Clathrin-mediated endocytosis of synaptic vesicle membranes involves the recruitment of clathrin and AP-2 adaptor complexes to the presynaptic plasma membrane. Phosphoinositides have been implicated in nucleating coat assembly by directly binding to several endocytotic proteins including AP-2 and AP180. Here, we show that the stimulatory effect of ATP and GTPγS on clathrin coat recruitment is mediated at least in part by increased levels of PIP2. We also provide evidence for a role of ADP-ribosylation factor 6 (ARF6) via direct stimulation of a synthetically enriched phosphatidylinositol 4-phosphate 5-kinase type 1γ (PIPKIγ), in this effect. These data suggest a model according to which activation of PIPK by ARF6-GTP facilitates clathrin-coated pit assembly at the synapse.

Introduction

Synaptic vesicle (SV)* membranes are formed and recycled by clathrin-mediated endocytosis at the presynaptic plasmalemma. This process involves the regulated and directed assembly of clathrin, AP180, and AP-2 adaptor complexes along with several accessory proteins at endocytotic “hot spots” surrounding the active zone (for review see Hannah et al., 1999; Brodin et al., 2000; Slepnev and De Camilli, 2000; Takei and Haucke, 2001). How precisely coat nucleation is regulated in time and space is unclear, but morphological data suggest that it is a compensatory event tightly coupled to vesicle exocytosis (Heuser and Reese, 1973; Gad et al., 1998).

Growing evidence implicates membrane lipids, in particular phosphoinositides, in the regulation of clathrin-mediated endocytosis (Jost et al., 1998; Cremona and De Camilli, 2001). Several endocytotic proteins such as the α and μ2 subunits of heterotetrameric AP-2 complexes (Gaidarov and Keen, 1999; Collins et al., 2002; Rohde et al., 2002), the ENTH domains of AP180 and epsin (Ford et al., 2001; Itoh et al., 2001; Mao et al., 2001), and the pleckstrin homology (PH) domain of the large GTPase dynamin (Baryliko et al., 1998) can interact directly with phosphoinositides, in particular phosphatidylinositol (4,5)-bisphosphate (PI(4,5)P2). Phosphatidylinositol 4-phosphate 5-kinase type 1γ (PIPKIγ) and synaptojanin 1, the major brain PI(4)phosphate 5-kinase and PI(4,5)P2 polyphosphoinositide phosphatase, respectively, are concentrated at synapses, where they undergo activity-dependent dephosphorylation (McPherson et al., 1996; Ishihara et al., 1998; Wenk et al., 2001). Moreover, elevated PI(4,5)P2 levels induced by genetic inactivation of synaptojanin 1 result in the accumulation of clathrin-coated vesicles at the synapse (Cremona et al., 1999; Harris et al., 2000). These data suggest that clathrin-dependent retrieval of SV membranes may at least in part depend on phosphoinositide metabolism.

Given the rapid turnover of phosphoinositides, it seems likely that PI(4,5)P2 synthesis is under tight regulatory control (Cremona and De Camilli, 2001), thereby linking it to the exo-endocytotic cycling of SV membranes.

