Abstract — To address the problem of food security, China produced potatoes as a staple food in 2015. However, there are increasing problems with continuous cropping production methods, potato continuous cropping has been inevitable. So it is necessary to research under the different potato continuous cropping ways, potato rhizosphere soil nutrients and enzyme activities which can direct potato fertilizer and ease potato continuous cropping obstacle. A two-growing season investigation was carried out during the spring and autumn of 2014 and 2015 to determine the different ways of potato continuous cropping on the overall growth of potatoes, soil nutrients, and enzyme activities. During continuous cropping nitrogen (N) content of rhizosphere soil was reduced; available potassium (Kav) was significantly reduced ($p \leq 5\%$), especially in spring and autumn continuous cropping; and total phosphorus (Ptot) was reduced during the growth stage. However, the total potassium (Ktot), available phosphorus (Pav), and organic carbon (Corg) increased before they decreased. For rhizosphere soil enzyme activities, urease initially increased and then decreased, and was lower in continuous cropping than multiple continuous cropping; in spring of 2015, invertase was the highest with continuous cropping. Catalase and polyphenol oxidase decreased initially before increasing. Continuous cropping in spring and autumn consumed more nutrients, especially potassium (K) than in spring. Therefore, potatoes planted in both spring and autumn enhanced the problems of continuous cropping. However, multiple continuous cropping that eased rhizosphere soil nutrient absorption and effectively improves soil nutrients and enzyme activities could provide an effective method for managing the negative impacts associated with continuous cropping.

Keywords — potato continuous cropping, rhizosphere, soil nutrients, soil enzyme activities, polyphenol oxidase.

I. INTRODUCTION

Follow the rice, wheat and maize, potato (Solanum tuberosum L.) is the fourth-most important food crop worldwide. It is one of the major crops in China as well. To date, the planting acreage and production of potato in China ranked as top one worldwide. In 2015, the potato staple strategy are put forward in our country, by advancing the potato food development, adjusting measures to local conditions enlarges planting area, from the current 5.3*10⁶m² to expand to 1.0*10⁶ hm²(Schirring, 2015). However, due to the limitations of different crops in different ecological conditions and authentic, and optional rotation crop limitations such as low efficiency and the urgency of the economic demand, makes the potato continuous cropping pattern is inevitable.

In Gansu, Sichuan and Inner Mongolia, due to rapid development of potato industry, its planted area extended to more than 65% of the country (Long et al., 2013), the potato continuous cropping patterns have been inevitable under the condition of limited arable land. Under the condition of several years of planting potato model continuously has inevitable. Especially with the comparative benefits the improvement of potato industry, potato planting area in the northwest China increases year by year. Dingxi area, Gansu province, the potato continuous cropping has amounted to more than five years in some part of arable land, the potato continuous cropping is common, thus resulting in increasing problems for effective agricultural management in China. These problems include an increase of pests and diseases (Jeffrey et al., 2015), and a negative impact on soil physicochemical properties, soil microbes, and allelopathy(Rice,1985; Zhang et al., 2015). Previous researchers reported that continuous cropping decreases yield, quality, and causes diseases and imbalances of soil ecology(Wu et al, 2009; Zhang et al., 2010); thus, seriously affecting the production and economic benefits of potatoes.
It is worth mentioning that with development of China, the potato continuous cropping is inevitable. So explore the different ways of continuous cropping patterns, research rhizosphere soil nutrient and enzyme activity is significant.

The negative impacts of continuous cropping have become a major constraint in potato cultivation (Meng et al., 2012). The negative impacts of continuous cropping were mainly caused by an increase of soil-borne diseases (Robert et al., 2014; Lai et al., 2011), the degradation of soil physical and chemical properties (Liu et al., 2009; Zhang et al., 2007), and root secretion and residue decomposition resulting in autotoxicity (Cheng et al., 2013; Wang et al., 2005). The negative impacts from continuous cropping of different crops are considerably different, but mainly affect the soil. Most studies have focused on vegetables (Wu et al., 2007; Xiao et al., 2012), melons and fruit (Zhao et al., 2008), soybeans (Miao et al., 2007), and Chinese medicinal herbs (Zhang et al., 2010; Hao et al., 2008). In continuous cropping systems, previous research reported that soil nutrients and enzyme activities were affected, and this effect was sustained in later growing seasons (Zhou et al., 2011). However, how the rhizosphere soil nutrients and soil enzyme activities at different growing stages are affected by continuous cropping needs to be determined. There has been limited research on overcoming the negative impact of continuous cropping and other production practices.

