb-lean nanofilayers that are uniformly and coherently embedded in a Nb-rich Ti-Nb alloy matrix (Fig. 1b). In the simulations of uniaxial tension tests, the displacement of the lower-left corner and the $x$-direction displacement of the left side of the nanocomposite are fixed at zero to prevent the rigid body translation and rotation (see Fig. 1b). The motivation for the choice of such a nanostructure is the advancements in fabrication techniques of composites and their various associated phenomena. The Ti-Nb nanocomposite has four structural feature variables (macroscopic degrees of freedom) related to the macroscopic mechanical properties, namely the Nb concentration ($C_{\text{Nb}}$) of the matrix ($M_{\text{Nb}}$) and nanofilayers ($F_{\text{Nb}}$), volume fraction of nanofilayers ($V_F$), and the number of nanofilayers ($N_F$). Following the novel approach of concentration modulation and concentration gradient layer structure developed by Zhu et al., $M_{\text{Nb}}$ and $F_{\text{Nb}}$ are set with 15–20 at.% and 5–10 at.%, respectively, with a 1% interval, to facilitate the stress-induced MT during loading and inverse MT during unloading. To systematically study the effect of $V_F$, a series of nanofilayers with the total areas of $8^2$ nm$^2$, $16^2$ nm$^2$, $24^2$ nm$^2$, $32^2$ nm$^2$, and $40^2$ nm$^2$ are adopted in the simulations, which correspond to the variation of $V_F$ from 1.56% to 39.06%. Correspondingly, three groups of $N_F$ are defined: 4, 16, and 64. The detail of four structural feature variables are also summarized in Supplementary Table 1 in the Supplementary information. The computational framework for the design of the Ti-Nb nanocomposite is represented schematically in Fig. 1c. A computing script framework is developed to concurrently handle multiple calculation tasks. With a multi-core workstation, more than 10 tasks are concurrently
calculated. We start by specifying the above four features ($M_{\text{Nb}}, F_{\text{Nb}}, V_f$, and $N_f$) with automatic nanocomposite modeling, which yields 540 candidates from a combinatorial point of view. Although the nanofillers could be randomly distributed in the matrix, we restrict the nanofillers to a square nanocomposite structure, a typical Archimedean lattice structure, to reduce the computational complexity. We then carry out HTP phase-field simulations for the established nanocomposite models and compute their microstructure evolutions and stress-strain (SS) curves under mechanical stress along the [100] direction as shown in Fig. 1b. The quantitative analyses of the SS curves are subsequently conducted, and the main mechanical properties are extracted, including the apparent incipient Young’s modulus ($E_I$), the apparent elastic stress limit ($\sigma_L$), and the hysteresis area ($A_H$). In the present study, the apparent elastic limit is defined as the critical point of the apparent elastic stage on a stress-strain curve obtained by the “backward convex splitting method”, as schematically explained in Figure S7 in the Supplementary information, where $E_I$ and $\sigma_L$ denote the apparent elastic stress limit and associated stress, respectively. The apparent Young’s modulus is defined by $E_I=\sigma_L/\varepsilon_L$. The hysteresis area of $A_H$ measures the size of the hysteresis area encircled by the whole SS curve. Based on the data sets from HTP phase-field simulations, we employ ML strategy to perform multi-objective optimization of the mechanical properties for the nanocomposites. The recommended candidates are further verified by the phase-field simulations and the underlying mechanisms are also clarified.

