ABSTRACT

High-resolution observations show that oscillations and waves in prominence threads are common and that they are attenuated in a few periods. In addition, observers have also reported the presence of material flows in such prominence fine-structures. Here we investigate the time damping of nonleaky oscillations supported by a homogeneous cylindrical prominence thread embedded in an unbounded corona and with a steady mass flow. Thermal conduction and radiative losses are taken into account as damping mechanisms, and the effect of these nonideal effects on the attenuation of oscillations is studied. In the presence of flow these damping mechanisms are modified and either fast kink modes are more (less) attenuated when they propagate parallel (antiparallel) to the flow direction for small mas flows. The presence of steady mass flows improves the efficiency of the nonadiabatic mechanisms on the damping of slow and thermal waves, whereas fast kink waves are more efficiently attenuated when they propagate parallel to the flow direction. Although the presence of steady mass flows improves the efficiency of nonadiabatic mechanisms on the attenuation of slow and thermal waves, fast kink waves are more efficiently attenuated when they propagate parallel to the flow direction.

Subject headings: Sun: corona — Sun: magnetic fields — Sun: oscillations — Sun: prominences

1. INTRODUCTION

Prominences and filaments are large-scale magnetic structures embedded in the solar corona and whose plasma density and temperature are akin to that of the chromosphere. High-resolution images of solar filaments (e.g., Lin et al. 2003, 2005, 2007) clearly show the existence of horizontal fine-structures within the filament body. This observational evidence suggests that prominences are composed of many field-aligned threads. These threads are usually sketched with respect to the filament long axis by an angle of 20° on average, although their orientation can vary significantly within the same prominence (Lin 2004). The observed thickness, \(d\), and length, \(l\), of threads are typically in the ranges \(0.2'' < d < 0.6''\) and \(5'' < l < 20''\) (Lin et al. 2005). Since the observed thickness is close to the resolution of present-day telescopes, it is likely that even thinner threads could exist. According to some models (e.g., Ballester & Priest 1989), a thread is believed to be part of a larger magnetic coronal flux tube which is anchored in the photosphere, with denser and cooler material near its apex, i.e., the observed thread itself. However, the process that leads to the formation of such structures is still unknown.

There is much evidence of small-amplitude waves and oscillatory motions in quiescent prominences (this topic has been reviewed by Oliver & Ballester 2002; Ballester 2006; Banerjee et al. 2007). Focusing on prominence fine-structures, some observers have detected oscillations and traveling waves in individual threads or groups of threads (Yi et al. 1991; Yi & Engvold 1991; Lin 2004; Lin et al. 2007), with periods typically between 3 and 20 minutes. In addition, mass flows along filament threads, with a flow velocity in the range \(5-25\) km s\(^{-1}\), have also been observed (Zirker et al. 1998; Lin et al. 2003, 2005). Moreover, it is noticeable that Zirker et al. (1998) and Lin et al. (2003) have detected flows in opposite directions within adjacent threads, a phenomenon known as counterstreaming. On the other hand, some observational works have suggested signatures of wave damping in prominence oscillations (Landman et al. 1977; Tsubaki & Takeuchi 1986; Lin 2004), but to date only Molowny-Horas et al. (1999) and Terradas et al. (2002) have studied in detail this phenomenon, in particular in two-dimensional Doppler velocity time series. This analysis showed that oscillations detected in large areas of a quiescent prominence were attenuated after a few periods. Although this quick attenuation seems to be a common feature of prominence oscillations, unfortunately no similar observational study focusing on the attenuation of individual thread oscillations has been performed yet.

From the theoretical point of view, the usual interpretation of thread oscillations is in terms of the adiabatic magnetohydrodynamic eigenmodes supported by the thread body. The first investigation of individual thread vibrations was performed by Joarder et al. (1997), whose work was extended and corrected by Diaz et al. (2001), considering a nonisothermal Cartesian thread surrounded by the coronal medium (based on the model by Ballester & Priest 1989), in the \(\beta = 0\) approximation. These authors found that only the low-frequency oscillatory modes are confined within the dense region, and that perturbations can achieve large amplitudes in the corona at long distances from the thread. Later, Diaz et al. (2003) assumed the same geometry, but took longitudinal propagation into account, and obtained a better confinement for the perturbations. Considering a more realistic and representative cylindrical geometry, Diaz et al. (2002) found that a nonisothermal cylindrical thread supports an even smaller number of trapped oscillations and that perturbations are much more efficiently confined within the cylinder in comparison with the Cartesian case. It is worthwhile to mention that the collective oscillations of multithread systems have also been investigated by Diaz et al. (2005) and Diaz & Roberts (2006), again in Cartesian geometry. See Ballester (2006) for a review about theoretical works.

The effect of steady mass flows on the oscillatory modes of magnetic structures has been theoretically investigated in some
works. The most relevant ones for the present investigation are Nakariakov & Roberts (1995), who studied the effect of steady flow in coronal and photospheric slabs, and Terra-Homem et al. (2003), who extended the former study to cylindrical geometry. In addition to producing a shift of the oscillatory frequency, both papers show that the main effect of the flow is to break the symmetry between wave propagation parallel and antiparallel to the flow direction and, for sufficiently strong flows, that slow modes can only propagate parallel to the flow direction, antiparallel propagation being forbidden.

