We present the first multi-wavelength follow-up observations of two candidate gravitational-wave (GW) transient events recorded by LIGO and Virgo in their 2009–2010 science run. The events were selected with low latency by the network of GW detectors (within less than 10 minutes) and their candidate sky locations were observed by the Swift observatory (within 12 hr). Image transient detection was used to analyze the collected electromagnetic data, which were found to be consistent with background. Off-line analysis of the GW data alone has also established that the selected GW events show no evidence of an astrophysical origin; one of them is consistent with background and the other one was a test, part of a “blind injection challenge.” With this work we demonstrate the feasibility of rapid follow-ups of GW transients and establish the sensitivity improvement joint electromagnetic and GW observations could bring. This is a first step toward an electromagnetic follow-up program in the regime of routine detections with the advanced GW instruments expected within this decade. In that regime, multi-wavelength observations will play a significant role in completing the astrophysical identification of GW sources. We present the methods and results from this first combined analysis and discuss its implications in terms of sensitivity for the present and future instruments.

**Key words:** gravitational waves – ultraviolet: general – X-rays: general

1. INTRODUCTION

Some of the key questions in the pursuit of sources of transient gravitational radiation detectable by LIGO (Abbott et al. 2009) and Virgo (Accadia et al. 2012) relate to their electromagnetic (EM) signatures and our ability to observe them (Abadie et al. 2012a). In several of these sources, such as core-collapse supernovae and neutron-star–neutron-star or neutron-star–black-hole mergers, energetics suggest gravitational waves (GWs) are likely to be accompanied by EM emission across the spectrum and over timescales ranging from seconds to days (Fryer et al. 2002; Piran 2004; Mészáros 2006; Nakar 2007; Corsi & Mészáros 2009). Multi-wavelength EM observations of such events have already set the paradigm for improved constraints on source astrophysics set jointly rather than separately. Prompt outbursts, as well as afterglows in X-ray, optical, and radio associated with gamma-ray bursts (GRBs) and supernovae have shed light on the progenitors and the astrophysics of these systems (Kulkarni et al. 1998; Bloom et al. 1999; Matheson et al. 2003; Berger et al. 2005; Gehrels et al. 2005; Soderberg et al. 2005, 2010; Berger 2009, 2011; Zhang & MacFadyen 2009). The benefit of coupling them to GW observations will be tremendous as this will bring the GW observations into astrophysical and cosmological context. Besides increasing detection confidence
(Kochanek & Piran 1993), multi-wavelength observations may improve source localization down to the arcsecond level, leading to identification of the host galaxy and measurement of the redshift (Schutz 1986; Sylvestre 2003; Stubbs 2008; Phinney 2009; Stamatakis et al. 2009; Bloom et al. 2009; Metzger et al. 2010; Metzger & Berger 2012). Conversely, the absence of any EM signature for an otherwise confident transient detection with the GW detectors alone will provide constraints on emission mechanisms, progenitors, and energetics.

LIGO (Abbott et al. 2009) and Virgo (Accadia et al. 2012) form a network of interferometric detectors aiming to make the first direct observations of GWs. In their 2009–2010 data-taking period this network consisted of three interferometers: LIGO-Hanford in Washington State in the USA, LIGO-Livingston in Louisiana in the USA, and Virgo in Italy. During these science runs of the instruments we implemented a first program that could allow prompt EM follow-up of candidate GW transients. Starting with GW data, low-latency searches for compact binary star coalescences (Abadie et al. 2011a) and un-modeled GW transients were performed. This allowed the prompt identification and sky localization of GW candidates, which for the first time were passed on to ground-based telescopes and Swift in order to be followed up. In an earlier publication (Abadie et al. 2012a) we presented the details of the implementation and testing of this low-latency search and its coupling to EM astronomy. In this paper we report on the analysis of the Swift data we collected as part of this program.

With the start of the 2009–2010 LIGO–Virgo runs we established a Target-of-Opportunity (ToO) program with Swift in order to search for possible afterglow in X-ray, ultraviolet, and optical wavelengths of a small number of GW transient candidates. The sensitivity of the GW detectors at the time made the chance of a detection small, but non-negligible. For the case of binary sources with at least one neutron star in the system, the rate of detectable merger events was predicted to be in the range of $2.7 \times 10^{-4}$ to 0.3 events per year (Abadie et al. 2010a). This ToO program was exercised twice; neither time led to detection of an EM counterpart to a GW transient. Nonetheless, the program addressed implementation questions and established the first joint observation and coordinated data analysis by the LIGO–Virgo network and Swift satellite.