Overview of high-throughput phase-field results

Based on the HTP phase-field simulations, we plot the obtained four features dependence of the mechanical properties of the nanocomposites in Fig. 2, in which $V_f$ increases from 1.56 to 39.06% on each row and $N_f$ decreases from 64 to 4 on each column. It can be seen that $E_I$ and $\varepsilon_L$ of the nanocomposites are widely distributed within 10–35 GPa and 0–3%, respectively. This tunable and variable modulus indicates that engineering the chemical composition and geometry of the nanocomposite offers great flexibility to tune the mechanical properties of the materials. According to the map shown in Fig. 2a, there is a rough trend that nanocomposites with larger $V_f$ exhibit lower $E_I$, although the Nb-rich nanofillers are assumed to have the same elastic constants as that of the matrix. It is also interesting that $F_{\text{Nb}}$ dramatically reduces $E_I$ at a lower $F_{\text{Nb}}$ ($F_{\text{Nb}} < 8\%$) (see Fig. 2a) and higher $V_f$ ($V_f > 14.06\%$), while $M_{\text{Nb}}$ and $N_f$ are negligible on $E_I$ for the whole $V_f$ range. These results suggest that coupling between nanofillers and matrix with different $C_{\text{Nb}}$ gives rise to $E_I$ superior to their inherent ones. As displayed in Fig. 2b, $\sigma_L$ also decreases with increasing $V_f$, which is consistent with the conclusion of $E_I$. In comparison, $\sigma_L$ increases with increasing $M_{\text{Nb}}$, indicating that the Nb-rich matrix effectively maintains the linear elasticity of the nanocomposites. The opposite variation tendencies are observed for $E_I$ and $\sigma_L$ with $F_{\text{Nb}}$ and $M_{\text{Nb}}$, manifesting that $F_{\text{Nb}}$ and $M_{\text{Nb}}$ play different roles in regulating the mechanical properties of the nanocomposites. Moreover, the calculated $A_H$ of the nanocomposites spans a large range from 0 MJ m$^{-3}$ to 3 MJ m$^{-3}$ for different features (Fig. 2c), and thus the embedding of nanofillers greatly reduces the energy loss during the loading-unloading cycle. Although the regulated effect of $N_f$ is not as obvious as other features, it can be seen from Fig. 2a to c that $N_f$ is also of great significance in fine-tuning mechanical properties of nanocomposites. All these results indicate that the mechanical properties of nanocomposites are nonlinearly affected by all four features.

Effect of the coherent nanocomposite

The widely tunable and variable mechanical responses of the nanocomposites could be attributed to the change in the MT nucleation critical stress and the local stress fields associated with the inserted nanofillers. Figure 3a plots the Landau free-energy density curves as a function of the order parameter for the Ti-Nb alloys with different $C_{\text{Nb}}$ at 300 K, in which the martensitic phase gradually transformed from an unstable state to a stable state with decreasing $C_{\text{Nb}}$. It is evident that the martensitic phase is stable in the Nb-lean cases ($C_{\text{Nb}} < 8\%$), while in the Nb-rich cases ($C_{\text{Nb}} \geq 12\%$), the martensitic phase could not nucleate without the aid of external loads. The critical stress for the stress-induced martensitic nucleation versus $C_{\text{Nb}}$ is further calculated (see Fig. 3b) and the results demonstrate that the critical stress increases exponentially with increasing $C_{\text{Nb}}$. For the heterogeneous nanocomposites, martensite thus preferentially nucleates in Nb-lean nanofillers and generates local stress fields associated with the $C_{\text{Nb}}$-dependent stress-free transformation strain (SFTS) tensors (see Fig. 3b) to promote the growth of martensite into the matrix, while the high critical stress in the Nb-rich matrix will confine the extent of growth. The critical stress for the nucleation (or growth) of martensite is the minimum stress for the nucleation (or growth) of martensite transformed from austenite in a homogeneous system. To qualitatively investigate and clarify the mechanism for the modulation of mechanical properties, we adopt a simplified 2-dimensional model with the nonperiodic condition and stress-free condition to explore the competitive relationship between the Landau energy and the elastic energy. It consists of 8 nm$^2$ martensite particle with Nb concentration of $f_{\text{Nb}}$ (denoted as the green square) and the adjacent 8 nm$^2$ austenitic matrix with Nb concentration of $m_{\text{Nb}}$ (denoted as the orange square), corresponding to the martensite volume fraction of 0.5. After relaxation, the interface between martensite and austenite moves toward the particle or matrix depending on $f_{\text{Nb}}$ and $m_{\text{Nb}}$. Different combinations of $f_{\text{Nb}}$ and $m_{\text{Nb}}$ will generate various martensite volume fractions as shown in Fig. 3c. The heatmap of martensite volume fraction after relaxation is divided by a dashed line into the suppressed and non-suppressed region, which is highlighted in blue and red colors, respectively. These results thus indicate that $F_{\text{Nb}}$ ($f_{\text{Nb}}$) and $M_{\text{Nb}}$ ($m_{\text{Nb}}$) significantly mediate the Landau free-energy and SFTS, and further regulate the MT nucleation critical stress and spread of martensite in the nanocomposites.