Turning to the damping of oscillations, its theoretical investigation has been undertaken by a number of recent papers. Among the proposed damping mechanisms to explain the attenuation (Ballai 2003), nonadiabatic effects are the most extensively investigated to date, although other candidates like wave leakage (Schutgens 1997a, 1997b; Schutgens & Toth 1999) and ion-neutral collisions (Fortezza et al. 2007) have also been studied. By removing the adiabatic assumption and taking into account thermal conduction and radiative losses as damping mechanisms, some works have studied the time damping in a homogeneous, unbounded plasma (Carbonell et al. 2004), in an isolated prominence slab (Terradas et al. 2005), and in a prominence slab embedded in the solar corona (Soler et al. 2007a, hereafter Paper I; Soler et al. 2008). The common main result of these studies is that nonadiabatic mechanisms can explain the observed damping times in the case of slow modes, whereas fast modes are much less attenuated by nonadiabatic effects. It is important to note that all these articles have studied the wave attenuation in models which attempt to represent the whole prominence body. Thus, none of them have neither considered the prominence fine-structure nor mass flows.

More recently, Carbonell et al. (2008) have performed the first attempt to study the combined effect of both nonadiabatic mechanisms and steady flows on the time damping of slow and thermal waves in a homogeneous, unbounded prominence plasma. These authors found that the mass flow does not modify the damping time of both slow and thermal waves with respect to the case without flow, but the period of the slow wave increases dramatically for flow velocities close to the nonadiabatic sound speed. Moreover, the thermal disturbance behaves as a propagating mode in the presence of flow. The present work goes a step forward with respect to Carbonell et al. (2008), since a more complicated geometry is assumed here. Our aim is to describe the effect of both mass flow and nonadiabatic effects on the oscillations supported by an individual prominence thread modeled as a homogeneous and infinite cylinder embedded in an unbounded and also homogeneous corona. For simplicity, the hot, coronal part of the magnetic tube that contains the thread is not taken into account. Gravity is also discarded. The inclusion of gravity would involve the consideration of a more complicated magnetic structure able to support the prominence material (e.g., Ballester & Priest 1989; Schmitt & Degenhardt 1995; Rempel et al. 1999). However, these kinds of configurations are unstable and incomplete, since they do not incorporate the physics that lead to stable solutions and, moreover, the obtained prominence widths are much smaller than those observed. Although some prominences and threads show unstable behavior, there are a number of observations of stable oscillating threads (e.g., Lin et al. 2003, 2005, 2007). For this reason and since the present work is focused on the study of waves in stable threads, we neglect the effect of gravity and consider a stable simplified model that allows us to deal with wave solutions.

This paper is organized as follows. The description of the model configuration and the basic equations for the discussion of linear nonadiabatic waves are given in §2. Then, the results are presented in §3, first for the case without flow and later extended by including a steady mass flow in the equilibrium. Finally, §4 contains our conclusions.

2. MODEL EQUATIONS

The model configuration considered in the present work (Fig. 1) is made of a homogeneous and isothermal plasma cylinder of radius \( a \) with prominence conditions (density \( \rho_p \) and temperature \( T_p \)) embedded in an unbounded corona (density \( \rho_c \) and temperature \( T_c \)). The cylinder is also unlimited in the axial direction. The internal temperature and density, as well as the coronal temperature, are considered as free parameters. However, the value
of the coronal density is given by imposing total pressure continuity across the interface between the flux tube and the external medium. In all the following expressions, the subscript 0 indicates local values, while subscripts \( p \) and \( c \) denote quantities explicitly computed with prominence and coronal parameters, respectively.

Given the model geometry, we use cylindrical coordinates, namely, \( r, \varphi, \) and \( z \), for the radial, azimuthal, and longitudinal coordinates, respectively. The magnetic field is uniform and oriented along the cylinder axis, \( B_0 = B_0 \hat{e}_z \), \( B_0 \) being the same constant in the thread and in the coronal medium. A steady mass flow is assumed along the \( z \)-direction, whose flow velocity can be different in the cylinder and in the corona. Thus, \( U_p = U_p \hat{e}_r \) and \( U_c = U_c \hat{e}_z \) correspond to the steady flow in the flux tube and in the corona, respectively.

