We search for hadronic decays of a light Higgs boson ($A^0$) produced in radiative decays of an $Y(2S)$ or $Y(3S)$ meson, $Y \rightarrow \gamma A^0$. The data have been recorded by the BABAR experiment at the $Y(3S)$ and $Y(2S)$ center-of-mass energies and include (121.3 $\pm$ 1.2) $\times$ 10$^6$ $Y(3S)$ and (98.3 $\pm$ 0.9) $\times$ 10$^6$ $Y(2S)$ mesons. No significant signal is observed. We set 90% confidence level upper limits on the product branching fractions $\mathcal{B}(Y(nS) \rightarrow \gamma A^0)\mathcal{B}(A^0 \rightarrow \text{hadrons})$ ($n = 2$ or 3) that range from $1 \times 10^{-6}$ for an $A^0$ mass of 0.3 GeV/c$^2$ to 8 $\times$ 10$^{-8}$ at 7 GeV/c$^2$.

A light CP-odd Higgs boson is expected in extensions to the standard model such as nonminimal supersymmetry [1]. Light, in this context, means a mass less than that of the $Y(1S)$ meson. Such a Higgs boson could be produced in radiative decays of the $Y(nS)$ mesons [2], $Y(nS) \rightarrow \gamma A^0$, where, in this analysis, $n = 2$ or 3. BABAR has previously searched for this process where the $A^0$ decays to muons [3], taus [4], or invisibly [5,6]. CLEO has used its $Y(1S)$ data sample to search in the muon-pair and tau-pair final states [7]. BABAR has also searched for violations of lepton universality in $Y(1S)$ decay [8], which could arise if the $A^0$ has the expected quantum numbers $J^{PC} = 0^{-+}$ and mixes with the $\eta_{b}(1S)$ [9].

Supersymmetry models in which $\tan^2 \beta$ is not small predict that the $A^0$ will decay predominantly into the heaviest kinematically available down-type fermion pair.
The earlier experimental results have ruled out much of the parameter space \([10,11]\). Regions not excluded tend to be dominated by hadronic decays, including decays to gluon pairs, \(gg\), at smaller \(\tan^2 \beta\), and to charm quark pairs, \(c\bar{c}\), at higher \(A^0\) mass.

This analysis searches for hadronic decays of the \(A^0\) in the mass range \(2m_\pi < m_{A^0} < 7 \text{ GeV}/c^2\) without attempting to specify the underlying partons to which the \(A^0\) decays. The analysis nominally assumes that the \(A^0\) is \(CP\)-odd but also relaxes this assumption to obtain results without specifying the \(CP\) state.

The data were collected by the \textit{BABAR} detector [12] at the PEP-II asymmetric-energy \(e^+ e^-\) collider at the SLAC National Accelerator Laboratory. They consist of 27.9 fb\(^{-1}\) at the center-of-mass (c.m.) energy of the \(Y(3S)\) and 13.6 fb\(^{-1}\) at the \(Y(2S)\), corresponding to \(N_{3S} = (121.3 \pm 1.2) \times 10^6\) \(Y(3S)\) and \(N_{2S} = (98.3 \pm 0.9) \times 10^6\) \(Y(2S)\) mesons. We also use a continuum [i.e., non-\(Y(nS)\)] background sample consisting of 78.3 fb\(^{-1}\) of data collected at the c.m. energy of the \(Y(4S)\), plus 11.8 fb\(^{-1}\) of data recorded 30–40 MeV below the \(Y(2S)\), \(Y(3S)\), or \(Y(4S)\) c.m. energies. All of the data used here were recorded after the installation of an upgraded muon identification system [13].

Simulated signal events with various \(\Lambda\) masses are used in the analysis. The \textit{EVGEN} event generator [14] is used to simulate particle decays. The \(A^0\) is simulated as a spin-0 particle, with equal branching fractions to whichever of \(gg\), \(s\bar{s}\), and \(c\bar{c}\) are kinematically available. Simulated events are produced both with and without the assumption that the \(A^0\) is \(CP\)-odd. \textit{JETSET} [15] is used to hadronize the partons, and \textit{GEANT4} [16] is used to simulate the detector response.

