ABSTRACT

This paper describes our approach for the triple scoring task at WSDM Cup 2017. The task aims to assign a relevance score for each pair of entities and their types in a knowledge base in order to enhance the ranking results in entity retrieval tasks. We propose an approach wherein the outputs of multiple neural network classifiers are combined using a supervised machine learning model. The experimental results show that our proposed method achieves the best performance in one out of three measures, and performs competitively in the other two measures.

1. INTRODUCTION

In the last decade, huge online structured knowledge bases (KBs) such as Wikidata, Freebase, and DBpedia have emerged. These KBs contain an enormous amount of entities (e.g., people) and their types (e.g., professions and nationalities). These data enable users to easily formulate a complex query to a KB such as querying a list of all scientists whose nationalities are Japan.

However, the KB also contains a lot of entity types that are rarely useful for humans when querying a KB. For example, Barack Obama has four professions in Freebase such as Politician, Lawyer, Law professor, and Author, but it is considered that people primarily want to retrieve Barack Obama as a Politician.

Recently, Bast et al. addressed this problem by assigning a relevance score to each pair of an entity and its type in KB. With these scores, we can enhance the ranking results of entity retrieval tasks by sorting the results based on these relevance scores.

In this paper, we describe our approach for this task. We use multiple neural network classifiers with the objective of predicting the probability of an entity type when a KB entity (\(P(t|e)\)) is given. Notably, we introduce an attention mechanism to our neural network model in order to enable the model to prioritize a small number of relevant features. In addition, we use another supervised machine learning model (i.e., gradient boosted regression trees (GBRT)) to convert the outputs of these classifiers into final relevance scores.

The proposed method was applied to the triple scoring task at WSDM Cup 2017. The results demonstrated that our method achieved best results in one out of three measures, and exhibited competitive performance in the other two measures.

2. OUR APPROACH

Given a KB entity \(e\) and its target type \(t\), our method predicts a score that represents the relevance of \(e\) belonging to \(t\). Here, we adopt a two-step approach: the first step is a classification step that aims to estimate the probability of \(e\) belonging to \(t\) (\(P(t|e)\)) using multiple neural network-based classifiers. The second step is a scoring step that uses a supervised machine learning model to convert the outputs of these classifiers to the target relevance score. In accordance with the task specifications for WSDM Cup 2017, our model assigns relevance scores to pairs of people and their professions, and people and their nationalities.

2.1 Classification Step

To train the classifier, we use all KB entities having only a single type, as done in the previous work by Bast et al. With this configuration, we can address this problem as a multi-class classification of entities over all possible types. It is important to note that, because our objective is assigning relevance scores to entities having multiple types, entities having only a single type can be safely used as training data.

2.1.1 Model

We use sets of words and entities that are relevant to \(e\) as inputs to the classifier. We adopt the neural bag-of-items model with a simple item-level attention mechanism to derive the representation of the set of items (i.e., words or entities). Specifically, given a set of items, \(x_1, x_2, ..., x_N\), we compute the weighted sum of their corresponding embedding as follows:

\[
c = \sum_{i=1}^{N} a(x_i) v_{x_i},
\]

Here, \(v_x \in \mathbb{R}^{d_w}\) is an embedding of \(x\), and \(a(x)\) is a function that computes the item-level attention weight for \(x\), which is defined as the following softmax function:

\[
a(x) = \frac{\exp(w_a^T u_x + b_a)}{\sum_{j=1}^{d_w} \exp(w_a^T u_{x_j} + b_a)},
\]

where \(w_a \in \mathbb{R}^{d_w}\) is a weight vector, \(b_a \in \mathbb{R}\) is a bias, and \(u_x \in \mathbb{R}^{d_w}\) is an attention embedding of \(x\). The function \(a(x)\) aims to capture the importance of the item \(x\), thereby allowing the model focus on a small number of relevant items.