Parallel thermal conduction to the magnetic field, radiative losses, and heating are considered as nonadiabatic effects. We assume that the plasma is fully ionized, and so the cross field or perpendicular thermal conduction is absolutely negligible. The contribution of neutrals to the thermal conduction in a partially ionized plasma has been investigated by Forteza et al. (2008). Radiation and heating are evaluated together by means of the radiation and heating are evaluated together by means of the corona, respectively. We also have that \( \tilde{B}_0 \) is the (complex) oscillatory frequency and \( k_z \) is the (real) longitudinal wavenumber, one can combine equations (3) and (6) to obtain the following relation between the perturbed pressure and density,

\[
p_1 = \tilde{\Lambda}_0^2 p_1, \tag{7}
\]

with

\[
\tilde{\Lambda}_0^2 = \frac{c_s^2}{\gamma} \left[ \frac{(\gamma - 1)\left(T_0/p_0\right)\kappa_{||} k_z^2 + \omega_T - \omega_p + i \gamma \Omega_0}{(\gamma - 1)\left(T_0/p_0\right)\kappa_{||} k_z^2 + \omega_T + i \Omega_0} \right], \tag{8}
\]

where \( \Omega_0 = \omega - U_0 k_z \) is the Doppler-shifted frequency (Terra-Homem et al., 2003), and \( \omega_p \) and \( \omega_T \) are defined in Paper I. We see than the complex quantity \( \tilde{\Lambda}_0 \) is a generalization, due to the presence of the flow, of the nonadiabatic sound speed defined in Paper I. The real part of \( \tilde{\Lambda}_0 \) plays the role of the sound speed when nonadiabatic effects are present. By means of this definition, one can see that the effect of nonadiabatic terms is to modify the medium sound speed, and so they most probably affect slow modes, since they are mainly governed by acoustic effects. See § 3.2.3 for more details about this quantity.

Now, following Terra-Homem et al. (2003), we combine the basic equations and arrive at the following expressions,

\[
\Upsilon^2 \left[ \Upsilon^2 - \left( \tilde{\Lambda}_0^2 + \nu^2 \right) \nabla^2 \right] \Delta + \tilde{\Lambda}_0^2 \nu^2 \frac{\partial^2}{\partial z^2} \nabla^2 \Delta = 0, \tag{9}
\]

\[
\left( \Upsilon^2 - \nu^2 \frac{\partial^2}{\partial z^2} \right) \Gamma = 0, \tag{10}
\]

where \( \nu^2 = B_0^2 / \mu p_0 \) is the Alfvén speed squared, \( \Upsilon \) is a linear operator defined as

\[
\Upsilon = \frac{\partial}{\partial t} + U_0 \frac{\partial}{\partial z},
\]

and \( \Delta \) and \( \Gamma \) are the divergence and the \( z \)-component of the rotational of the velocity perturbation, respectively,

\[
\Delta = \nabla \cdot v_1, \tag{12}
\]

\[
\Gamma = (\nabla \times v_1) \cdot \hat{e}_z. \tag{13}
\]

Equation (10) is the same as equation (14) of Terra-Homem et al. (2003) and governs torsional, Alfvén waves, which are not damped by nonadiabatic mechanisms and so are not considered in the present investigation. On the other hand, equation (9) represents fast and slow magnetosonic waves, together with the thermal or condensation mode (Field 1965). If nonadiabatic terms are neglected, \( \tilde{\Lambda}_0 = c_s \) and then our equation (9) reduces to equation (13) of Terra-Homem et al. (2003), which in the absence of flow \( (U_0 = 0) \) is equivalent to the well-known equation (17) of Lighthill (1960).

Next, the cylindrical symmetry of the model allows us to write the divergence of the velocity perturbation in the following form,

\[
\Delta = R(r) \exp(i \omega t + i n \varphi - i k_r z), \tag{14}
\]

where \( n \) is an integer that plays the role of the azimuthal wave number. Expressions for the perturbed quantities as a function of \( \Delta \) can be found in Appendix A. Now, applying this last expression to equation (9), one finds that \( R(r) \) satisfies the well-known Bessel equation of order \( n \),

\[
r^2 \frac{d^2 R}{dr^2} + r \frac{dR}{dr} + \left( m_0^2 r^2 - n^2 \right) R = 0, \tag{15}
\]

Here, \( p_0, \rho_0, T_0, B_0, \) and \( U_0 \) are the equilibrium gas pressure, density, temperature, magnetic field, and flow velocity, respectively. We also have that \( p_1, \rho_1, T_1, B_1 = B_\parallel \hat{e}_z + B_\perp \hat{e}_r + B_e \hat{e}_\varphi, \) and \( v_1 = v_r \hat{e}_r + v_\varphi \hat{e}_\varphi + v_z \hat{e}_z \) are the linear gas pressure, density, temperature, magnetic field, and velocity perturbations, respectively. Finally, \( c_s^2 = \gamma_0 p_0 / \rho_0 \) is the adiabatic sound speed squared, \( \kappa_{||} = 10^{-11} T^{5/2} \) W m\(^{-1}\) K\(^{-1}\) is the thermal conductivity parallel to the magnetic field, and \( L_\rho \) and \( L_T \) are the partial derivatives of the heat-loss function with respect to density and temperature, respectively (see Paper I for details).