Furthermore, the geometric features (i.e., $N_f$ and $V_f$) modulate the strength and distribution of the generated stress field. We perform simplified simulations to investigate the local stress field $\sigma_1$ (Fig. 3d–i) generated by the lattice mismatch between the embedded martensitic fillers (V3 with $F_{\text{Nb}} = 7\%$) and the matrix with different $N_f$ and $V_f$. The local stress field probability distribution is further summarized in Fig. 3j–l. We observe that an increase in $V_f$ results in the gradual expansion of the local stress distribution range, such that $V_f$ greater than 25% produces a second stress distribution peak around 400 MPa. In addition, the increase of $V_f$ not only increases the maximum value of the local stress field (represented by the red dashed line) but also significantly increases the probability that the local stress is greater than the critical stress of martensite spread into the matrix, as indicated by the blue dashed line in Fig. 3s–u for the median value (i.e., 600 MPa). Moreover, $N_f$ also regulates the distribution and probability density of the local stress field. Contrary to $V_f$, a smaller $N_f$ increases the maximum value of the local stress field and the probability of $\sigma_1 \geq 600$ MPa. Hence, $V_f$ and $N_f$ effectively affect the magnitude and extent of the local stress field. The shear component $\sigma_2$ also contributes to the nucleation and growth of the MT process. The high shear stress region in the nanocomposite beyond the critical shear stress is very small and highly localized, as shown in Figure S5 in the Supplementary information. Therefore, all four features regulate the nucleation and spread of the MT process by altering the MT nucleation critical stress and the local stress field distribution.
Machine learning guided optimization of the nanocomposites

As previously discussed, reducing the Young’s modulus while maintaining a large $\varepsilon_L$ is critical for the ideal orthopedic implant. Through the HTP phase-field simulations of the initial hundreds of nanocomposites, we have obtained the structures with widely tunable mechanical properties. However, an exhaustive search for the optimal one is intractable and computationally expensive. To remedy this, we apply the Artificial Neural Network (ANN) method to achieve the highly efficient multiobjective optimization of the nanocomposites. Since the $A_H$ of training samples is tiny (minimum and average values are 0 MJ m$^{-3}$ and 0.51 MJ m$^{-3}$, respectively) compared with other SMAs, such as TiNi (~10 MJ m$^{-3}$)\textsuperscript{42}, we select the other two mechanical properties (i.e., $E_I$ and $\sigma_L$) for the multiobjective optimization based on the Pareto front\textsuperscript{43}. On the Pareto front, we use a selection strategy to find the three “best” configurations as the candidate and verify them by the phase-field simulation. Our selection strategy transforms the
two-objective optimization problem into a single-objective optimization problem by calculating the normalized distance \( \delta \) from a point in search space to the target (\( E_1 = 10 \) GPa, \( \sigma_L = 500 \) MPa), and the normalized Euclidean distance \( \delta \) is given by

\[
\delta = \sqrt{\left(\frac{E_1 - E_{1*}}{35}\right)^2 + \left(\frac{\sigma_L - \sigma_{L*}}{500}\right)^2} = \sqrt{\left(\frac{E_1 - 10}{35}\right)^2 + \left(\frac{\sigma_L - 500}{600}\right)^2}
\]

(1)

In order to avoid samples with poor performance dominating the construction of the ML model, we classify the calculated configurations from the HTP phase-field simulations by performing K-Means clustering using the mechanical properties (i.e., \( E_1 \) and \( \sigma_L \)) as the input variable. As illustrated in Fig. 4a, the calculated configurations are grouped into three data sets, in which Cluster 1 shows poor mechanical performance in terms of its large \( E_1 \) and low \( \sigma_L \). We thus select Cluster 0 and Cluster 2 (324 samples) as training data for the construction of ANN model. As shown in