The formation of clathrin-coated endocytotic intermediates has been reconstituted from lysed nerve terminal membranes incubated with brain cytosol and nucleotides (Takei et al., 1996). Detailed morphometric analysis by EM revealed...
that the presence of clathrin/AP-2–coated buds on native synaptic membranes was potently stimulated by ATP and GTP\(\gamma S\), a nonhydrolysable analogue of GTP (Takei et al., 1996). This effect may be contributed to some extent by an inhibition of clathrin-coated vesicle fission induced by the GTP\(\gamma S\) block of dynamin function (Takei et al., 1996). However, by analogy to other vesicular transport events, one might also speculate that GTP\(\gamma S\) could act in part by locking a small GTPase in the GTP-bound conformation (Springer et al., 1999). More specifically, ADP-ribosylation factor (ARF) family members have been implicated in clathrin-coated budding events at the Golgi complex and at the cell periphery (Stamnes and Rothman, 1993; Traub et al., 1993; West et al., 1997). ARF has been shown to trigger assembly of vesicle coats onto membranes by directly interacting with coat proteins (Donaldson et al., 1992; Stamnes and Rothman, 1993; Traub et al., 1993; Zhao et al., 1997; Austin et al., 2002) or by stimulating phospholipase D (PLD) activity (Kristakis et al., 1996; West et al., 1997; Arneson et al., 1999). Additionally, ARF family members have been found to recruit and activate PI kinases, which mediate PI(4,5)P\(_2\) synthesis (Godi et al., 1999; Honda et al., 1999). However, so far, the physiological role of ARFs in the recruitment of clathrin/AP-2 coats at the plasma membrane (Robinson and Kreis, 1992; West et al., 1997) and in SV recycling has remained unclear. Among the different ARF family members known to date, only ARF6 is localized to the plasma membrane, where it has been implicated in regulating actin dynamics and membrane turnover (D’Souza-Schorey et al., 1998; Randazzo et al., 2000; Brown et al., 2001). ARF6 has also been demonstrated to regulate clathrin-mediated endocytosis from the apical (Altschuler et al., 1999) and basolateral surface (Palacios et al., 2002) of polarized MDCK cells. Consistent with a putative role of ARF6 in SV recycling, mSec7, a brefeldin A–insensitive ARF6-specific guanine nucleotide exchange factor (GEF) has been demonstrated to function at the synapse (Ashery et al., 1999). Here, we show that activated ARF6 facilitates clathrin/AP-2–coated pit nucleation from synaptic membranes via the stimulation of PIP\(_2\) production mediated by PIPKI\(\gamma\) activation.

Results

Clathrin/AP-2 recruitment to synaptic membranes is not inhibited by brefeldin A

ARF family members have been shown to facilitate vesicle budding by stimulating recruitment of coat components to the plasma membrane (Springer et al., 1999). Therefore, we tested the effect of brefeldin A (BFA) on clathrin/AP-2 recruitment in our assay. BFA inhibits nucleotide exchange factors acting on ARF family members except most of those specific for ARF6 (Randazzo et al., 2000). Consistent with earlier observations on AP-2 association with the plasma membrane of intact cells (Robinson and Kreis, 1992), no effect on the ATP- and GTP\(\gamma S\)-dependent recruitment of AP-2 and AP180 to LP2 membranes (Fig. 2) was seen. When isolated Golgi membranes were used instead of synaptic membranes, addition of BFA completely blocked clathrin binding to the Golgi complex (unpublished data; Robinson and Kreis, 1992). In agreement with these results, it has been found that BFA does not affect SV recycling, the main traffic pathway mediated by clathrin/AP-2 coats at the synapse (Mundigl et al., 1993).

Together, our data implicate a GTPase distinct from ARF1-5 (Randazzo et al., 2000) in the stimulation of ATP/GTP\(\gamma S\)-induced coat recruitment to synaptic membranes. Such a GTPase could be ARF6, the BFA-insensitive ARF family member known to act at the cell surface. Consistent with this possibility, we observed recruitment of a substantial amount of ARF6 along with clathrin, AP180, and AP-2 to LP2 membranes on incubation with cytosol in the presence of ATP and GTP\(\gamma S\) (Fig. 1 A).

Clathrin/AP-2 recruitment to synaptic membranes is not inhibited by brefeldin A

ARF family members have been shown to facilitate vesicle budding by stimulating recruitment of coat components to the plasma membrane (Springer et al., 1999). Therefore, we tested the effect of brefeldin A (BFA) on clathrin/AP-2 recruitment in our assay. BFA inhibits nucleotide exchange factors acting on ARF family members except most of those specific for ARF6 (Randazzo et al., 2000). Consistent with earlier observations on AP-2 association with the plasma membrane of intact cells (Robinson and Kreis, 1992), no effect on the ATP- and GTP\(\gamma S\)-dependent recruitment of AP-2 and AP180 to LP2 membranes (Fig. 2) was seen. When isolated Golgi membranes were used instead of synaptic membranes, addition of BFA completely blocked clathrin binding to the Golgi complex (unpublished data; Robinson and Kreis, 1992). In agreement with these results, it has been found that BFA does not affect SV recycling, the main traffic pathway mediated by clathrin/AP-2 coats at the synapse (Mundigl et al., 1993).