In this paper we present the results from the EM follow-up program involving only Swift; results from the sister program involving the follow-up of GW candidates by ground-based optical and radio telescopes will be the subject of a forthcoming publication. The paper is organized as follows. In Section 2 we describe the Swift observatory. Then, in Section 3, we review the procedure for targeting EM follow-up of GW events, as described in detail in Abadie et al. (2012a). The Swift observations and analysis of data are described in Section 4. In Section 5 we present our formalism for combining results from the joint GW–EM search, including the simulation work we performed. We conclude in Section 6 with a discussion and outlook for this kind of joint search.

2. THE SWIFT OBSERVATORY

The Swift Gamma-Ray Burst Mission (Gehrels et al. 2004), developed and launched under NASA’s Medium Explorer Program, is unique for its broad wavelength sensitivity and rapid response. Three telescopes are co-aligned. The Burst Alert Telescope (BAT; Barthelmy et al. 2005) is a broad field of view (FOV) coded-aperture instrument with a CdZnTe detector plane, designed to search for transient events such as GRBs. Approximately 100 GRBs are discovered by BAT each year. In response to a BAT trigger, the spacecraft performs an autonomous slew to point the two narrow FOV instruments. The Ultra-Violet and Optical Telescope (UVOT; Roming et al. 2005) performs follow-up observations of GRBs in the 170–600 nm band, with a $0.28 \times 0.28$ FOV. The X-Ray Telescope (XRT; Burrows et al. 2005) has an effective area peaking at 110 cm$^2$ (at 1.5 keV), a $0.4 \times 0.4$ FOV, and an energy bandpass of 0.3–10 keV. While spacecraft slewing can be initiated autonomously, achieving re-pointing within approximately 2 minutes, the process can also be initiated from the ground. The Swift Mission Operations Center, located near the University Park campus of the Pennsylvania State University, receives over 1000 requests for ToOs from the astronomical community each year. Response time to a ToO depends on scientific priority and urgency. Due to communication limitations and human-in-the-loop commanding, observation of the highest priority ToOs is typically achieved within 4 hr, although frequently the response time is less than 1 hr. In this way, a ground-based observatory such as LIGO–Virgo can provide the trigger for a transient event, with Swift providing prompt follow-up observations in the X-ray, UV, and optical bands.

3. SELECTION OF GRAVITATIONAL-WAVE TRANSIENTS

The LIGO–Virgo EM follow-up program took place during two observing periods spanning a bit over two months from 2009 December 17 to 2010 January 8 and from 2010 September 2 to 2010 October 20. The details of the implementation and testing of the end-to-end search on the GW end have been described elsewhere (Abadie et al. 2012a). Here we will summarize the key features and expand on aspects that were specific to the joint program with Swift.

3.1. Event Selection

GW candidate events were selected for follow-up based primarily on their False Alarm Rate (FAR), the rate at which an event of equal or greater significance is expected to occur in the absence of a true signal. For this run, in order to trigger a Swift follow-up, we set a nominal threshold on the candidate events’ FAR at no more than one event per 35 days of triple coincident running (i.e., the GW instrument configuration when all three detectors were acquiring sensitive data). To avoid trying to image unusually poorly localized events, an additional constraint was placed on candidates that 20% or more of the a posteriori (see Section 3.2) weighted probability in the event sky map must be covered by up to five $0.4 \times 0.4$ tiles selected for follow-up as Swift fields. The number of fields picked for the Swift follow-up program reflected a compromise between the need to cover as large an area in the sky as possible and the requirement to be minimally disruptive of Swift’s other science targets. If five fields were targeted by Swift for each LIGO–Virgo candidate, the correct location of GW events of high significance could be imaged with a probability greater than 50% (Abadie et al. 2012a). Additionally, manual and automated checks were performed on data quality in each interferometer before sending any alerts, eliminating events which had an obvious problem associated with them. For events which passed all data selection criteria, observation requests were sent to Swift through web-based ToO submission.118