The search for the \(A^0\) uses hadronic events in which the full event energy is reconstructed. The selection criteria were optimized using simulated signal events and the continuum data set. The highest-energy photon in each event is taken to be the radiative photon from the \(Y(nS)\) decay. The \(A^0\) candidate is constructed by adding the four-momenta of the remaining particles in the following order. The first added are \(K^0_S \rightarrow \pi^+ \pi^-\) candidates that have mass within 25 MeV/c\(^2\) of the true mass [17] and whose reconstructed vertices are separated from the interaction point by at least 3 times the uncertainty on the vertex location. Charged hadron identification is then used to assign the proton, \(K^+\), or \(\pi^+\) mass to charged tracks. Tracks are labeled protons only if they are in the angular acceptance of the \textit{DIRC} (Detector of Internally Reflected Cherenkov light) hadron identification system [12] and if there is another track identified as an antiproton. Neutral pion candidates are formed from pairs of photons, requiring the invariant mass of the photon pair to be between 100 MeV/c\(^2\) and 160 MeV/c\(^2\) and to have a \(\pi^0\) energy greater than 200 MeV. Finally, any remaining unused photons are added. Photons, including those used to reconstruct \(\pi^0\) mesons, are required to have a minimum energy of 90 MeV. All energies and momenta are in the c.m. frame.

Events are required to have a radiative photon energy greater than 2.5 GeV \(Y(3S)\) or 2.2 GeV \(Y(2S)\) and to have at least two charged tracks among the \(A^0\) decay products. The \(A^0\) mass resolution is improved by constraining the radiative photon and all \(A^0\) decay products to come from a common vertex and the sum of the photon and \(A^0\) four-momenta to be that of the c.m. system. To ensure that the full event energy is correctly reconstructed, the probability of the \(\chi^2\) of the constrained fit is required to be greater than a value that ranges from 0 at low \(A^0\) mass to 0.01 at \(m_{A^0} = 7 \text{ GeV}/c^2\). Events in which \(m_{A^0} > 5 \text{ GeV}/c^2\) are rejected if the radiative photon, when combined with any other photon in the event, forms an invariant mass within 50 MeV/c\(^2\) of the \(\pi^0\) mass or, for \(m_{A^0} > 6 \text{ GeV}/c^2\), within 50 MeV/c\(^2\) of the \(\eta\) mass.

Additional criteria are used to reject radiative Bhabha events, \(e^+ e^- \rightarrow \gamma e^+ e^-\), or radiative muon pairs, \(e^+ e^- \rightarrow \gamma \mu^+ \mu^-\). An event is rejected if it was identified as a Bhabha at the trigger level, if either of the two highest-momentum tracks is identified as an electron or a muon, or if the angle between the radiative photon and the second-highest-momentum track is less than 1 rad. These criteria reject 96% of the continuum sample at a cost of 10–20% in signal efficiency and, according to simulation, reduce these backgrounds to negligible levels.

The analysis proceeds along two parallel paths labeled “\(CP\)-all,” in which no assumption is made on the \(CP\) nature of the \(A^0\), and “\(CP\)-odd,” in which it is assumed to be \(CP\)-odd. Events in which the \(A^0\) decays to \(\pi^+ \pi^-\) or \(K^+ K^-\) are excluded from the \(CP\)-odd analysis.

The analysis selects 371 740 events (\(CP\)-all) or 171 136 events (\(CP\)-odd) in the combined \(Y(2S)\) and \(Y(3S)\) (“on-peak”) data set with \(0.29 < m_{A^0} < 7.1 \text{ GeV}/c^2\) (Fig. 1).

An \(A^0\) signal would appear as a narrow peak in the candidate mass spectrum. The number of signal events at a particular hypothesis mass is computed as the number of events in a mass range (“window”) centered on that value, less the number of background events in the window. The width of the window depends on the \(A^0\) mass resolution and was optimized along with the other selection criteria. It varies for \(CP\)-all from 3 to 26 MeV/c\(^2\) as \(m_{A^0}\) increases from 0.29 to 7 GeV/c\(^2\). The \(CP\)-odd windows are the same width as \(CP\)-all above 2 GeV/c\(^2\) but are larger at lower masses.

Background events are from \(Y(nS)\) decays and from continuum. Continuum, which is dominant, mostly consists of the initial-state radiation (ISR) production of a light vector meson (clearly visible in Fig. 1) and nonresonant hadrons. The \(Y(nS)\) backgrounds are primarily radiative decays to a light meson or nonresonant hadrons. At the highest \(A^0\) candidate masses, there is an additional contribution from hadronic \(Y(nS)\) decays in which a \(\pi^0\) daughter is misidentified as the radiative photon. Simulation indicates that the fraction of \(B\bar{B}\) events satisfying the selection criteria is negligible.
criteria is negligible, so events recorded at the $Y(4S)$ c.m. energy can be used in the continuum sample.