Together, our data implicate a GTPase distinct from ARF1-5 (Randazzo et al., 2000) in the stimulation of ATP/GTP\(\gamma S\)-induced coat recruitment to synaptic membranes. Such a GTPase could be ARF6, the BFA-insensitive ARF family member known to act at the cell surface. Consistent with this possibility, we observed recruitment of a substantial amount of ARF6 along with clathrin, AP180, and AP-2 to LP2 membranes on incubation with cytosol in the presence of ATP and GTP\(\gamma S\) (Fig. 1 A).
specific nucleotide exchange factor mSec7 in nerve terminals (Ashery et al., 1999). pAbs that recognize ARF6 but not ARF1 (Fig. 3A) detect high level expression of ARF6 in several tissues, including brain, as previously reported (Cavagnagh et al., 1996; Yang et al., 1998; and unpublished data). The subcellular distribution of ARF6 as well as that of other well-characterized synaptic markers was analyzed in fractions of pig brain (obtained by the procedure of Maycox et al. [1992]). ARF6 was found in synaptosomes (P2) and within synaptosomes was primarily localized to the plasma membrane–containing fraction (LP1; Fig. 3B). The LP2 fraction, mostly comprising SV and endosomal membranes, was highly enriched in the SV protein synaptophysin, but contained only relatively low levels of ARF6. ARF6 was also present (but not enriched) in highly purified clathrin-coated vesicles isolated from nerve terminals (Fig. 3B) or whole brain (not depicted). Consistent with these biochemical data, activated HA-tagged ARF6(Q67L) accumulated at synapses in transfected cortical neurons grown in vitro, as demonstrated by its enrichment in synaptophysin-positive structures. (Fig. 3C). We conclude that ARF6 is present at synapses, where it is found predominantly in plasma membrane fractions from which SV recycling occurs.

**Effect of ARF6 mutants on clathrin/AP-2 recruitment to synaptic membranes**

To investigate directly whether ARF6 can trigger AP-2/clathrin coat formation, we tested recombinant myristoylated ARF6 mutants for their ability to facilitate clathrin/AP-2 recruitment to carbonate-washed LP2 membranes devoid of endogenous membrane-bound ARF6 (Fig. 1A). Reactions were performed in the presence of 200 μM GTP instead of GTPγS to prevent generalized activation of all endogenous GTPases. Addition of 1 μM recombinant ARF6(Q67L), an ARF6 mutant locked in the GTP-bound state due to defective GTP hydrolysis, was sufficient to promote recruitment of clathrin, AP-2, and AP180 as efficiently as addition of GTPγS in the absence of exogenous ARF.
ARF6-GTP interacts directly with PIPK1γ
To obtain possible insights into the mechanism by which ARF6-GTP stimulates clathrin/AP-2 recruitment to synaptic plasma membranes, we used an affinity purification approach. In pull-down experiments, NH2-terminal GST fusion constructs of the constitutively active ARF6(Q67L) or the GTP-binding defective mutant ARF6(T27N) were analyzed for their ability to retain various endocytotic proteins. Considering that ARF1 directly interacts with AP-1 complexes at the trans-Golgi network and AP-3 complexes on endosomal membranes, we initially focused on coat components as putative interactors of ARF6. No association of either ARF6 mutant with clathrin or subunits of AP-2 could be detected. Likewise, we did not detect any interaction of GST-ARF6 with AP180, amphiphysin I, dynamin I, and auxilin, or the SV protein synaptotagmin I (Fig. 5 A).

A variety of endocytotic proteins including AP-2 have been found to interact with the membrane via phosphoinositides (Gaidarov and Keen, 1999; Ford et al., 2001; Itoh et al., 2001; Mao et al., 2001; Collins et al., 2002; Rohde et al., 2002). Moreover, members of the ARF family have been shown to stimulate phosphatidylinositol kinases in different systems (Godi et al., 1999; Honda et al., 1999; Skippen et al., 2002). Therefore, we investigated whether ARF6 interacts with PIPK1γ, an isoform of PI(4)P 5-kinase highly enriched in brain (Ishihara et al., 1998) and concentrated in (Fig. 4 C). Like corresponding mutants of other GTPases, ARF6(T27N) may trap GEFs in a stable complex, preventing activation of endogenous ARF6.
the presynaptic compartment (Wenk et al., 2001). Indeed, GST-ARF6(Q67L) efficiently pulled down PIPKIγ (Fig. 5A). By contrast, little interaction was seen between PIPKIγ and the inactive GDP-bound mutant GST-ARF6(T27N). Similar results were seen if N-myristoylated hexahistidine-tagged ARF6 mutants were used instead (unpublished data).