---

**Fig. 3** Schematic diagrams for the understanding of physical origin to achieve the specified properties of the nanocomposites. a Landau free-energy curves with different \( C_{Nb} \), b SFTS tensors component, and MT critical stress with different \( C_{Nb} \), and c the ability that Nb-rich matrix inhibits the spread of martensite in fillers into matrix determined by \( F_{Nb} \) and \( M_{Nb} \). d–r Local stress field on the [100] direction of Ti-Nb nanocomposites of different \( V_F \) and different \( N_F \) and s–u local stress field probability distribution with \( V_F = 1.56, 6.28, 14.06, 25.00, \) and 39.06\% for different \( N_F \).
Supplementary Figure 8, all four features are independent of each other and have certain correlations with the mechanical properties. Moreover, since the chemical features (i.e., $F_{Nb}$ and $M_{Nb}$) are sampled linearly while the geometric features (i.e., $N$ and $V_1$) are sampled squarely in the HTP phase-field simulations, we treat the geometric features by square root transformation as $N^*_1 = \sqrt{N}$ and $V^*_1 = 64 \times \sqrt{V_1}$ to eliminate the influence of the numerical differences on the prediction performance of the ML model. In order to predict new configurations with better properties, a large unexplored search space is created by increasing the resolution of four structural features: We allow $F_{Nb}$ to vary from 5.0 to 10.0% with an interval of 0.2% and $M_{Nb}$ to vary from 15.0 to 20.0% with an interval of 0.2%. For geometric features, we set $N^*_1$ from 2 to 8 in steps of 2 and $V^*_1$ from 8 to 40 in steps of 4. Overall, 42588 virtual samples ($C_{16}C_{16}C_{7}C_{7}$) are formed out of which only 324 are computationally studied.

Figure 4b-c show the ten-fold cross-validation performance of $E_1$ and $\sigma_1$ obtained by the ANN algorithm. As we can see, the ANN model has a great cross-validation performance for $E_1$ ($R = 0.9889$) and $\sigma_1$ ($R = 0.9536$). According to the hyperparameters determined by the cross-validation, we use all 324 training data samples to train two new ANN models to predict the $E_1$ and $\sigma_1$ of samples in the unexplored search space. According to our selection strategy, three new configurations with improved properties are screened out in the search space, which are selected as promising nanocomposite configurations for the next set of phase-field simulations. Their predicted and calculated mechanical properties are shown in Table 1. The predicted $E_1$ is higher than the calculated value with an average prediction error of 1.86%, while the predicted $\sigma_1$ is higher than the calculated value with an average prediction error of 9.46%, indicating that the ML model yield accurate predictions for the unexplored nanocomposites. The calculated properties of the three recommended configurations (denoted as red pentagons) are compared with those from HTP phase-field simulations (denoted as blue dots) in Fig. 4d. Improvements can be observed for the recommended configurations and the red pentagon sample with the most obvious performance improvement is selected as the configuration of the ideal orthopedic implant. Compared with the result of HTP phase-field simulations, the normalized Euclidean distance $\delta$ is reduced from 0.231 to 0.200, decreasing by 13.4%. Thus, we could locate the configuration with the best compromise of low $E_1$ and large $\sigma_1$ with the aid of ANN. The optimized configuration (as shown in Fig. 5b) is composed of Nb-rich TiNb matrix ($M_{Nb} = 18.4\%$) and 25.0% volume fraction of Nb-lean TiNb square fillers ($F_{Nb} = 7.2\%$) with $N_1 = 16$, which will be discussed in detail below. It is also worth to mention that the application of the proposed data-driven approach based on the HTP phase-field simulations is not confined to the design of the present orthopedic implant with low $E_1$ and large $\sigma_1$, but applies to a wide range of materials and structures with target mechanical and other functional properties.

**Ideal orthopedic implant design strategy**

The comparison of $E_1$ and $\varepsilon_1$ of the constructed nanocomposites designed from the ML-aided simulation with those of Ti2448 (Ti-24Nb-4Zr-8Sn in wt.%), a typical metallic biomaterial, and other state-of-the-art systems proposed in the literature, are shown in Fig. 5a. It is readily seen that the candidate nanocomposite for the ideal orthopedic implant exhibits an ultralow $E_1$ relative to other reported systems, which is essential for metallic biomaterials. The nanocomposite also outperforms Ti2448 in terms of the relatively large elastic strain limit and small hysteresis area. The SS curve of the designed nanocomposite during the loading-unloading cycle together with that of uniform bulk Ti2448 is shown in Fig. 5c with.
Table 1. Predicted and calculated value of properties of new nanocomposite.