Assuming perturbations of the form \( \tilde{f}_1(r, \varphi) \exp(i \omega t - i k_r z) \), where \( \omega \) is the (complex) oscillatory frequency and \( k_z \) is the (real)
with

\[ m_0^2 = \frac{\left( \Omega_0^2 - k_z^2 v_{\text{mr}}^2 \right) \left( \Omega_0^2 - k_z^2 v_{\text{mc}}^2 \right)}{\left( v_{\text{mr}}^2 + \lambda_0^2 \right) \left( \Omega_0^2 - k_z^2 v_{\text{mr}}^2 \right)}, \]

\[ \hat{\Omega}_0^2 = \frac{\Omega_0^2}{v_{\text{mr}}^2 + \lambda_0^2}, \]

The radial wavenumber squared, \( m_0^2 \), is in general a complex quantity; hence, no pure bodylike or surfacelike waves are possible in nonadiabatic magnetohydrodynamics. If one assumes that \( \text{Re}(m_0^2) > |\text{Im}(m_0^2)| \) (i.e., nonadiabatic effects produce a small correction to the adiabatic wave modes), the dominant wave character depends on the sign of \( \text{Re}(m_0^2) \). Thus, oscillations are mainly bodylike if \( \text{Re}(m_0^2) > 0 \) and solutions of equation (15) are Bessel functions. On the contrary, if \( \text{Re}(m_0^2) < 0 \), oscillations are mainly surfacelike (or evanescent) and solutions of equation (15) are modified Bessel functions. In this work we assume no wave propagation in the coronal medium, so the evanescent condition in the corona is imposed on the perturbations, namely, \( \text{Re}(m_0^2) < 0 \). On the other hand, the present ordering of sound and Alfvén speeds does not permit the existence of surface waves within the fibril, so \( \text{Re}(m_0^2) > 0 \) is assumed. Then \( R(r) \) is a piecewise function,

\[ R(r) = \begin{cases} A_1 J_0(m_p r), & r \leq a, \\ A_2 K_0(n r), & r > a, \end{cases} \]

with \( n^2 = -m_0^2, A_1 \) and \( A_2 \) being complex constants. The functions \( J_0 \) and \( K_0 \) are the usual Bessel and modified Bessel functions of order \( n \), respectively (Abramowitz & Stegun 1972). In order to obtain the dispersion relation that governs the behavior of wave modes, we impose the continuity of the Lagrangian radial displacement, \( v_f / \Omega_0 \), and the total pressure perturbation, \( p_I \), at the cylinder edge, \( r = a \). After some algebra, the following expression is obtained,

\[ \frac{\rho_c}{\rho_p} \left( \Omega_c^2 - k_z^2 v_{\text{mc}}^2 \right) m_p J_0'(m_p a) = \left( \Omega_p^2 - k_z^2 v_{\text{mr}}^2 \right) n_c K_0'(n a) J_0(n a), \]

where the prime denotes the derivative taken with respect to \( r \). Equation (19) is formally identical to equation (21) of Terra-Homem et al. (2003), since our nonadiabatic terms are enclosed in the definition of \( m_p \) and \( n_c \). If both nonadiabatic effects and the flow are dropped, equation (19) simply reduces to the well-known dispersion relation of Edwin & Roberts (1983).

The solution of equation (19) for a real \( k_z \) is a complex frequency, \( \omega = \omega_R + i \omega_I \). The oscillatory period \( (P) \), damping time \( (\tau_D) \), and the ratio of both quantities are computed as follows,

\[ P = \frac{2\pi}{|\omega_R|}, \quad \tau_D = \frac{1}{\omega_I}, \quad \frac{\tau_D}{P} = \frac{1}{2\pi} \frac{|\omega_R|}{\omega_I}. \]

3. RESULTS

3.1. Configuration without Flow

In this section we first perform a study of the solutions of the dispersion relation (eq. [19]) in the absence of steady flow. In this case, \( U_p = U_c = 0 \) and so \( \Omega_p = \Omega_c = \omega \). This situation corresponds to the case studied by Edwin & Roberts (1983) with the addition of nonadiabatic effects. Unless otherwise stated, the following equilibrium parameters are used in all computations: \( T_p = 8000 \text{ K}, \rho_p = 5 \times 10^{-11} \text{ kg m}^{-3}, T_c = 10^6 \text{ K}, \rho_c = 2.5 \times 10^{-13} \text{ kg m}^{-3}, B_0 = 5 \text{ G}, \) and \( a = 30 \text{ km} \). Thus, the characteristic speeds of the internal and external media are \( c_{\text{T},p} = 11.56 \text{ km s}^{-1}, c_{\text{T},p} = 11.76 \text{ km s}^{-1}, c_{\text{T},c} = 163.51 \text{ km s}^{-1}, c_{\text{T},c} = 166.33 \text{ km s}^{-1}, \) and \( v_{\text{A},c} = 892.06 \text{ km s}^{-1}. \) In addition, both prominence and coronal plasmas are taken as optically thin (see Table 1 in Paper I for the values of parameters \( \chi^2 \) and \( \alpha \) of the heat-loss function).

In the absence of flow, the complex oscillatory frequencies obtained by solving equation (19) for a fixed, real, and positive \( k_z \) appear in pairs, \( \omega_1 = \omega_R + i \omega_I \) and \( \omega_2 = -\omega_R + i \omega_I \). The solution \( \omega_1 \) corresponds to a wave propagating toward the positive \( z \)-direction (parallel to magnetic field lines), whereas \( \omega_2 \) corresponds to a wave that propagates toward the negative \( z \)-direction (antiparallel to magnetic field lines). For short, we call them parallel and antiparallel waves, respectively. Both parallel and antiparallel wave modes are equivalent and show exactly the same physical properties when no flow is considered. For the sake of simplicity, the results presented in this section correspond to parallel waves, which have a positive phase speed. Equivalent results for antiparallel waves are deduced by considering negative phase speeds.