The interaction between ARF6 and PIPKIγ appeared to be direct because GST-ARF6 bound to radiolabeled PIPKIγ synthesized by coupled transcription/translation in vitro (unpublished data). To determine the isoform specificity for different ARF family members, hexahistidine-tagged myristoylated ARF6(Q67L) or ARF1(Q71L) were compared for their ability to bind to PIPKIγ or the trans-Golgi clathrin adaptor AP-1, a protein complex known to bind to both ARF1 and ARF6 (Austin et al., 2002). Although both ARF1(Q71L) and ARF6(Q67L) displayed similar affinities for AP-1, as detected by Western blotting of the affinity-purified material for the AP-1 subunit γ-adaptin, only ARF6 was able to effectively pull-down PIPKIγ (Fig. 5B). By contrast, a control protein (arfaptin 2) did not

Figure 4. ARF6-GTP stimulates clathrin/AP-2 recruitment to synaptic membranes. (A) Coat recruitment to LP2 membranes was performed and analyzed as described in the legend to Fig. 1. Samples containing 1 µM ARF6 mutants were incubated in the presence of 200 µM GTP and analyzed by quantitative immunoblotting against clathrin heavy chain (HC), AP180, α-adaptin, Hsc70, and synaptotagmin I. (B) Dose dependence of the stimulatory effect of ARF6(Q67L) on clathrin recruitment to membranes as shown in A. Values were normalized to the amount of clathrin bound in the presence of ATP and GTPγS (100%). (C) Dose dependence of the inhibitory effect of ARF6(T27N) on clathrin recruitment to membranes as shown in A. Values were normalized to the amount of clathrin bound in the presence of ATP and GTPγS (100%).

Figure 5. Activated ARF6 interacts with PIPKIγ in brain. (A) ARF6(Q67L) but not ARF6(T27N) specifically affinity purifies PIPKIγ. Western blot analysis of proteins pulled down by GST and GST–ARF6 fusion proteins (80 µg) from a detergent extract of rat brain. Samples were analyzed by SDS-PAGE and immunoblotting. 5% Std., 5% of the extract used for affinity purification. (B) PIPKIγ specifically interacts with ARF6(Q67L). Immunoblot analysis of PIPKIγ affinity purified with myristoylated His6-tagged ARF6(Q67L), ARF1(Q71L), or arfaptin 2 as described under A. 5% Std., 5% of the extract used for affinity purification. (C) PIPKIγ can be cross-linked to ARF6(Q67L) during recruitment of clathrin/AP-2 to synaptic membranes. LP2-membranes were incubated with brain cytosol, myristoylated His6-tagged ARF6, and nucleotides. DTSP was added where indicated. His6-tagged ARF6 was recovered and cross-linked proteins were analyzed by immunoblotting. Top, immunoblot analysis with antisera against PIPKIγ, AP180, large and medium subunits of the AP-2 complex β2-adaptin, α-adaptin, and μ2-adaptin, respectively, and clathrin heavy chain (HC). Bottom, Coomassie-stained gel demonstrating that equal amounts of ARF6 have been recovered in each sample.
interact with either AP-1 or PIPKIγ. Together, these results show that ARF6 specifically binds to PIPKIγ in vitro in a GTP-dependent manner, but not to clathrin/AP-2 coat components.

To finally determine whether ARF6 associated with PIPKIγ during clathrin/AP-2 recruitment to synaptic membranes, we performed chemical cross-linking experiments. To this aim, LP2 membranes were first incubated with cytosol, ATP, ARF6(T27N)-His6 or ARF6(Q67L)-His6, and GDP or GTP, respectively. 3,3′-Dithio-bis(propionic acid N-hydroxysuccinimide ester) (DTSP), a cleavable amine-reactive cross-linking reagent was added, samples were solubilized under denaturing conditions, and ARF6-His6 was recovered by Ni-NTA affinity chromatography. ARF6(Q67L) but not its inactive GDP-bound counterpart (T27N) became efficiently cross-linked to PIPKIγ (Fig. 5 C). No interaction was seen with clathrin, AP180, or any of the individual subunits of the AP-2 adaptor complex. Our combined data suggest that ARF6-GTP directly interacts with PIPKIγ on synaptic membranes.