the red curve and gray curve, respectively. The SS curve of Ti2448 features a typical characteristic of a large stress hysteresis with an obvious stress plateau, which is consistent with the experimental observations. By contrast, the stress plateau completely disappears in the SS curve of an ideal orthopedic implant, and exhibits a quasi-linear elasticity and almost hysteresis-free mechanical behavior. As shown in Fig. 5a, compared with the state-of-the-art functional material16, such as Ti2448 (Ti-24Nb-4Zr-8Sn in wt.%), NICSMA (nanowire in situ composite with SMA), Gum metals et al., the nanocomposite designed by HTP calculations and ML are superior in mechanical properties in terms of their linear super-elasticity, ultralow Young’s modulus, large apparent elastic stress limits, and near-hysteresis-free. These properties in the nanocomposites designed by ML-assisted HTP calculations are comparable with the recently reported phase-field simulation results via concentration modulation and concentration gradient film designs20–23.

To gain a thorough understanding of the exceptional mechanical properties, the microstructure evolutions corresponding to the marked points of the loading-unloading SS curve are analyzed, and the results are displayed in Fig. 5d. As shown Fig. 5e, abundant martensitic particles are observed in the nanofillers, while the matrix still presents an austenite phase when the nanocomposite is quenched to 300 K in a stress-free configuration. These observations are because the martensitic phase is more stable in the Nb-lean fillers (FNb = 7.2%), as illustrated in Fig. 3a.
The temperature-induced martensitic particles are composed of multivariants in self-accommodating domain patterns. These martensitic particles behave as seeding beds of martensite, eliminating the nucleation barriers for MT. Upon loading, the stress-induced martensite re-orientation occurs, and the favored variants (such as V2, V3, and V4) dominate and gradually fill the fillers. These martensitic variants gradually and continuously grow into the matrix, which is significantly different from the common avalanche-like discontinuous MT. With increasing stress (Fig. 5g and h), the existing martensitic variants continue to expand in the matrix, which is also accompanied by the formation and merging of new martensitic configurations in the matrix. At the end of the loading (600 MPa), the martensitic domains spread almost over the entire area of the nanocomposite with a volume fraction of 94.6%, as illustrated in Fig. 5i, in which the remaining parent phase mainly originates from the martensitic variant interfaces. In the process of unloading, these remaining parent phases initiate the inverse martensite to austenitic transition in the matrix, and the austenite gradually spread from the matrix towards the interfaces of the nanocomposite (Fig. 5j). The martensite completely disappears in the matrix when the applied stress is reduced to 75 MPa (Fig. 5k). In addition, the Nb-lean fillers also transform back to the initial self-accommodating multivariants martensite configurations after unloading, which contributes to the zero-residual strain in a loading-unloading cycle. Therefore, the nanocomposite experiences macroscopically continuous MT throughout the loading and unloading procedure rather than a sharp first-order transition as that in typical SMAs, which thus exhibits linear super-elasticity and ultralow $E_z$ (Fig. 5d). The continuous characteristics of the forward and backward MTs originate from the embedded nanofillers with local heterogeneity that induce nonuniform local stress field associated with the geometrical structure and the variation of MT critical stress due to the change of $C_{ub}$ as discussed above. For a given nanocomposite, nonuniform stress field appears under a certain applied load, as shown in Supplementary Figure 6. The variation in local stresses tailor the total free-energy landscape with multiple local minima and facilitates the pseudo-high-order MT in the nanocomposite.