3.1.1. Dispersion Diagram and Eigenfunctions of Magnetoo acoustic Modes

Magnetoo acoustic modes supported by a magnetic cylinder have been extensively investigated (e.g., Spruit 1982; Edwin & Roberts 1983; Cally 1986). Fast oscillations with \( n = 0, n = 1 \), and \( n \geq 2 \) correspond to sausage, kink, and fluting or ballooning modes, respectively. On the basis that thread oscillations are observed in Doppler time series, this work is mainly focused on kink modes, which produce displacements of the thread axis from its original position. The fundamental fast kink mode is trapped for realistic values of the thickness and width of threads. Regarding slow modes, the fundamental modes and their harmonics are all trapped for any value of \( k_z \) and \( n \), but all of them have an almost identical frequency, as in the slab case (Paper I). Thus, we also restrict ourselves to the fundamental slow mode with \( n = 1 \) for simplicity. An additional solution of equation (19) is the thermal mode which, in the absence of flow, has a purely imaginary frequency (see § 3.1.3).

Figure 2 displays the phase speed diagram corresponding to the fundamental modes with \( n = 0 \) and 1 (compare this with Fig. 2
of Paper I). One can see that the behavior of slow modes and the fast sausage mode is similar to that in a slab. An important difference with the results of Paper I is that in the cylindrical case the fast kink mode does not couple with the external leaky slow modes enclosed in the region $\text{Re}(\tilde{\omega}) < \omega_P/k_z < \text{Re}(\Omega_0)$, because its phase speed in the long-wavelength limit is $c_k < \text{Re}(\tilde{\omega})$, with $c_k^2 = (\rho_p v_{\Lambda,\rho}^2 + \rho_v v_{\Lambda,v}^2)(\rho_p + \rho_v)$.

Next, we plot in Figure 3 the eigenfunctions corresponding to the radial and longitudinal velocity perturbations, $v_r$ and $v_z$, and the total pressure perturbation, $P_T$, for the fundamental slow and fast kink magnetoacoustic modes. Contrary to the slab case of Soler et al. (2007b, Fig. 4), perturbations are efficiently confined within the cylinder for any value of the longitudinal wavenumber. Thus, this suggests that the influence of the corona on the damping of oscillations could be of smaller importance than in a magnetic slab. On the other hand, the expected velocity polarization is obtained, the slow mode being mainly polarized along the longitudinal direction ($v_z \gg v_r$) and the fast kink mode being responsible for transverse, radial motions ($v_r \gg v_z$).

### 3.1.2. Damping Times of Fast Kink and Slow Waves and Comparison with a Longitudinal Slab

We now compute the period, damping time, and their ratio for the fundamental fast kink and slow modes for a wide range of $k_z (10^{-10} \text{ m}^{-1} < k_z < 10^{-2} \text{ m}^{-1})$. This range includes the values corresponding to the observed wavelengths in prominences ($10^{-5} \text{ m}^{-1} \lesssim k_z \lesssim 10^{-6} \text{ m}^{-1}$). In Figure 4 these results are compared with those obtained for a longitudinal slab whose half-width is equal to the cylinder radius (i.e., the case analyzed in § 4.4 of Paper I). We see that the results of the slow mode are almost identical in both cylindrical and slab geometries; hence, the reader is referred to Paper I for a description of the slow mode behavior.

On the contrary, the results of the fast kink mode show significant differences between the slab and the cylinder. For small and intermediate $k_z$, both the period and damping time in a cylinder are larger than in a slab. This effect is specially noticeable for the damping time in the observed range of wavelengths, which is larger than in the slab. This suggests that the fast kink mode damping time due to nonadiabatic effects is much larger than typical lifetimes of filament threads and prominences. Hence, nonadiabatic fast kink waves are in practice undamped when these results are applied in the solar context.

### 3.1.3. Thermal Mode

Now we turn our attention to the thermal or condensation mode. The condensation instability has been studied in uniform, unbounded plasmas (Field 1965), in coronal slabs (van der Linden & Goossens 1991), and in coronal cylinders (An 1984). Since the thermal mode has a purely imaginary frequency, we now assume that $\omega = is$, where $s$ is real and often called the damping (or growing) rate. The situation $s > 0$ corresponds to a damped thermal mode, whereas $s < 0$ occurs if the mode is thermally unstable. The sign of $s$ can be estimated a priori by considering the stability criterion provided by Field (1965),

$$\kappa_{||,p} k_z^2 + \rho_p \left( L_T,\rho - \frac{\rho_p}{T_p} L_{\rho,p} \right) > 0.$$  \hfill (21)