**ARF6-GTP and PIPKIγ colocalize in transfected cells**

The biochemical interaction of ARF6 with PIPKIγ was supported by morphological studies of cotransfected cells. Consistent with previous data (Brown et al., 2001), ARF6(Q67L)-EGFP expressed in Cos7 cells was found in peripheral plasma membrane invaginations, vacuolar structures, and membrane ruffles. In these structures, it colocalized with cotransfected PIPKIγ-p90 (Fig. 6 A). By contrast, little if any colocalization was seen between PIPKIγ and the inactive GDP mutant of ARF6 (Fig. 6 B). As expected, PIPKIγ-containing structures were highly enriched in PI(4,5)P₂, as visualized by coexpression of PHPLCδ1-EGFP, a specific interactor for this phosphoinositide (Fig. 6 C).

**ARF6 directly activates PIPKIγ on liposomes**

Given the interaction of ARF6-GTP with PIPKIγ, we asked whether ARF6 might regulate phosphatidylinositol 4-phosphate 5-kinase activity in bovine brain cytosol. To this end, cytosol was incubated with γ[32P]ATP, phosphatidylinositol 4-phosphate 5-kinase activity in bovine brain cytosol. To this end, cytosol was incubated with γ[32P]ATP, phosphatidylinositol 4-phosphate 5-kinase activity in bovine brain cytosol.
4-phosphate (PI4P)–containing liposomes, and neomycin to prevent PIP\sub{2} degradation. Lipid products were analyzed by TLC, and the amount of incorporated radioactivity was quantified. Addition of 1 \textmu M recombinant myristoylated ARF6(Q67L)-GTP greatly stimulated PI4P 5-kinase activity compared with ARF6(T27N). A slightly less pronounced increase in PI4P kinase activity was seen if wild-type ARF6-GTP was used instead (Fig. 7 A). Under these conditions (i.e., addition of neomycin), no formation of phosphatidic acid from 3H-labeled phosphatidylcholine was detectable (unpublished data).

To analyze whether ARF6 directly activates PIPKI\gamma\, we monitored the activity of recombinant PIPKI\gamma-p90 in an in vitro assay using liposomes made of total brain lipids as a substrate. Liposomes were incubated with recombinant PIPKI\gamma and myristoylated ARF6, or mutants thereof, in the presence of 200 \textmu M GTP and \gamma\textsuperscript{[\textsuperscript{32}P]}ATP. Lipid products were analyzed as described above. Myristoylated ARF6(Q67L) induced a strong increase in kinase activity compared with the basal activity seen in the absence of ARF (Fig. 7 B). A similar (albeit weaker) effect was produced by wild-type ARF6. By contrast, the GTP-binding defective mutant ARF6(T27N) failed to enhance kinase activity (Fig. 7 B). The stimulatory effect of ARF6 on PIP\sub{2} generation from total brain lipids was smaller than that observed with liposomes containing high concentrations of PI(4)P (compare Fig. 7 A with Fig. 7 B), presumably due to incomplete substrate saturation of the enzyme. These data suggest that ARF6-GTP stimulates PIPKI\gamma activity under conditions mimicking physiological substrate levels.

Although addition of activated ARF6 increased formation of PIP\sub{2} from total brain lipids, no effect on PIP\sub{2} generation was detectable (Fig. 7 C). Moreover, immunodepletion of PIPKI\gamma from cytosol almost completely abolished PIP\sub{2} formation (see also Wenk et al., 2001), and this defect could not be restored by addition of exogenous ARF6-GTP or mutants thereof (Fig. 7 C). This indicates that ARF6-mediated stimulation of PIP\sub{2} synthesis is indeed primarily due to activation of PIPKI\gamma. In summary, these results demonstrate a direct interaction between activated ARF6 and PIPKI\gamma in brain cytosol that results in a strong stimulation of PI(4)P 5 kinase activity and PIP\sub{2} formation.
ARF6-GTP stimulates PIP₂ formation on synaptic membranes

Also, we investigated whether ARF6-mediated clathrin/AP-2 coat recruitment (Fig. 1 and Fig. 4) is accompanied by an increase of PIP₂ levels in synaptic membranes. We stimulated coat recruitment to LP2 membranes with γ[32P]ATP and GTP in the absence or presence of the different ARF6 mutants. As shown in Fig. 7 D, 1 μM recombinant ARF6(Q67L) stimulated PIP₂ synthesis up to 2.5-fold compared with the amount of PIP₂ formed in the presence of cytosol alone. In contrast, ARF6(T27N) failed to affect PIP₂ levels in LP2 membranes. Addition of wild-type ARF6-GTP resulted in an intermediate stimulation of PIP₂ formation (Fig. 7 D). Collectively, our data suggest that ARF6-GTP stimulates PIP₂ synthesis at the synapse by activating PIPKγ.