Finally, we adopt a multi-layer perceptron (MLP) classifier having a single hidden layer with \(l\) units, ReLU non-linearity, and dropout with a probability \(p\). Using Eq. (1), we compute two feature vectors \(c_w\) and \(c_e\) using the sets of words and entities, re-
respectively. We then build a feature vector by concatenating $L_2$-normalized versions of vectors $\frac{x_{w}}{|w|}$ and $\frac{x_{e}}{|e|}$ and feed the vector to MLP.

### 2.1.2 Corpus

As explained in the previous section, we train the classifier using sets of words and entities relevant to $e$. To extract words and entities relevant to $e$, we use the following two sources: (1) the corresponding Wikipedia articles of $e$ (denoted by article), and (2) Wikipedia sentences that contain a link anchor that corresponds to $e$ (denoted by sentence). In both cases, words are extracted simply by tokenizing the text, and entities are the referent entities of link anchors in the text. Further, in the latter case, we restrict the words to the contextual words of the link anchor in a window of length $m$.

We extracted Wikipedia articles directly from the July 2016 Wikipedia dump obtained from Wikimedia Downloads. We also used public wiki-sentences dataset to obtain the Wikipedia sentences. In addition, we used words and entities appearing five times or more in the corpus, and simply ignored the other words and entities.

#### 2.1.3 Training

All parameters used in this model were initialized randomly and updated using back-propagation. We trained the model using stochastic gradient descent (SGD) and the learning rate was controlled by Adam [8]. The batch size was fixed at 100, the training consisted of one epoch, and the categorical cross-entropy was used for the loss function. We used NVIDIA Tesla K80 GPU to train the model.

Regarding hyper-parameters, the number of embedding dimensions $d_w$ and $d_e$ were 300 and 10, respectively; the number of units in the hidden layer $t$ was 2,000, and the dropout probability $p$ was 0.5. We also selected the context window size $m$ from 5 and 10.

In addition, we optionally introduced class weights to the loss function because the distribution of the target type was highly imbalanced. We adopted a weighted loss function based on the class weight heuristic implemented in Scikit-learn.

We trained classifiers with various configurations. Table 1 shows the list of configurations used to train the classifiers. For each type of the two corpus (i.e., article and sentence), we created eight classifiers with different training configurations, such as class weights and attention mechanism in the enabled or disabled state, using either both words and entities or only entities as input, and changing the context window size. In addition, we trained these classifiers for both profession and nationality domains. Therefore, the total number of the classifier instances was 32.

### 2.2 Scoring Step

To convert the outputs of the above-mentioned classifiers into relevance scores, we adopt gradient boosted regression trees (GBRT) [9]. Given an entity $e$ and a type $t$, our scoring model predicts the relevance score ranging from 0 to 7.

#### 2.2.1 Features

We compute features based on two types of outputs of each classifier, the probability $P(t|e)$ and the unnormalized version of $P(t|e)$, which is the corresponding input value to the softmax layer of the MLP. For each of the two values, we compute three features, the value itself, and the difference between the value and the minimum and the maximum value among all valid types. It should be noted that the maximum value corresponds to the output value of the predicted type of the classifier.

Further, we observe that some pairs of types co-occur very frequently in the KB (e.g., Singer and Singer-songwriter). In order to incorporate this to the model, we also use the point-wise mutual information (PMI) on the type co-occurrence data in the KB. In particular, we add the feature representing the PMI score between the target type $t$ and the type predicted by each classifier when these two types are not equal. Moreover, apart from the classifier outputs, we also include the number of valid types associated with $e$ in the feature set.

#### 2.2.2 Dataset

In order to train the model, we use the dataset obtained from the WSDM Cup web site. It comprises two domains, professions and nationalities, of person entities retrieved from Freebase. The professions dataset and the nationality dataset contain relevance scores for 515 and 162 entity–type pairs with 134 and 77 distinct entities, respectively. We then use this dataset for feature selection and parameter tuning described below.