Since for prominence conditions this inequality is verified for any real value of $k_z$, the thermal mode is always a damped solution,
and therefore, we expect $s > 0$. According to van der Linden & Goossens (1991), see Appendix B for more details, the evanescent assumption in the corona ($m^2_c < 0$) together with the body-wave assumption within the fibril ($m^2_p > 0$) is satisfied in a narrow range of $s$. However, there is an extremely narrow range of $k_z$ ($1.68 \times 10^{-7} \leq k_z \leq 1.70 \times 10^{-7}$) in which $m^2_p > 0$ and $m^2_c > 0$, and so the evanescent assumption is not verified. Then, the thermal mode does not exist as a nonleaky solution in such a range of $k_z$. Despite this, the fundamental thermal mode and all its harmonics have an almost identical damping rate $s$, whose value is also almost independent of the azimuthal wave-number, $n$. For this reason and for the sake of simplicity, we again restrict ourselves to solutions with $n = 1$ and focus on the fundamental mode.

Figure 5 displays the spatial distribution of perturbations $v_r$, $v_z$, and $P_T$ corresponding to the fundamental thermal mode with $n = 1$. We see that the velocity field is dramatically polarized along the cylinder axis and that the eigenfunctions are very similar to those obtained for the slow mode (compare with Fig. 3, top). On the other hand, the damping time ($\tau_D = 1/s$) is plotted in Figure 6 as a function of $k_z$. One can see that this mode is very quickly attenuated and that radiative losses from the prominence plasma are responsible for the attenuation in the observed wavelength range, whereas prominence thermal conduction is only relevant for large $k_z$. Coronal mechanisms have a negligible effect.

### 3.2. Effect of Steady Flow

Hereafter, we include a steady mass flow in the model in order to assess its influence on the oscillatory modes described above. With no loss of generality, we assume no flow in the external medium, i.e., $U_c = 0$. Moreover, the internal flow is assumed flowing toward the positive $z$-direction, i.e., $U_p > 0$. Note that any other possible configuration can be obtained by means of a suitable election of the reference frame.

#### 3.2.1. Phase Speed Shift

The reader is referred to Terra-Homem et al. (2003) for a detailed description of the modification of the phase speed diagram.
due to the presence of flow. In short, the symmetry between parallel \((\omega_R > 0)\) and antiparallel \((\omega_R < 0)\) waves is broken by the flow. Phase speeds of slow and fast parallel waves are now in the ranges \([\text{Re}(\tilde{c}_{T_r}) + U_p, \text{Re}(\tilde{\lambda}_p) + U_p]\) and \([v_{\lambda_p} + U_p, v_{\lambda_c}]\), respectively. On the other hand, phase speeds of slow and fast antiparallel waves lie now within the regions \([-\text{Re}(\tilde{\lambda}_p) + U_p, -\text{Re}(\tilde{c}_{T_r}) + U_p]\) and \([-v_{\lambda_c}, -v_{\lambda_p} + U_p]\), respectively. For a flow velocity larger than the internal nonadiabatic sound speed (see Carbonell et al. 2008), the phase speed of antiparallel slow waves is dragged to positive values, and so they become parallel waves in practice. These solutions were called backward waves by Nakariakov & Roberts (1995). An equivalent phenomenon can also occur for fast waves for a super-Alfvénic flow, i.e., \(U_p > v_{\lambda_p}\). Note that super-Alfvénic flows seem to be unrealistic in light of observations.

Regarding thermal modes, the real part of their frequency now acquires a positive value, and their phase speed is equal to the flow velocity. Thus, thermal modes behave as parallel-propagating waves with respect to the static, external reference frame. Although this result could be relevant for the observational point of view, since thermal modes might be detected as propagating waves in filament threads (Lin et al. 2007), their extremely quick attenuation makes them undetectable in practice.
3.2.2. Influence on the Damping Time

Regarding the effect of the flow on the damping time of oscillations, we plot in Figure 7 the dependence of the period, damping time, and their ratio as a function of the flow velocity. The longitudinal wavenumber has been fixed to $k_{\alpha} = 10^{-2}$, which corresponds to a value within the observed range of wavelengths. The flow velocity is considered in the range $0 \text{ km s}^{-1} < U_p < 30 \text{ km s}^{-1}$, which corresponds to the observed flow speeds in quiescent prominences. In agreement with Carbonell et al. (2008), the antiparallel slow wave becomes a backward wave for $U_p > 8.5 \text{ km s}^{-1}$, which corresponds to the nonadiabatic sound speed (eq. [8]). This causes the period of this solution to grow dramatically near this flow velocity. However, the period of both parallel and antiparallel fast kink waves is only slightly modified with respect to the solution in the absence of flow, and the thermal wave now has a finite period, which is comparable to that of the parallel slow mode.