118 https://www.swift.edu/secured/too/too_request.htm
During the course of the EM follow-up program, GW candidate transient events were selected by transient-finding algorithms for un-modeled bursts as well as compact binary star coalescences (Abadie et al. 2012a). Two such events met all criteria and were submitted for follow-up with Swift. These were identified by one of the generic transient-finding algorithms, called coherent WaveBurst (Klimenko et al. 2011). This algorithm uses wavelet decomposition to search for GWs without relying on specific waveform models. The “January” event occurred at 8:46 UTC on 2010 January 7. This was an event close to the end of the first LIGO–Virgo observation period, during which we lowered the nominal thresholds to 1 event per day for the FAR and 10% for the weighted probability of the event skymap. The thresholds were adjusted as the first LIGO–Virgo observation period was approaching an end in order to exercise the follow-up process at least once. The “September” event, which occurred at 6:42 UTC on 2010 September 16, passed all nominal criteria for follow-ups. This event was later (in 2011 March) revealed to be a “blind injection” artificially inserted into the interferometers as a test of our detection procedures (Abadie et al. 2011b, 2011c, 2012b). While both of these events were ultimately tests of the system rather than plausible candidates, they demonstrate the viability of performing rapid follow-ups of potential GW signals using Swift.

3.2. Position Errors and Tiling

The typical uncertainty in sky location of a GW signal is large (typically tens of square degrees) relative to the FOV of Swift’s XRT and UVOT instruments. This may be in part addressed by imposing the requirement for the reconstructed sky location to overlap with nearby galaxies. We have used information from the Gravitational Wave Galaxy Catalog (GWGC; White et al. 2011) in order to fold into the tiling algorithm location, extent, and blue luminosity of known galaxies within a distance less than 50 Mpc, since the GW interferometer network would not be likely to detect neutron star binary coalescences beyond this distance. In this way, locations with a known galaxy from this catalog were given greater weight than those without galaxies present.

For the earlier “winter” run in which the January event occurred, skymap tiles with galaxies or globular clusters at a distance less than 50 Mpc had their estimated probability increased by a factor of three, whereas for the later “autumn” run the estimated relative probability of each tile in the skymap was calculated according to

\[
P \propto \sum_i \frac{M_i L}{D_i},
\]

where \(M_i\) is the blue light luminosity of a galaxy (a proxy for star formation rate; Phinney 1991; Kopparapu et al. 2008; Abadie et al. 2010a), \(L\) is the likelihood from only the GW skymap, and \(D_i\) is the distance of the galaxy from Earth (Nuttall & Sutton 2010). The index \(i\) sums over each galaxy associated with the skymap tile. Only \(\sim 8\%\) of tiles in a typical skymap were associated with one or more galaxies, while \(P\) was set to zero for tiles with no associated galaxy (Abadie et al. 2012a). After this summation was performed, the resulting likelihoods were renormalized to a probability of unity over the entire skymap. In this way we constructed the a posteriori probability skymaps that we used for prioritizing the Swift observations.

For both events selected for follow-up, several tiles were chosen and passed on for imaging as Swift fields according to the procedures outlined above. The probability skymaps produced by coherent WaveBurst without galaxy weighting and containing the top 1000 tiles are shown in Figure 1. The maps show large spreads in probability on the sky, the first due to their relatively low significance, the second due to worse sensitivity in Virgo relative to the LIGO interferometers. Simulations show that, despite the relatively small size of Swift fields with respect to the extent of our probability skymaps, sources originating in or close to nearby galaxies can be correctly localized with reasonable success rates (see Abadie et al. 2012a and discussion in Section 5). The regions containing the fields imaged by Swift are shown with an asterisk on each skymap, with precise coordinates of each field given in Tables 1 and 2.

4. OBSERVATIONS WITH SWIFT

The ToO requests were submitted manually via the Web within 2 hr from the collection of GW data. The initial two requested pointings for each event were submitted as “high priority” (but not the highest); this reflected a compromise between capturing the early light and being minimally disruptive to Swift operations. Swift observations with the XRT and UVOT instruments of the specified targets were performed in the following \(\sim 12\) hr. Rapid follow-up could significantly increase the likelihood of a detection, as several types of potential GW/EM sources (e.g., short GRBs) have afterglows that fade...
below detectability on a timescale of ~1 hours. The highest probability region of the January event skymap was observed by Swift in five overlapping fields (Figure 2). Each of these was observed twice that month. For the September event two disjoint Swift fields were observed (Figure 2). Note that the fields shown are explicitly for the XRT analysis, whereas the UVOT has a slightly smaller FOV. Each September event field was observed on two days, one in 2010 September and the other in 2010 December. Details of the observations are given in Tables 1 and 2.