Masking or degradation of PIP₂ interferes with clathrin/AP-2–coated pit assembly and receptor-mediated endocytosis

Finally, if the ARF6-mediated stimulation of PIPKγ played a major role in mediating the effect of ATP/GTPγS on clathrin/AP-2 recruitment, one would expect that masking PIP₂ with a PIP₂-binding module or degradation of PIP₂ by an inositol phosphatase would inhibit such recruitment to synaptic membranes or in living cells. We performed recruitment

---

Figure 8. **Effects of PIP₂ masking or degradation on clathrin/AP-2–coated pit assembly.** (A) Recombinant human PHPLC₁ inhibits ATP/GTPγS-induced membrane recruitment of clathrin/AP-2 coat components. Clathrin/AP-2 recruitment onto presynaptic membranes was performed as described in Fig. 1 in the presence or absence of ATP/GTPγS, purified PHPLC₁, or BSA. Samples were analyzed by quantitative Western blotting using antisera against clathrin heavy chain (HC), α-adaptin, synaptotagmin I as a membrane marker, and Hsc70 as a control. (B and C) Overexpression of membrane-targeted HA-tagged inositol 5-phosphate phosphatase domain of synaptojanin 1 (HA-IPP1-CAAX) mislocalizes clathrin and AP-2. Cos7 cells expressing HA-IPP1-CAAX were fixed 24 h after transfection and analyzed for the distribution of AP-2 (B) or clathrin (C) by immunofluorescence microscopy. Bar, 20 μm.
experiments in the presence of the recombinant PH domain of human PLCγ1 (PHPLCγ1), a specific PI(4,5)P_2-binding protein. Addition of recombinant PHPLCγ1 to synaptic membranes inhibited the ATP/GTPγS-induced binding of clathrin and AP-2 in a concentration-dependent manner, whereas addition of GST had no effect (Fig. 8 A). Likewise, overexpression of the prenylated HA-tagged inositol 5-phosphatase domain of synaptojanin 1 (HA-IPP1-CAAX), a PI(4,5)P_2-degrading enzyme, in Cos7 cells resulted in the mislocalization of AP-2 to patch-like structures (Fig. 8 B). Similar (albeit less dramatic) effects were seen on peripheral clathrin-positive puncta. By contrast, a pool of clathrin remained associated with the trans-Golgi network in transfected cells (Fig. 8 C).

Consistent with its effects on clathrin/AP-2–coated pit formation and with previous observations (Malecz et al., 2000), cells expressing HA-IPP1-CAAX displayed a strongly reduced ability to internalize Texas red epidermal growth factor (EGF; Fig. 9 A) or Alexa® 488-transferrin (Fig. 9 B). Similar (albeit slightly less pronounced) effects on transferrin uptake were seen on overexpression of EGFP-tagged PHPLCγ3 (unpublished data).

**Discussion**

In the present work, we have investigated mechanisms involved in the nucleotide-dependent regulation of clathrin-coated pit nucleation at the synapse. Our results implicate ARF6 in this process and demonstrate two effects of the GTP-bound form of this small GTPase; stimulation of the recruitment of clathrin/AP-2 to presynaptic membranes and binding plus activation of PIPKIγ. They also suggest that the two effects are related and that PI(4,5)P_2 production by PIPKIγ stimulation represents the major mechanism through which ARF6 enhances clathrin/AP-2 recruitment. The action of GTP-ARF6 on clathrin/AP-2 recruitment mimics the effect of GTPγS, and its effects are antagonized by experimental manipulations that prevent either ARF activation (i.e., dominant-negative ARF6) or PI(4,5)P_2 production and availability (i.e., kinase inhibition, PIPKIγ depletion, and PI(4,5)P_2 hydrolysis by synaptojanin’s inositol 5’-phosphatase domain). These results strongly indicate that enhanced clathrin coat recruitment mediated by a stimulation of PI(4,5)P_2 synthesis plays a major role in the GTPγS-stimulated nucleation of morphologically detectable clathrin-coated pits on synaptic membranes (Takei et al., 1996), although a block or delay in fission may also contribute to this ultrastructural change.