On the other hand, we see that the damping time of both slow and thermal modes is not affected by the presence of flow, as in Carbonell et al. (2008). Nevertheless, the attenuation of the fast kink mode in the present case is influenced by the flow. The larger the flow velocity, the more attenuated the parallel fast kink wave, whereas the opposite occurs for the antiparallel solution. This behavior can be understood with the help of Figure 8, which displays the phase speed of the parallel fast kink mode and its damping time for a wider range of the flow velocity and for different values of the thread density. We see that for a specific value of the flow velocity the parallel fast mode phase speed coincides with that of the external leaky slow modes, which is in the range $[\text{Re}(\tilde{c}_T), \text{Re}(\tilde{c}_w)]$. Then, for this flow velocity, the parallel fast kink wave couples with the external slow modes by means of a
“weak” coupling, according to the nomenclature from Soler et al. (2008). This coupling causes a minimum in the damping time as is clearly seen in Figure 8b. On the other hand, a similar argument can be adopted to explain the increase of the antiparallel fast mode damping time with $U_n$, since the phase speed of the antiparallel wave moves away to the phase speed region of (antiparallel) external slow modes, i.e., $[\Re(\Lambda_c), -\Re(\tilde{c}_{T,c})]$, as the flow speed increases. For parallel waves, the flow velocity for which the coupling takes place depends on the thread density in such a way that the smaller the density, the smaller the flow velocity. Hence, the minimum of the damping time moves to smaller values of the flow velocity for a small thread density. Nevertheless, this minimum takes place at a flow velocity of about 40 km s$^{-1}$ for a representative thread density of $\rho_p = 5 \times 10^{-11}$ km s$^{-1}$, which is a larger velocity than those observed by at least a factor of 2. Moreover, even the smallest damping time is several orders of magnitude larger than the lifetimes of prominence threads, meaning that the effect of the flow is not enough to obtain a reasonable and realistic attenuation for kink modes.

3.2.3. Nonadiabatic Sound Speed

Next, we study the influence of the steady mass flow on the value of the internal nonadiabatic sound speed. Since the internal nonadiabatic sound speed corresponds to the value of the flow velocity for which antiparallel slow waves become backward waves, it is interesting to assess its behavior as a function of the wave-number and the flow velocity. We perform a study similar to that by Carbonell et al. (2008) and compute the internal nonadiabatic sound speed as a function of $k_z$ for different values of the flow velocity (Fig. 9). The dependence on $k_z$ is the one explained by Carbonell et al. (2008) and presents three different plateaus. For large $k_z$, the dominant mechanism is prominence thermal conduction, and the nonadiabatic sound speed coincides with the isothermal value. For intermediate $k_z$, the nonadiabatic sound speed does not depend on nonideal effects, and its value corresponds to the adiabatic sound speed. For small $k_z$, including the observed region of wavelengths, the nonadiabatic sound speed becomes slightly smaller than the isothermal one, and prominence radiation is the governing mechanism. On the other hand, one can see that the effect of the flow is to widen the range of $k_z$, in which the nonadiabatic sound speed matches the adiabatic value: the larger the flow, the wider the range. For large flow velocities, the transition between the intermediate-$k_z$ (adiabatic) and the small-$k_z$ plateaus takes place within the observed wavelength region.

4. CONCLUSIONS

In the present work we have studied the combined effect of both nonadiabatic effects and a steady mass flow on the damping of oscillations supported by an individual, cylindrical, and homogeneous prominence thread. Our main conclusions are summarized as follows.

1. In the absence of flow, slow modes are efficiently damped by nonadiabatic effects, while fast kink waves are in practice non-attenuated, since their damping times are much larger than typical lifetimes of filament threads.

2. The damping by nonadiabatic mechanisms of transverse, kink oscillations is much less efficient in the present, cylindrical case than in the slab geometry.

3. The thermal wave is a nonpropagating solution in the absence of flow, and its attenuation by radiative losses is extremely quick.

4. The presence of flow breaks the symmetry between waves propagating parallel or antiparallel to the flow. For a flow velocity larger than the internal nonadiabatic sound speed, antiparallel slow waves become backward waves.

5. In the presence of flow, the thermal mode behaves as a wave that propagates parallel to the flow, and its motions are mainly polarized along the longitudinal direction. Nevertheless, this oscillatory behavior cannot be likely observed in practice due to its quick damping.

6. The damping time of both slow and thermal waves is not affected by the flow. On the contrary, for realistic values of the flow velocity, the larger the flow, the larger the attenuation of parallel fast kink waves, whereas the contrary occurs for antiparallel fast kink solutions. Nevertheless, this effect is not enough to observe realistic damping times in the case of fast kink modes.

In agreement with previous studies, the consideration of nonadiabatic mechanisms provides damping times that are compatible with observations in the case of slow modes, which can be related to long-period oscillations. The main effect of the flow on these solutions is that only propagation parallel to the flow is allowed for strong enough flows. The negligible attenuation of fast kink modes in the absence of flow is slightly improved in the case of parallel waves when flow is present, the damping time being diminished by an order of magnitude for realistic flow velocities. However, the damping time is still several orders of magnitude larger than the lifetimes of filament threads, and therefore, neither nonadiabatic mechanisms nor mass flows provide reasonable fast mode damping times applicable to prominences. For this reason, it is likely that another damping mechanism is responsible for a more efficient attenuation of transverse thread motions, resonant absorption being a good candidate which should be investigated.

On the other hand, the investigation of the effect of flow, and in particular counterstreaming flows, on the damping of collective transverse oscillations of cylindrical multithread models is interesting in light of the present results and could be the subject of future research.