### 4.1. X-Ray Results

We analyzed the Swift-XRT data with custom scripts which use the software described in Evans et al. (2007, 2009). For each field we combined the observations and produced a single image and exposure map. We then used the source detection and point-spread function (PSF) fitting code described in Goad et al. (2007) and Evans et al. (2009) to identify and localize sources in the field. This method uses a sliding-cell detection algorithm, with a fixed cell size of $21 \times 21$ pixels ($49\,^{\prime\prime}6 \times 49\,^{\prime\prime}6$, which encloses $93\%$ of the PSF). An initial run with a detection significance threshold of 3 (i.e., $S/\sigma_S$) is at least 3, where $S$ is the estimated number of net source counts in the cell, and $\sigma_S$ is the uncertainty in this value, determined using the background estimated from an annular box of size 51 pixels) revealed no sources in any of the observations, however for faint sources this box size is sub-optimal. We performed a second source search with a reduced detection threshold of 1.5$\sigma$. We measured the mean background level in each field and, using a circular source region of radius 10 pixels centered on the position of each of these “reduced-threshold” detections, we applied the Bayesian test of Kraft et al. (1991), only accepting sources which this test determined to be detected with at least 99.7% confidence (i.e., $3\sigma$ detections). While this method makes us more sensitive to faint sources, it also increases likelihood of getting false positives due to background inhomogeneities, thus these detections should be treated with caution. A detection system optimized for faint sources is under development. The positions of the reduced-threshold detections are given in Tables 3 and 4.

Each of these reduced-threshold detections had very few photons, therefore it was not useful to perform a detailed spectral analysis. We determined the mean count-rate of each detection using the Bayesian method of Kraft et al. (1991) and then applied corrections for PSF losses and instrumental effects, following the processes described by Evans et al. (2007, 2009). We used PIMMS\(^{119}\) to determine a count-rate-to-flux-conversion factor, assuming an absorbed power-law spectrum with a photon index of 1.7. For the January event the assumed absorbing column was $4 \times 10^{20}$ cm$^{-2}$, giving a 0.3–10 keV conversion factor of $4.2 \times 10^{-11}$ erg cm$^{-2}$ counts$^{-1}$; for the September event the absorbing column was $3 \times 10^{21}$ cm$^{-2}$, giving a 0.3–10 keV conversion factor of $5.1 \times 10^{-11}$ erg cm$^{-2}$ counts$^{-1}$. A change of 0.2 in the assumed index of the power-law spectrum would result in a ~10% change in these conversion factors. The absorbing columns were taken as the Galactic values in the direction of the event, determined from Kalberla et al. (2005) assuming the abundances of Anders & Grevesse (1989).

Given the sky area covered by the Swift observations (0.126 square degrees per XRT field after instrumental corrections are applied) we expect to find a number of serendipitous sources in the XRT data. To quantify the likelihood of serendipitous source detection, we used the 2XMMi-DR3 catalogue (Watson et al. 2009), which is substantially dominated by serendipitous X-ray sources found by the XMM-Newton observatory (Jansen et al. 2001).

We selected from this catalogue all unique good sources (i.e., with a quality flag of 0; for the flag definition see Watson et al. 2009). For consistency with 2XMMi-DR3 we

convert the 0.3–10 keV XRT count-rates into 0.2–12 keV fluxes, using an absorbed power-law spectrum with a column of $N_H = 3 \times 10^{20}$ cm$^{-2}$ and a power-law photon index $\Gamma = 1.7$, as used for 2XMM$^{120}$. For each XRT source we then counted the number of 2XMMi-DR3 sources with values of the 0.2–12 keV flux—as measured with the EPIC MOS-1 camera (Turner et al. 2001) onboard Swift—as the source in question. This was then scaled by the ratio of the brightness expected in a single Swift source, since this was very short.

In preparing for the event collection and Swift follow-up, we constructed a utility catalog that would allow us to look up the X-ray history of each field selected for observation in order to help determine if any of the observed sources coincide with known steady-state or variable sources. This X-ray source catalog, which we call XGWC,$^{121}$ combines public data from the HEASARC Master X-ray Catalog$^{122}$ and the GWGC. Upon examination of XGWC/HEASARC for known X-ray sources within the observed fields we found two X-ray sources (one of which was observed twice by Swift) in the catalog which were within the fields for the January event. Both were of unknown type. These catalog sources are likely to be associated with the reduced-threshold source 8 reported in Table 3.

Notes.

$^a$ $N_s$ is the number of 2XMMi-DR3 sources which are at least as bright as the Swift source, which are expected in a single Swift field. See the text for details.

$^b$ The significance of the difference in count-rate between the difference epoch observations.