The number of background events is obtained from a fit to the data that contains three components: continuum, nonresonant $Y(nS)$ radiative decay, and resonant $Y(nS)$ radiative decay. The continuum component is the candidate mass spectrum of the continuum data set multiplied by a normalization factor $C_N (\approx 0.5)$. Because the efficiency for detecting the ISR photon depends on c.m. energy, $C_N$ is not simply the ratio of integrated luminosities. It is left as a free parameter in the nominal fit but, as described below, is fixed to a calculated value for systematic studies. The nonresonant $Y(nS)$ component is a 16-knot cubic spline, fixed to 0 at the minimum $A^0$ mass. The resonant component includes five relativistic Breit-Wigner functions to represent the resonances for which CLEO saw some evidence in the study of $Y(1S) \rightarrow \gamma h^+ h^- (h = \pi$ or $K)$ [18]: $f_0(980), f_2(1270), f_2(1525), f_0(1710),$ and $f_4(2050)$. The masses and widths are fixed [17], and possible interference between the resonances is neglected in the fit. These resonances are all broad compared to an $A^0$ signal. The spacing of the knots, typically 0.5 GeV/c$^2$, is large enough that the cubic spline cannot conform to a narrow resonance.

The background fit (Fig. 1) has 21 free parameters and is made to 1362 bins of width 5 MeV/c$^2$, ranging from 0.29 to 7.1 GeV/c$^2$. The fit $\chi^2$ are 1268 ($CP$-all) and 1293 ($CP$-odd) for 1341 degrees of freedom. Subtracting the normalized continuum mass spectrum from both the data and the fit gives the $Y(nS)$ decay spectrum and the nonresonant and resonant radiative $Y$ decay components of the fit (Fig. 2).

The uncertainty on the background in each mass window is both statistical and systematic. The systematic error is the sum in quadrature of the change in the total background arising from each of 17 alternative fits: the five nominal light resonances are removed one at a time, and 11 additional resonances are included one at a time. The 11 are established resonances [17] with even total angular momentum, charge conjugation quantum number of +1, and isospin 0. The 17th alternative fit is performed with $C_N$ fixed to the midpoint of the range of values found from four different methods of determining it. Two of the methods are the nominal fits to the $CP$-odd and $CP$-all samples, and two use ISR-produced narrow resonances in four different final states: $e^+ e^- \rightarrow \gamma \omega, \omega \rightarrow \pi^+ \pi^- \pi^0; e^+ e^- \rightarrow \gamma \phi, \phi \rightarrow K^+ K^-; e^+ e^- \rightarrow \gamma J/\psi, J/\psi \rightarrow \pi^0 + \pi^0$; and $e^+ e^- \rightarrow \gamma J/\psi, J/\psi \rightarrow \pi^0 + \pi^0$. First, the number of each of these resonances is compared in on-peak and continuum data. Second, the same ratios are obtained using simulated samples of these ISR events, together with the calculated production cross sections [19] and the recorded luminosities. The resulting value of $C_N$ is 4.5% larger than nominal for $CP$-all and 2.7% for $CP$-odd. The fit qualities are good in all alternative fits. The systematic errors are small compared to statistical errors, except near resonances.

The $A^0$ signal is evaluated at hypothesis masses that range from 0.291 GeV/c$^2$ to 7.000 GeV/c$^2$ in 1 MeV/c$^2$.
steps for the CP-all analysis (6710 mass hypotheses) and from 0.300 GeV/c^2 to 7.000 GeV/c^2 in 1 MeV/c^2 steps for CP-odd (6701 masses). Figure 3 shows the nominal statistical significance of the resulting A^0 signal, defined as the number of events divided by the statistical error, as a function of mass. The largest upwards fluctuations are 3.5σ at 3.107 GeV/c^2 for CP-all and 3.2σ at 0.772 GeV/c^2 for CP-odd. Including background systematic errors, the significance of these two, which are located near the J/ψ and ρ resonances, respectively, are reduced to 2.8σ and 2.2σ. The largest remaining fluctuations are 2.9σ at 1.295 GeV/c^2 for CP-all and 3.1σ at 4.727 GeV/c^2 for CP-odd. Figure 4 histograms the statistical significance of the signal measured at each mass, overlaid with the distribution expected in the absence of a signal.

The signal extraction technique is studied using many simulated experiments. Each experiment consists of two candidate mass distributions, one for on-peak data and the other for continuum. The continuum event distributions are obtained from the full Y(4S) data, which is 11 times larger than the on-peak data set. The nonresonant Y(nS) events are generated from a smooth threshold curve, and the resonant events are generated from relativistic Breit-Wigner functions. The full signal extraction is then performed. The average bias on the A^0 signal yield is less than 1.5 events for all masses when there is no signal.

These studies are also used to calculate the expected distribution of statistical significance in the absence of signal (Fig. 4) and to evaluate the significance of the largest apparent A^0 signals. The fraction of background-only CP-all simulated experiments that contain a fluctuation of nominal statistical significance ≥ 3.5σ is 33%. The fraction of CP-odd simulated experiments that contain a fluctuation ≥ 3.2σ is 63%. We therefore see no evidence of signal. The studies further indicate that large correlations between the resonant and nonresonant Y(nS) components make the uncertainties on the yields of the resonances unreliable.