Although at present there have been lots of research about the potato continuous cropping obstacle, but the potato production practice of continuous cropping is not practically solved. This study based on the potato continuous cropping, under the different modes of the potato continuous cropping research on rhizosphere soil nutrient and enzyme activity of comparative analysis, aimed at the production of continuous cropping potatoes offer ideas and solutions. The objectives of this study were 1) to evaluate the effect of the continuous potato cropping on rhizosphere soil nutrients and enzyme activities on the growth characteristics of potatoes; and 2) to show the negative impacts of potato continuous cropping, direct the potato production. The results from the present study should provide a greater understanding of the negative impacts of continuous cropping and contribute to the improved management of potato cultivation.

II. MATERIALS AND METHODS

2.1 Site descriptions

The experiment was conducted in 2014 and 2015 in the field at the experimental station in the college farming area, southwest Sichuan Agricultural University, Chengdu, Sichuan Province (southwest China, N 30° 67’, E 104° 06’). The soil chemical characteristics were: pH (1:1 water) 5.08, organic carbon (C<sub>tot</sub>) 18.72 mg/kg, total nitrogen(N<sub>tot</sub>) 2.68 g/kg, total phosphorus (P<sub>tot</sub>) 0.58 g/kg, total potassium(K<sub>tot</sub>) 13.00 g/kg, available nitrogen(N<sub>av</sub>) 138.68 mg/kg, available phosphorus(P<sub>av</sub>) 18.72 mg/kg, available potassium(K<sub>av</sub>) 126.31 mg/kg. The plant site before the experiment had been previously planted with a potato crop in 2013. The present study included A (multiple continuous cropping), B (potato continuous cropping in spring), and C (potato continuous cropping in spring and autumn) cultivation. All three cropping were conducted in a randomized block design of three replications in two years and two growing seasons.

About 30 g whole potato tubers, cultivar Chuanyu 117, were planted at a depth of 8 cm. Six potatoes were planted into the compartment with control soil from each pot (60 × 40 × 35 cm). Before potato planting, experimental plots were uniformly tilled and a compound fertilizer 750 kg·ha<sup>-1</sup> (N-P2O5-K2O 15-15-15) was initially used as a base fertilizer. Fertilizer was not added again. Standard agronomic practices were equally performed in all treatments. The sampling periods were before seeding, flowering, tuber bulking, and maturity. In autumn 2014 and 2015, the land of A and B was idle, and C was planted with potatoes (its index was not measured because planting in autumn was for enhancing the negative impacts of continuous cropping).

2.2 Rhizosphere soil nutrients

The initial soil samples were ground by mortar and pestle to pass a 0.15 mm sieve to remove plant residues and stones prior to chemical analysis. Total nitrogen(N<sub>tot</sub>), phosphorus (P<sub>tot</sub>), and potassium(K<sub>tot</sub>) were measured using the method described by Bao (2005). Soil organic carbon (C<sub>tot</sub>) was determined using the Walkley-Black method; total nitrogen(N<sub>tot</sub>) was assayed using the Kjeldahl method; total phosphorus(P<sub>tot</sub>) was measured by phosphomolybdate-blue spectrophotometry; total potassium(K<sub>tot</sub>) was measured by NaOH molten-flame photometry; organic matter was measured by heat dilution using potassium dichromate volumetry; alkali-hydrolyzed nitrogen(N<sub>av</sub>) was measured by alkali-hydrolyzed reduction diffusion; available phosphorus(P<sub>av</sub>) was measured using 0.5 mol/L NaCO₃; and available potassium(K<sub>av</sub>) was measured by NH₄OAc leaching and flame spectrophotometry.

2.3 Rhizosphere soil enzyme activities

Soil enzyme analysis was performed on the same samples that were air-dried ground, passed through a 1-mm mesh, and maintained at room temperature (Guan, 1989). Invertase activity was determined using 3,5-dinitrosalicylic acid colorimetry; urease activity was measured using phenol-sodium hypochlorite sodium colorimetry; polyphenol oxidase was measured using phenol colorimetry; and catalase was assayed using a titration method described by Guan (1989).