These results suggest a new route for achieving desirable mechanical properties to meet the requirement of different applications by nanocomposite engineering. In particular, the designed Ti-Nb nanocomposite realizes a perfect combination of ultralow modulus, linear super-elasticity, and near-hysteresis-free, which cannot be obtained in common materials and will enable many new advanced applications. For instance, the achieved $E_z$ in the current Ti-Nb-based alloys without compromising their good bio compatibility and superior corrosion resistance is of particular importance for biomedical applications. The mismatch in the Young’s modulus between the common implant materials (~110 GPa) and human bone usually causes stress shielding, leading to bone degradation and implant loosening originated from inhomogeneous stress distribution between the implant and the adjacent bone. The elastic modulus of 16.13 GPa in the designed nanocomposite match closely to that of human bone and thus is promising in overcoming this stress-shielding issue completely. To verify the functional stability of the designed nanocomposite, the repeated loading-unloading cycles are performed for the ideal orthopedic implant. The second SS curve and the corresponding evolution of microstructures are illustrated in Supplementary Figure 1 in the Supplementary information, which coincide with those in the first one, indicating the mechanical stability of the designed ideal orthopedic implant. In addition, we perform calculations of nanocomposites with organized (triangular and honeycomb-array) and random arrays of nanofillers. Supplementary Figure 2 in the Supplementary information shows the simulation results, viz., the SS curves, corresponding microstructures and their evolutions. The SS curves indicate that the mechanical behavior of the nanocomposite is also insensitive to the nanofiller distribution profile. Moreover, we investigate the effect of different shapes of nanofillers on the mechanical properties of the designed nanocomposite. As shown in Supplementary Figure 3 in the Supplementary information, the SS curves of the nanocomposites with square, hexagonal, and spherical nanofillers are almost coincide, indicating that the mechanical properties of the nanocomposite are insensitive to the shape of nanofillers. Last but not least, we also verify that the results remain almost unchanged within the loading rate range of 20 MPa s$^{-1}$ – 500 MPa s$^{-1}$, as shown in Supplementary Figure 4 in the Supplementary information. Experimental preparation of the proposed fine nanocomposite is a great challenge currently; yet, recent fabrications of size and composition-controlled nanocomposites using colloidal synthesis method, replacement reaction, and accumulative roll bonding (ARB) suggest the promising strategies to pursue$^{40,46,47}$. The combination of HTP phase-field simulations and the ML approach thus provides an efficient paradigm for designing target properties of shape memory alloys, which will also be beneficial to a wide range of functional materials.

**DISCUSSION**

In conclusion, we have developed a HTP phase-field simulations to accelerate the design of microstructures with desired mechanical properties. HTP phase-field simulations are performed for various Ti-Nb nanocomposites designed by five structural feature variables and it is found that the mechanical responses of the nanocomposites are widely tunable and variable. Based on the combination of HTP phase-field simulations and ML techniques, we design a Ti-Nb alloy nanocomposite with ultralow modulus, linear super-elasticity, and nearly free hysteresis, which is promising for biomaterial applications. These superior mechanical properties attribute to the nonuniform stress distribution and the modulation of the critical stress that facilitates continuous MT. The present approach developed by the combination of phase-field simulations and ML is thus an important extension to the previous method of concentration simulations to regulate the MTs, jointly to provide theoretical guidance for the experiments.

**METHODS**

**Phase-field model**

The Ti-Nb-based alloys undergo diffusionless and reversible MT between the cubic $\alpha$-austenite (point group m3m) and orthorhombic $\alpha'$-martensite (point group mmm) phases$^{48}$ during thermomechanical loading, as shown in Fig. 1a. This cubic-to-orthorhombic MT is associated with six possible variants (V1–V4). Since ML demands a large amount of simulation results, two-dimensional phase-field simulations within the plane stress condition are conducted in the present work to illustrate the developed methodology of phase-field simulations integrated with ML. As a result, there are four possible variants (V1–V4) corresponding to four different SFTS filters after dropping the out-of-plane strain. All the SFTSs can be found in the Supplementary information. In the phase-field model, a continuous structure order parameter $\eta_i (i = 1 - 4)$ is employed to characterize the MT, with $\eta_1 = 0$ and $\eta_i = 1$ representing austenitic and $i$-th martensitic variant, respectively. The total free-energy of the system $F$ consists of the Landau free-energy $f_{\text{LR}}$ the gradient energy $f_{\text{gr}}$ and the elastic energy $f_{\text{el}}$.

$$ F = \int \left( f_{\text{LR}} + f_{\text{gr}} + f_{\text{el}} \right) \mathrm{d}V. $$

The microstructure evolution of the MT is governed by the time-dependent Ginzburg-Landau-TDA equation:

$$ \frac{\partial \eta_i(r,t)}{\partial t} = -L \frac{\partial f}{\partial \eta_i(r,t)} + \zeta_i(r,t), i = 1 \sim 4, $$

where $L$ is the kinetic parameter, and $\zeta_i(r,t)$ is the Stochastic-Langevin noise term accounting for the effect of thermal fluctuations$^{52}$. All the phase-field simulation parameters employed...
in the present work are from Ref. 29 and listed in Supplementary Table 2 in the Supplementary information.
