Aim: The present study was conducted to determine the major risk factors for accelerated atherosclerosis.

Materials and methods: Patients between 50 and 70 years who had documented evidence of atherosclerotic vascular disease at three or more than three arterial sites in a short span of time were included in this study.

Results: Majority (83%) had diabetes for over 15 years mostly with poor control and most common dyslipidemia was low high-density lipoprotein (HDL). Evidence of coronary artery disease (CAD) was noted in all cases. Next common site for atherosclerosis was observed in carotid and lower limb arteries. Three amputation were done which showed evidence of inflammatory arthritis.

Conclusion: Accelerated atherosclerosis is an important complication of long-standing uncontrolled diabetes. Dyslipidemia characterized by low HDL and other inflammatory arthritic conditions also contribute to accelerated atherosclerosis.

Clinical significance: Intermittent claudication or pain in leg in long-standing diabetic cases particularly associated with CAD should arouse suspicion of peripheral arterial diseases. Early detection and management of peripheral arterial disease can save the involved limb from amputation.

Keywords: Accelerated atherosclerosis, Amputation, Cerebrovascular disease, Coronary artery disease, Diabetes mellitus, Intermittent claudication, Peripheral artery disease.

Five patients (83.3%) had hypertension and 4 patients (66.6%) had both diabetes and hypertension. Four patients (66.6%) had obesity. Almost all diabetic cases had been suffering with diabetes for over 15 years; 80% of diabetics had poor control of diabetes (HbA1c > 8%). The mean HDL was 34.7 ± 4.11 mg/dL (Table 2).

Documented coronary atherosclerosis was seen in all six cases; next common site for atherosclerosis was observed in carotid and peripheral arteries in lower limbs (Fig. 1). Evidence of aortic atherosclerosis in the form of aortic calcification was observed in one case (Table 3). Two cases presented with symptoms of vascular ischemia. Of these, one underwent lower limb amputation, whereas another needed amputation of left index finger and later left 5th toe amputation. Three cases had chronic kidney disease and three showed evidence of inflammatory arthritis.

DISCUSSION

Our study addresses the clinical concept of “accelerated atherosclerosis,” a term used currently not unoften. It is worthwhile to note that cases of accelerated atherosclerosis involving coronary arteries, cerebrovascular tree, and peripheral arteries are more commonly seen these days. As evident in our small study, type II diabetes mellitus appears to be the key factor behind accelerated atherosclerosis. It is well known that atherosclerotic involvement of coronary, cerebrovascular, and large diameter peripheral arteries, such as carotids and/or arteries of extremities is due to macrovascular complication of diabetes.12,13 It would be prudent to mention here that clinicians more often than not are preoccupied with microvascular complications of diabetes at the expense of macrovascular involvement of peripheral vessels.

Moreover, the causes of accelerated atherosclerosis need to be worked out in each case. In our study, uncontrolled long-standing type II diabetes mellitus (T2DM) has been associated with accelerated atherosclerosis. The second important cause was dyslipidemia characterized by low HDL.14 Diabetes along with hypertension increases the speed and extent of inflammation. Despite this, there are other clinical conditions associated with high inflammatory state like rheumatoid arthritis,6 systemic lupus erythematosus15, ankylosing spondylitis,16 psoriasis,17 human immunodeficiency virus,18 and Tangier’s disease.19 Rapid involvement of limb vessels leads to dreaded complication of peripheral gangrene, which may result in amputation as happened in three of our subjects. Surprisingly, only 2 (33.3%) of our patients were tobacco users. One was smoker and the second was smoker as well as oral tobacco user. This low incidence could be due to small sample size in this study.

CONCLUSION

Diabetics are particularly prone to accelerated atherosclerosis. Besides coronary arteries, other arteries, especially...
those of limbs, may get involved at an early stage and progress rapidly. Therefore, clinicians must look for signs of limb ischemia in these patients as a routine. Early detection and treatment of limb ischemia may help in reducing incidence of amputations.