2.4 Statistics analysis

The analysis were carried out using Microsoft Office Excel 2007, variance for the data was performed by DPS. Means were separated by LSD at the 0.05 probability level.
III. RESULTS AND DISCUSSION

3.1 Nitrogen contents of rhizosphere soils

In 2014, compared with before seeding, in maturity stage, the content of total nitrogen (N$_{\text{tot}}$) in rhizosphere soil was reduced by 4.41, 14.55, and 14.71%, for A1, B1, and C1, respectively. However, except for C2, the content of total nitrogen (N$_{\text{tot}}$) varied smoothly in spring of 2015, the A2 was reduced by 1.01%, and B2 and C2 increased by 0.51 and 16.16%, respectively. The C content decreased with continuous cropping years. In maturity stage of 2014, the alkali-hydrolyzable nitrogen (N$_{\text{av}}$) content reduced by 22.74, 26.10, and 20.26%, for A1, B1, and C1, respectively; and in A2 and B2 increased by 28.89, and 18.46%, however, C2 decreased by 9.15%. In tuber bulking stage, the content of alkali-hydrolyzable nitrogen (N$_{\text{av}}$) changed rapidly. Alkali-hydrolyzable nitrogen (N$_{\text{av}}$) content showed little difference in different continuous cropping ways in the spring of 2014, and were reduced in 2015. The variation of total nitrogen (N$_{\text{tot}}$) showed the opposite trend.

|                                           | 2.60 ± 0.05ab |              |              | 1.97 ± 0.16a   | 1.98 ± 0.32a  | 1.98 ± 0.06a  |

A1, B1, C1 stand for A, B, C in 2014, A2, B2, C2 stand for A, B, C in 2015. In the same year, values within a column followed by different lowercase letters are significantly different at the 0.05 probability level, as determined by Fisher’s least significant difference test; n = 3.

3.2 Phosphorus contents of rhizosphere soils

From Table 2, total phosphorus (P$_{\text{tot}}$) was decreased with growth as the continuous cropping years increased. These three treatments showed the significant effects on the total phosphorus (P$_{\text{tot}}$). A1 increased by 3.32%, and B1 and C2 were reduced by 15.49 and 14.53%, respectively. In 2015, the content of total phosphorus (P$_{\text{tot}}$) was reduced by 13.11, 23.07 and 15.71% for A2, B2, and C2, respectively. Throughout the growth stages, there was a considerable change in total phosphorus (P$_{\text{tot}}$) content. In maturity stage, the total phosphorus (P$_{\text{tot}}$) content ranged from 0.500 to 0.600 g/kg. The variation of available phosphorus (P$_{\text{av}}$) content is different from total phosphorus (P$_{\text{tot}}$). In spring of 2014, available phosphorus (P$_{\text{av}}$) was reduced by 46.99, 39.56, and 39.42% for A1, B1, and C1, respectively. In contrast to that in 2015, it increased by 28.35, 25.03, and 11.96% for A2, B2, and C2, respectively. Even though the total phosphorus (P$_{\text{tot}}$) in the whole growth period fluctuated largely, its content did not significantly reduce. In the spring of 2014, phosphorus content increased, total phosphorus (P$_{\text{tot}}$) was insignificantly different from multiple continuous cropping, and the available phosphorus (P$_{\text{av}}$) content was more reduced than multiple continuous cropping in the spring of 2015.

A1, B1, C1 stand for A, B, C in 2014, A2, B2, C2 stand for A, B, C in 2015. In the same year, values within a column followed by different lowercase letters are significantly different at the 0.05 probability level, as determined by Fisher’s least significant difference test; n = 3.

### 3.3 Potassium contents of rhizosphere soils

As for total potassium ($K_{tot}$), in maturity stage, there was minimal difference between each treatment. Total potassium ($K_{tot}$) increased before it decreased. Eventually, the contents were reduced by 5.39, 1.85, 1.57%, for A1, B1, and C1, respectively, and then increased by 4.00, 4.37, and 0.00% for A2, B2, and C2, respectively. Available potassium ($K_{av}$) was reduced by 5.54, 23.92, and 24.46% for A1, B1, and C1, respectively, but thereafter increased by 30.55, 126.47, and 21.02% for A2, B2, and C2, respectively. From Table 3, total potassium ($K_{tot}$) content in rhizosphere soil was relatively stable, but the available potassium ($K_{av}$) content varied greatly. Potato continuous cropping in spring and autumn was lower than multiple continuous cropping year by year. Potatoes, as a high potassium crop, required more potassium for self-growth. In present study, potato continuous cropping consumed a small amount of total potassium ($K_{tot}$), but large amounts of available potassium ($K_{av}$). This can directly affect the application of fertilizer in production.

|                   | 56.10 ± 4.27h   | 90.95 ± 3.59f   | 84.95 ± 2.90f   | 67.89 ± 2.74g   | 56.10 ± 4.27h   | 90.95 ± 3.59f   | 84.95 ± 2.90f   | 67.89 ± 2.74g   | 56.10 ± 4.27h   | 90.95 ± 3.59f   | 84.95 ± 2.90f   | 67.89 ± 2.74g   |