In the absence of a significant signal, we calculate a 90% confidence level (C.L.) upper limit for each hypothesis mass on the product branching fractions B_{3S} = B(Y(3S) → γA^0)B(A^0 → hadrons) and B_{2S} = B(Y(2S) → γA^0)B(A^0 → hadrons), assuming that the Y(3S) and Y(2S) decays are described by the same matrix element. This implies that B_{2S} = B_{3S}Γ_{3S}/Γ_{2S}R(m_{A^0}), where Γ_{3S} and Γ_{2S} are the full widths of the Y(3S) and Y(2S), respectively, and R accounts for the difference in phase space. R is within a few percent of unity for all A^0 masses.

The calculation uses the relationship ¯N = ¯B + N_{3S}′B_{3S}′R, where ¯N is the expected number of observed events for the given value of B_{3S}, B is the expected background, N_{3S}′ ≡ N_{3S} + N_{2S}Γ_{3S}/Γ_{2S}R(m_{A^0}), and ε is the signal efficiency. We calculate a likelihood L(B_{3S}) defined as the probability of observing N or fewer events given that value of B_{3S} where N is the number actually observed. L(B_{3S}) is obtained by integrating over the uncertainties in ¯B, N_{2S}, N_{3S}, and ε, which are assumed to be Gaussian. The 90% C.L. upper limit B_{90} is calculated assuming a uniform prior above 0: ∫_{B_{90}} L(B_{3S})dB_{3S} = 0.90 ∫_{0}^{∞} L(B_{3S})dB_{3S}.

The efficiency is calculated using simulated events. The efficiency for the CP-all analysis ranges from a peak of 22% near m_{A^0} = 0.6 GeV/c^2 to less than 1% at high
FIG. 5 (color online). 90% C.L. upper limits on product branching fractions (BF) (left axis) \( \mathcal{B}(Y(3S) \rightarrow \gamma A^{0})\mathcal{B}(A^{0} \rightarrow \text{hadrons}) \) and (right axis) \( \mathcal{B}(Y(2S) \rightarrow \gamma A^{0})\mathcal{B}(A^{0} \rightarrow \text{hadrons}) \), for (a) \( \text{CP}-\text{all} \) analysis and (b) \( \text{CP}-\text{odd} \) analysis. The overlaid curves (red online) are the limits expected from simulated experiments, while the light gray curves (blue online) are the limits from statistical errors only. The \( Y(2S) \) limits do not include the phase space factor, which is at most a 3.5% correction.

Masses, while, for the \( \text{CP}-\text{odd} \) analysis, it ranges from 12% near 0.9 GeV/c\(^2\) to less than 1% at high masses.

The uncertainty on the efficiency is typically 11% (\( \text{CP}-\text{all} \)) or 7% (\( \text{CP}-\text{odd} \)) below the \( c\bar{c} \) threshold and 25% above. This includes contributions from uncertainty in tracking (1.5–3.5% depending on mass), photon and \( \pi^0 \) reconstruction (5–10%), and particle identification (3–5%), but the dominant contribution is due to the \( A^0 \) decay branching fractions. This uncertainty is evaluated by varying the assumed branching fractions. Below the \( c\bar{c} \) threshold, it is changed from 50% \( s\bar{s} \) and 50% \( gg \) to 100% \( gg \). Above the \( c\bar{c} \) threshold, it is changed from one-third each \( gg, s\bar{s}, \) and \( c\bar{c} \) to 50% \( c\bar{c} \), 25% \( gg \), and 25% \( s\bar{s} \). The resulting systematic errors are 8% for \( \text{CP}-\text{all} \) or 4% for \( \text{CP}-\text{odd} \) below the \( c\bar{c} \) threshold and 21% above. The resulting 90% C.L. upper limits are shown in Fig. 5.

In conclusion, we have searched for hadronic final states of a light Higgs boson produced in radiative decays of the \( Y(2S) \) or \( Y(3S) \) and find no evidence of a signal. Upper limits on the product branching fraction \( \mathcal{B}(Y(nS) \rightarrow \gamma A^{0})\mathcal{B}(A^{0} \rightarrow \text{hadrons}) \) range from \( 1 \times 10^{-6} \) at 0.3 GeV/c\(^2\) to \( 8 \times 10^{-5} \) at 7 GeV/c\(^2\) at the 90% C.L.

We are grateful for the excellent luminosity and machine conditions provided by our PEP-II colleagues and for the substantial dedicated effort from the computing organizations that support BABAR. The collaborating institutions wish to thank SLAC for its support and kind hospitality.