123 For the September event we excluded the second observation of each source, since this was very short.
determining the count-rate using the Bayesian method (Kraft et al. 1991). The significance of any variability was then found simply by dividing the difference in the two bins by the errors in the two bins, added in quadrature. This is given in Tables 3 and 4; two sources show moderate (between 2σ and 2.5σ) evidence for variability (January source 1 and September source 6).

In addition to the observations reported above, a further follow-up observation was performed for the January trigger on 2010 January 30. This observation, ObsID 00031592001, contained 5.4 ks of data, centered at R.A. = 88:73, decl. = −40:96, i.e., overlapping heavily with field 00031577. Including the data from this field causes sources 1 and 4 to be registered as above-threshold detections. For source 4, the count-rate of the final observation was almost identical to the first; inclusion of this data, approximately 5200 are well-measured point-like sources that are not near the coincidence-loss limit of the data. Raw photometry was corrected for coincidence loss, exposure time, and large scale sensitivity. The number of detections in each field ranged from 250 to 2800 depending on the Galactic latitude of the field and the exposure time. Of the nearly 6800 sources that were detected in the UVOT data, approximately 5200 are well-measured point-like sources that are not near the coincidence-loss limit of the data. Of these, 11 are not near chip edges or bright stars but show very significant variability (>7σ) between the two epochs. Their coordinates are shown in Table 7. Such significant variability is likely to reflect real phenomena, such as active galaxies or variable stars, which are expected to be detected in any deep field. However, none of these variable sources corresponded to any X-ray detections and none show variability beyond a few 0.1 mag, which would be consistent with a tentative classification as normal variable stars or active galaxies. Further monitoring would be needed to determine their nature.

4.2. Optical and UV Results

The LIGO–Virgo target fields were observed by the Swift UVOT with the clear white filter (160–800 nm) or, if ground analysis indicated that the field contained a star too bright for observation in white, the broadband u filter (centered at 346.5 nm with full width at half-maximum of 78.5 nm) or narrow NUV uvm2 filter (centered at 224.6 nm with FWHM of 49.8 nm).

We first attempted to identify any UVOT counterparts to the X-ray reduced-threshold sources identified in the XRT images, photometering any source within 5″ of the XRT position using the standard UVOTSOURCE code and calibrations from Poole et al. (2008) and Breeveld et al. (2011). The results are listed in Tables 5 and 6. For the January event, XRT reduced-threshold detection 7 fell off the smaller UVOT field and was not measured. UVOT counterpart sources to XRT reduced-threshold detections 1, 2, 3, and 4 were found in at least one epoch. However, they had corresponding sources in the Digital Sky Survey (DSS) and showed no photometric variation beyond the 1σ–2σ level. No counterparts to XRT reduced-threshold detections 5, 6, and 8 were found in UVOT.

For the September event, XRT reduced-threshold detections 1, 7, and 8 fell outside of the UVOT field. No counterparts to XRT reduced-threshold detections 2, 4, 11, and 12 were found by UVOT. Reduced-threshold detections 3 and 10 were also found by UVOT and correspond to DSS sources. XRT reduced-threshold detections 5, 6, and 9 correspond to very marginal detections in a crowded field and are either very faint objects or spurious detections. The apparent dimming of the UVOT counterpart to source 5 is spurious as this source was on the edge of one UVOT image and only a partial flux could be measured. In short, no XRT reduced-threshold detection corresponds to either an optical transient or a variable source for either the January or September event.

We next performed a blind search for variable targets within the field. In this instance, we photometered the entire field using the DAOPHOT (Stetson 1987) PSF photometry program. We photometered all data using a quadratically variable PSF and found photometry and image subtraction to be excellent, provided the PSF was based on stars not near the coincidence-loss limit of the data. Raw photometry was corrected for coincidence loss, exposure time, and large scale sensitivity. The number of detections in each field ranged from 250 to 2800 depending on the Galactic latitude of the field and the exposure time. Of the nearly 6800 sources that were detected in the UVOT data, approximately 5200 are well-measured point-like sources that are not near the coincidence-loss limit of the data. Of these, 11 are not near chip edges or bright stars but show very significant variability (>7σ) between the two epochs. Their coordinates are shown in Table 7. Such significant variability is likely to reflect real phenomena, such as active galaxies or variable stars, which are expected to be detected in any deep field. However, none of these variable sources corresponded to any X-ray detections and none show variability beyond a few 0.1 mag, which would be consistent with a tentative classification as normal variable stars or active galaxies. Further monitoring would be needed to determine their nature.