APPENDIX A

EXPRESSIONS FOR THE PERTURBATIONS

Expressions for the perturbations as functions of the divergence of the perturbed velocity, $\Delta = \nabla \cdot \mathbf{v}_1$, and its derivative are given as

$$v_r = -\frac{(\Omega_0^2 - k_0^2 \tilde{\lambda}_0^2)}{\Omega_0^2 m_0} \frac{\partial \Delta}{\partial r}.$$  

(A1)
\[ v_\varphi = -i \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2 m_0^2} \right) \frac{n}{r} \Delta, \quad (A2) \]
\[ v_z = -i \frac{\Lambda_0^2 k_z}{\Omega_0} \Delta, \quad (A3) \]
\[ \rho_1 = i \frac{\rho_0}{\Omega_0} \Delta, \quad (A4) \]
\[ p_1 = i \frac{\rho_0 \Lambda_0^2}{\Omega_0} \Delta, \quad (A5) \]
\[ T_1 = \frac{T_0}{\Omega_0} \left( \frac{\Lambda_0^2}{c_z^2} - 1 \right) \Delta, \quad (A6) \]
\[ B_r = -B_0 k_z \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2 m_0^2} \right) \frac{n}{r} \Delta, \quad (A7) \]
\[ B_\varphi = -i B_0 k_z \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2 m_0^2} \right) \frac{n}{r} \Delta, \quad (A8) \]
\[ B_z = i B_0 \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2 m_0^2} \right) \Delta, \quad (A9) \]
\[ p_m = i \rho_0 v_\lambda^2 \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2} \right) \Delta, \quad (A10) \]
\[ p_T = p_1 + p_m = i \rho_0 \left( \frac{\Omega_0^2 - k_z^2 \Lambda_0^2}{\Omega_0^2 m_0^2} \right) \Delta. \quad (A11) \]

**APPENDIX B**

**REGION OF NONEXISTENCE OF THE THERMAL MODE**

Following a similar argument to that used by van der Linden & Goossens (1991), let us consider that the thermal mode frequency in the absence of flow is given by \( \omega = is \), with \( s \) a real quantity. So, from equation (16) one obtains

\[ m_0^2 = - \left( \frac{(s^2 + k_z^2 c_\lambda^2)}{(v_\lambda^2 + \Lambda_0^2)} \right) \left( \frac{(s^2 + k_z^2 \Lambda_0^2)}{(s^2 + k_z^2 c_\lambda^2)} \right) = - \left( \frac{(s^2 + k_z^2 c_\lambda^2)}{(v_\lambda^2 + \Lambda_0^2)} \right) \frac{A}{B}. \quad (B1) \]

Quantities \( A \) and \( B \) are the following third-order polynomials in \( s \),

\[ A = s^3 - N_2 s^2 + k_z^2 c_\lambda^2 s - k_z^2 c_\lambda^2 N_2, \quad (B2) \]
\[ B = s^3 - N_3 s^2 + k_z^2 c_\lambda^2 s - k_z^2 c_\lambda^2 N_1, \quad (B3) \]

with

\[ N_1 = \frac{(\gamma - 1)}{\gamma} \left( \frac{T_0}{\rho_0} k_z^2 + \omega_T - \omega_p \right), \quad (B4) \]
\[ N_2 = (\gamma - 1) \left( \frac{T_0}{\rho_0} k_z^2 + \omega_T \right), \quad (B5) \]
\[ N_3 = \frac{N_2 v_\lambda^2 + N_1 c_\lambda^2}{v_\lambda^2 + c_\lambda^2}. \quad (B6) \]

The condition \( m_p^2 > 0 \) implies that \( \text{sgn}(A_p) \neq \text{sgn}(B_p) \). The solutions of \( A = 0 \) are a pair of complex conjugate roots and a real root, while the same stands for the roots of \( B = 0 \). Then, the condition \( m_0^2 > 0 \) is only verified in the region between the real roots of \( A_p = 0 \) and \( B_p = 0 \), namely, \( s_{A_1} \) and \( s_{B_1} \), respectively, which are very close to each other. On the other hand, the external evanescent requirement \( (m_\rho^2 < 0) \) is verified outside the region between the real solutions of \( A_\rho = 0 \) and \( B_\rho = 0 \), namely, \( s_{A_1} \) and \( s_{B_1} \), respectively. By computing these real roots (Fig. 10), one obtains that both regions do not overlap except for \( 5.04 \times 10^{-3} \leq k_z a \leq 5.10 \times 10^{-3} \). Thus, outside this extremely narrow overlapping region, the thermal mode exists with a damping rate in the range \( s_{B_1} < s < s_{A_1} \), where both conditions \( m_p^2 > 0 \) and \( m_\rho^2 < 0 \) are satisfied.
Fig. 10.—Damping rate per wavenumber vs. the wavenumber, both in dimensionless units. The shaded zone indicates the region where the thermal mode does not exist as an evanescent-like solution, i.e., the overlap of the regions where $m_c^2 > 0$ (between solid lines) and $m_c^2 < 0$ (between dashed lines) are both satisfied.