3.4 Organic carbon contents of rhizosphere soils

The annual organic carbon ($C_{tot}$) content of rhizosphere soils decreased before increasing. In spring of 2014, the organic carbon ($C_{tot}$) content in maturity stage was reduced by 36.25, 25.26 and 24.84% for A1, B1, and C1, respectively, than before seeding. In 2015, it increased by 17.10, 31.13 and 67.27% for A2, B2, and C2, respectively. This implies that the higher the initial organic carbon ($C_{tot}$) content of soil, the faster it decreased. Organic carbon ($C_{tot}$) is the main source of soil nutrients; however, in this experiment, the
organic carbon ($C_{\text{org}}$) content of potato continuous cropping in spring and autumn was higher, decreased lower, and increased faster than multiple continuous cropping and continuous cropping in autumn.

### Table 4: Organic carbon contents of rhizosphere soils

|                        | Before seeding | Flowering | Tuber bulking | Maturity |

3.5 Enzyme activities of rhizosphere soils

Table 5 showed that urease steadily increased in 2014, with the maximum level in flowering stage. In maturity stage, it increased by 34.00, 22.37, 21.71%, for A1, B1, and C1, respectively, and it increased by 20.33, 9.24, and 5.83%, for A2, B2, and C2, respectively. Although over both years urease increased, it was lower in 2015 than that in 2014. The rhizosphere soil invertase activity in maturity stage increased by 52.07, 7.65, 11.24%, for A1, B1, and C1, respectively. In spring of 2015, A2, and B2 in maturity stage decreased by 52.92 and 19.39%, respectively, whereas C2 increased by 25.47%. For catalase, B1 and C1 were reduced by 13.68 and 8.62%, whereas A1 increased by 13.86%. In 2015, catalase increased by 9.88, 6.13 and 11.88%, for A2, B2, and C2, respectively. In present study, there was little difference between the treatments in 2014, with only small variations. In maturity stage, A1 increased by 3.67%, and B1 and B2 were reduced by 10.05 and 1.66%, respectively. However, in 2015, polyphenol oxidase activity changed considerably, especially in tuber bulking stage. Eventually, the activity of polyphenol oxidase increased by 27.97, 25.28, 5.24%, for A2, B2, and C2, respectively.

Table 6: The tuber yield of all three A, B, C variants (kg ha⁻¹)

IV. DISCUSSION

It is generally hypothesized that the soil nutrients 
decreased annually with continuous cropping (Xiao et al., 2012). But in this research, the available phosphorus (P\text{\text{av}}), the available potassium (K\text{\text{av}}), the content of organic carbon (C\text{\text{tot}}) content were different. This illustrated that the different 

polyphenol oxidase activity increased with 

In the present study, there were significant differences in polyphenol oxidase activity 
under continuous cropping. Therefore, soil polyphenol oxidase can be considered as an indicator of the negative 
impact of continuous potato cropping, but requires further verification.

As for the result of the tuber yield, there is a certain 
relationship between the tuber yield and continuous 
cropping years, the method of cultivation pattern. But a small difference soil change between multiple continuous 
cropping (A) and potato continuous cropping in spring (B) 
and continuous cropping in spring and autumn (C) in the 
short term of continuous cropping for two years, there is a significant difference between them for continuous cropping 
over three years. Potato continuous cropping consumed 
more nutrients, especially available nutrients. We think 

Polyphenol oxidase (PPO) is secreted by the plant roots, 
increasing soil microbial activity and the decomposition of 
plant and animal residues, releasing compound enzymes 
(Claus et al. 2010; Yoruk et al., 2003). These are 
biodegradable soil phenolics that slow down the allelopathy 
between plants, thereby creating advantageous conditions 
for plants to expand their habitats. In the present study, 

| Year | A  | B  | C  |
|------|----|----|----|
| 2014 | 7190 | 6985 | 7019 |
| 2015 | 7190 | 6215 | 6343 |
increased the negative impact. Multiple continuous cropping reduced the rhizosphere soil nutrient absorption, but negated the negative impacts of continuous cropping.

ACKNOWLEDGMENTS

This work was jointly supported by the National Science-Technology Support Plan Projects (2012BAD06B0407) and Sichuan Breeding Research Project (2011N0098-15-5). We express our gratitude to Huang Qiang and Zha Li for assistance in soil sampling and testing.