4.3. Summary of EM Findings

The XRT analysis produced 20 reduced-threshold detections and the UVOT analysis identified nearly 6800 sources in the follow-ups of the two events. However, all observations in

X-ray, UV, and optical bands were consistent with expectations for serendipitous sources and no single source displayed significant variability in the XRT or UVOT analyses.

5. COMBINED GW–EM RESULTS

Information from the EM observations associated with a GW candidate event will have to be combined with GW data in order to establish key quantities associated with a combined GW–EM search for transients, like event significance or astrophysical reach. In this section we present a formalism for combining results from such joint observations. For the purpose of its validation we performed simulations using possible models of GW and EM signals. In the process we verified the overall search procedure and estimated the increase in sensitivity of the search which resulted from the Swift follow-up observations. Although this is presented within the context of the LIGO–Virgo–Swift search, it can be straightforwardly extended to other joint searches as well.

In the way the search was conducted, a typical joint candidate event is characterized by the strength of the GW signal expressed in terms of the coherent network amplitude \(\eta\) which is the detection statistic itself for coherent WaveBurst. This quantity is generally proportional to the signal-to-noise ratio and is described in detail in Klimenko et al. (2011) and in Abadie et al. (2012b). Joint candidate events are also characterized...
by the measured X-ray flux, \( S \), and the sky location of the X-ray source, \( \Omega \equiv [\mathrm{RA}, \mathrm{decl.}] \). In addition to these, a skymap, i.e., the probability distribution for the location of a potential GW source, \( p_{\Omega}(\Omega) \), is produced and used to select fields for imaging. We define the joint detection statistic for an event as the logarithm of the joint likelihood ratio, sometimes also referred to as the Bayes factor, given by

\[
\Lambda_{\text{joint}}(\eta, S, \Omega) = \Lambda_{\text{GW}}(\eta)\Lambda_{\text{EM}}(S)\Lambda_{\text{corr}}(\Omega). \tag{2}
\]

In the above equation \( \Lambda_{\text{GW}} = p(\eta \mid \text{signal})/p(\eta \mid \text{noise}) \) is the likelihood ratio for a GW candidate, measuring its significance. \( \Lambda_{\text{EM}}(S) = p_{\Omega}^{-1}(S) \) is the inverse of the probability density of observing an accidental, serendipitous X-ray source which is not correlated with the GW signal. The remaining term \( \Lambda_{\text{corr}}(\Omega) \) is the probability for a GW source to be in the location of the X-ray source, which measures positional correlation between GW and EM signals. Detection statistics based on the likelihood ratio or the Bayes factor construction have been previously suggested and used in the context of searches for GW bursts (Clark et al. 2007; Cannon 2008; Abadie et al. 2011d) and GWs from compact binary coalescence (Abadie et al. 2010b; Biswas et al. 2012). In deriving Equation (2) (see the Appendix for details) we assumed that the dominant background in the EM sector is serendipitous X-ray sources that happen to be within the observed fields by chance. We neglected contributions to this from possible spurious sources—due to, e.g., instrumental artifacts—in the XRT analysis. In order to check if this assumption is justified we estimated from the 2XMMi-DR3 catalogue (Watson et al. 2009) that one expects to find at least one serendipitous source with flux equal or greater than \( 5.4 \times 10^{-13} \) erg cm\(^{-2}\) s\(^{-1}\) within five Swift fields. Visual inspection of the XRT data would identify artifacts at or above this flux level, and they would be excluded from the analysis. No such artifacts were found in the fields analyzed in this paper. We also assumed that inhomogeneities in the distribution of serendipitous sources over the sky are small. As already mentioned, for every LIGO–Virgo candidate event Swift was nominally going to observe five 0.4 \( \times \) 0.4 fields. The way the end-to-end search pipeline was constructed, only the most probable tiles according to the skymap \( p_{\Omega}(\Omega) \) were observed as Swift fields. This resulted in a natural selection bias. As a result, the position correlation term, \( \Lambda_{\text{corr}}(\Omega) \), had a negligible effect in separation of real events from background events. After verifying this through simulations we drop it from the right-hand side of Equation (2), and the final expression for the detection statistic for the joint LIGO–Virgo and Swift search becomes

\[
\rho_{\text{joint}}(\eta, S) = \rho_{\text{GW}}(\eta) + \rho_{\text{EM}}(S), \tag{3}
\]

where \( \rho_{\text{GW}}(\eta) \) and \( \rho_{\text{EM}}(S) \) are logarithms of \( \Lambda_{\text{GW}}(\eta) \) and \( \Lambda_{\text{EM}}(S) \), respectively.