#### 2.2.3 Training

For both the profession and the nationality domains, we train both the regression model and the classification model. In order to select a subset of the most relevant features, we perform feature selection: we first perform a greedy forward feature selection based on the performance of 10-fold cross validation, and simply select a set of features that give the best performance. We also tune the hyper-parameters of GBRT using the selected features and the 10-fold cross validation, and use the hyper-parameters that provide the best performance. In addition, the performance was evaluated using the mean absolute error for the regression model and the accuracy for the binary classification model.

### 2.3 Implementation

We implement the classifier explained in Section 2.2.1 using Python, Keras, and Theano. Further, our scoring model described in Section 2.2 is implemented using Python and Scikit-learn. We also use Hyperopt for performing the hyper-parameter search of GBRT.
3. EXPERIMENTS

In this section, we first describe the performance evaluation of the classifiers presented in Section 2.1. Then, we present the official results of the triple scoring task at WSDM Cup 2017.

3.1 Evaluating Classifiers

In order to independently evaluate the performances of the proposed classifiers, we randomly selected 10% of the KB entities having a single type, and measured the classification accuracy using these selected entities.

Table 1 shows the accuracies of the classifiers corresponding to various training configurations presented in Section 2.1. As can be seen in the table, the attention mechanism effectively improved the performance, while the use of class weights degraded the accuracy in general. Further, the classifiers trained with the article corpus generally performed better than those trained with the sentence corpus.

We also found in our experiments that incorporating the outputs of classifiers that achieve lower accuracies often improved the performance of the scorer. Therefore, we adopted a strategy to use the outputs of various classifiers rather than focusing on the outputs of a single accurate classifier.

Further, in order to investigate how the attention model works in practice, we inspected the words and entities having large attention weights $w^a_u$ in Eq.(4a). Table 2 shows the top 10 words and entities having large weights in classifier 1, which was trained for the profession domain. It appeared that our classifier effectively focused on words and entities that strongly indicate a profession. For example, the top words included various professions, such as physicists and economists, and all the top entities, were the lists or categories that were strongly associated with a profession.

3.2 Competition Results

We submitted our proposed method to the triple scoring task at WSDM Cup 2017. In this competition, the submitted methods were evaluated based on the following three measures:

- **Accuracy**, which is the percentage for which the estimated score differs from the score from the ground truth by at most 2.
- **Average score difference**, which is the average score difference between the estimated scores and the ground truth scores.
- **Kendall’s $\tau$**, which is the average Kendall’s $\tau$ score between the estimated scores and the ground truth scores. The $\tau$ score is computed for each entity, and the final score is averaged over all entities.

Experiments were conducted using the 710 entity–type pairs containing the instances of 513 profession pairs and 197 nationality pairs. We used different scoring models trained with the corresponding dataset for each domain. Note that the accuracy described here is different from the accuracy used to evaluate the classifiers in the previous section.

Table 3 shows the official results of our methods based on the regression model (reg) and the binary classification model (clf) with the other top 5 methods proposed by competitors in terms of accuracy. The table lists the accuracies (acc.), the average score differences (avg. diff.), and the Kendall’s $\tau$ scores (Kendall).

Our regression model achieved the best performance in terms of the Kendall’s $\tau$ scores among all the other methods, and performed competitively in the accuracy and the average score difference. Further, our binary classification model showed better performance, particularly in terms of accuracy.

4. CONCLUSIONS

In this study, we proposed an approach for assigning a relevance score to each entity–type pair in a given KB. We trained neural network-based multiple classifiers by directly using the KB data, and converted the results of these classifiers into target relevance scores using a supervised machine learning model (i.e., GBRT). It is worth noting that we introduced an item-based attention model to the neural network model, which was not applied for this kind of task previously. The experimental results show the superiority of our approach; we achieved the best performances in terms of Kendall’s $\tau$ scores, and performed competitively in terms of accuracy and average score difference. We have publicized the source code of our proposed