We simulated the search by processing a population of model GW signals which were paired with plausible X-ray fluxes. The set of GW injections was the same with the one used previously (Abadie et al. 2012a) for methodological studies of joint GW–EM observations. These injections sampled the known galaxies within 50 Mpc according to the GWGC and were weighted to reflect each galaxy’s blue light luminosity. Their intrinsic strength (at the source) spanned ad hoc standard candle values over three orders of magnitude. For the purpose of this analysis and to approximate a more realistic distribution of events that are relatively close to our detection threshold, we imposed that they fall below detectability, which implies \( \eta \lesssim 3.5 \), at distances outside the 50 Mpc range. For the low-latency search in 2009–2010, 3.5 was the typical threshold value for \( \eta \). Translating this value into strain at the detector and ultimately at the source depends mildly on the waveform morphology and polarization state of the GW burst and rather strongly on the frequency content of it (Abadie et al. 2012b). In order to set the scale, at 50% detection efficiency during the 2009–2010 run and for GW bursts with energy content near 150 Hz this value of \( \eta \) corresponds to an isotropic energy at the level of \( 5.6 \times 10^{-2} \) M\(_{\odot}\) c\(^2\) emitted in GWs from a hypothetical source at the Virgo Cluster (16 Mpc; Abadie et al. 2012b).

All such simulated events were added to LIGO and Virgo data and analyzed as in the actual search. We used these simulated GW signals to compute the coherent network amplitude, \( \eta \), and its probability distribution, \( p(\eta \mid \text{signal}) \), which is needed for calculation of the joint statistic in Equations (2) and (3). Models for X-ray counterparts were based on GRB afterglows observed by Swift. In order to set the scale of possible X-ray fluxes for counterparts, we considered several short hard GRBs and some bright and dim long GRBs (Zhang et al. 2009). The host galaxies of all selected GRBs had \( z < 1 \). We sampled the observed X-ray afterglow light curves for the observed GRBs at different time lags (\( \sim 10^4 \) s, \( 10^5 \) s, \( 10^6 \) s) relative to the time of arrival of the burst. For a possible X-ray counterpart to GWs from a source at 50 Mpc away this analysis gave us a wide range of flux values, \( S_{50\text{Mpc}} \), from \( 10^{-14} \) erg s\(^{-1}\) cm\(^{-2}\) to \( 10^{-8} \) erg s\(^{-1}\) cm\(^{-2}\) in the absence of any other guidance, we performed simulations for each order of magnitude in that range. For a given \( S_{50\text{Mpc}} \) every GW signal was paired up with a corresponding X-ray flux, which was scaled up (as it was positioned anywhere within the 50 Mpc range) according to the distance to the source. Computation of the joint detection statistic, Equation (3), also requires estimates of the background noise in GW detectors and flux distribution of serendipitous X-ray sources. Background noise in GW detectors is dominated by high amplitude instrumental artifacts. It is typically estimated by time-shifting data from one detector with respect to the other. In our simulations we used estimates for background noise from the coherent Wave-Burst search for GW bursts with LIGO and Virgo in their 2010 science run (Abadie et al. 2012b). In the EM sector, on the other hand, serendipitous X-ray sources observed in coincidence with a GW signal are the main source of false alarms. As in assessing the background in the XRT analysis we presented in Section 4.1, we used also here the 2XMMi-DR3 catalogue (Watson et al. 2009) of serendipitous sources for the estimation of the flux distribution for such sources. For both types of backgrounds we fitted analytical models to the data and computed \( p(\eta \mid \text{noise}) \) and \( p_{\Omega}^{-1}(S) \) appearing in the definition of the joint likelihood ratio in Equation (2). For each simulated GW signal complemented by an X-ray counterpart of a given flux, the last step of the analysis involved the calculation of the joint detection statistic \( \rho_{\text{joint}} \) as given by Equation (3). Using estimates for the GW and X-ray backgrounds, the false alarm probability (FAP) of observing a background event with joint statistic \( \rho_{\text{joint}} \geq \rho_{\text{joint}} \) in a point long search was computed. This defined the significance of the observed event. Figure 3 shows the efficiency in detecting these simulated GW–EM signals as a function of FAP, \( P_0 \), in a joint LIGO–Virgo–Swift search using five or ten Swift fields and for a wide range of X-ray counterpart fluxes. The efficiency is defined as the fraction of simulated signals with FAP, \( P_0 \leq P_0 \). For comparison, we also plot the efficiency curve for the GW only search which does not use any (Swift) EM follow-up.
from the seven total fields observed showed results consistent with expectations for serendipitous sources. Given the lack of EM candidates standing out above background, these particular observations do not increase our confidence in the validity of the GW transients as established by the GW detectors alone.

Combining GW and EM astronomy will be pivotal in maximizing the science in the advanced detector era of gravitational interferometers; it may not only increase our confidence in the detection of GWs but also complete our understanding of the astrophysics of the observed systems (Bloom et al. 2009; Phinney 2009; Stamatikos et al. 2009; Metzger & Berger 2012). Our prototype observing program and end-to-end analysis has been the first step in joint X-ray and GW observations. We demonstrated their feasibility and the considerable added value joint observations bring. Improvements to these will continue to be made in the future on both the EM and GW side. The relatively narrow FOV of instruments such as Swift with respect to the limited pointing resolution abilities of GW interferometers makes identifying the position of the source on the sky non-trivial. A possible fourth detector site in India, Japan, or elsewhere and continued refinements in source localization algorithms are likely to reduce the sky-position error area. On the EM side, a more highly optimized faint source detection scheme for XRT transients might yield improvement in EM sensitivity. In late 2011 Swift implemented onboard software changes to allow automatic scheduling sequences of partially overlapping XRT FOV exposures in response to ToO observation requests for targets with position uncertainties larger than the FOV—this will assist the follow-up of GW targets. A significant role will also be played by prompt follow-up campaigns in the optical band that may provide rapid sub-degree source localizations. Such localizations may facilitate the subsequent follow-up with narrow FOV instruments including Swift, thus significantly improving the chances of capturing the X-ray signatures of GW sources.

In order to carry out multimessenger astrophysics with GWs, it will be extremely important to have Swift and/or Swift-like satellites capable of rapid pointing, multi-wavelength observations and of as wide an FOV as possible operating concurrently with the advanced GW detector network later in this decade. Maximizing the science from GW astronomy will require sensitive partner instruments all across the EM spectrum. The successful completion of this end-to-end program of EM follow-ups by Swift and other observatories during the most recent science runs of the LIGO–Virgo network provides confidence that such joint observations will be both technically feasible and scientifically valuable endeavors in the future.

DERIVATION OF THE JOINT LIKELIHOOD RATIO

In this section we derive from first principles equation (2) that we used in Section 5 in order to establish the detection statistic of the joint GW–EM search. Using Bayes’ theorem, the probability skymap for a potential GW source, \( p_m(\Omega) \), can be written as

\[
p_m(\Omega \mid \eta, \text{signal}) = \frac{p(\eta \mid \Omega, \text{signal})p(\Omega \mid \text{signal})}{p(\eta \mid \text{signal})},
\]

where \( p(\eta \mid \Omega, \text{signal}) \) and \( p(\eta \mid \text{signal}) \) are the conditional probabilities to measure a GW signal with coherent network \( \Omega \), and \( p(\eta \mid \text{signal}) \) is the prior probability distribution for source location, which in this search is determined by the distribution of galaxies in the GWGC catalog and distance weighting, see Equation (1).

The joint likelihood ratio is defined as

\[
\Lambda_{\text{joint}}(\eta, S, \Omega) = \frac{p_m(\Omega | \eta, \text{signal})}{p_m(\Omega | \eta, \text{noise})} \int_{\Omega} \int_{\Omega'} p(\Omega' | \text{signal}) p(S' | \text{signal}) p(S' | \text{signal}) d\Omega' dS'.
\]

This expression can be simplified further by postulating

\[
p(S, \Omega | S', \Omega', \text{signal}) = \delta(S - S')\delta(\Omega - \Omega') \quad \text{and} \quad p(S' | \text{signal}) = 1.
\]

Defining \( \Lambda_{\text{EM}}(S) = p_m(\Omega | S, \text{signal}) \) and \( \Lambda_{\text{GW}}(\Omega) = p_m(\Omega) \), we arrive at the form for the joint likelihood ratio given in Equation (2). We stress that the particular form of \( \Lambda_{\text{EM}}(S) \) and \( \Lambda_{\text{GW}}(\Omega) \) is a consequence of the simplifying assumptions about Swift’s ability to measure the flux and location of an X-ray source that are justified in Section 5. In general, these quantities are going to be non-trivial ratios of likelihoods estimating odds of an X-ray candidate source to be a counterpart to GW based on its brightness and location.