The strong stimulatory effect of ARF6 on PIPKIγ extends to this brain-enriched enzyme a property previously demonstrated for predominantly nonneuronal isoforms of PIPK (Honda et al., 1999; Skippen et al., 2002). It was also shown that PLD stimulation by ARF family proteins, including ARF6, may play a role in enhanced PI(4,5)P_2 production by generating phosphatidic acid, a reported activator of PI(4)P 5-kinases (Brown et al., 1993; West et al., 1997; Arneson et al., 1999). This effect may synergize with the direct effect of ARF6 on PIPKIγ in the generation of PI(4,5)P_2 at the synapse. Although ARF6 appears to have a broad distribution in the nervous system, the weak immunocytochemical signal produced by available antibodies to endogenous ARF6 in
brain tissue did not allow its reliable subcellular localization. However, transfected activated ARF6(Q67L) appears to be concentrated at synapses, and an ARF6-specific GEF, mSec7, regulates SV traffic (Ashery et al., 1999). Furthermore, PIPKIγ is highly expressed in brain (Ishihara et al., 1998) and concentrated at synapses (Wenk et al., 2001). Thus, our findings, obtained primarily using cell-free systems, are likely to reflect a physiological process occurring in vivo.

The precise interplay between mSec7 and other brain ARF6-specific GEFs, and their role in the activation of ARF6 at the presynaptic plasma membrane remains to be investigated. It seems possible that ARF6 may synergize with the synthetically enriched focal adhesion protein talin in activating PIPKIγ at the synapse (Di Paolo et al., 2002; Ling et al., 2002). The finding that enhanced PI(4,5)P2 production may play a critical role in the recruitment of endocytotic clathrin coats is supported by a large body of data besides those presented here. Biochemical and structural studies have demonstrated an interaction of the clathrin adaptor AP-2, AP180, and dynamin with PI(4,5)P2 (Barylko et al., 1998; Gaidarov and Keen, 1999; Ford et al., 2001; Mao et al., 2001; Rohde et al., 2002). Genetic disruption of the polyphosphoinositide phosphatase synaptojanin (Cremona et al., 1999; Harris et al., 2000) and other manipulations that disrupt its function and therefore lead to an accumulation of PI(4,5)P2 in neurons, enhance the presence of clathrin coats on synaptic membranes both in vivo (Cremona et al., 1999; Gad et al., 2000) and in cell-free systems (Cremona et al., 1999; Wenk et al., 2001; Kim et al., 2002). Our data are also consistent with (and further support) recent reports suggesting that ARF6 (Altschuler et al., 1999; Palacios et al., 2002) and PIPK (Barbieri et al., 2001) regulate clathrin-mediated endocytosis from the plasma membrane.

As cell fractionation data indicate, neither ARF6 nor PIPKIγ are enriched in crude SV (Wenk et al., 2001, and this paper). Instead, ARF6 is localized in plasma membrane fractions (Cavenagh et al., 1996; Yang et al., 1998), consistent with a role in priming the membrane for coating. PIPKIγ is found primarily in the cytosol (Wenk et al., 2001), but as shown by EM (Wenk et al., 2001) and biochemically (this paper), is recruited by GTPγS, and therefore most likely by ARF6-GTP, to the membranes at which clathrin-coated pits nucleate. A GTPγS-stimulated recruitment of clathrin/AP-2 coats to endosomes was demonstrated by Robinson and co-workers in nonneuronal cells (West et al., 1997). This “mislocalization” of endocytotic clathrin coats was shown to be dependent on enhanced PI(4,5)P2 production on endosomes, and has been attributed to PLD activation by an ARF GTPase. Excess PI(4,5)P2 on endosomes can also be generated by overexpression of an active form of ARF6 (Brown et al., 2001). As shown by Honda et al. (1999) and by our present results, a major mechanism through which active ARF6 may stimulate PI(4,5)P2 production is via the recruitment and activation of a PI(4)P 5-kinase activity. We speculate that in neuronal cells, PI(4,5)P2 is segregated at the plasma membrane by the coordinate action of PI(4)P 5-kinases, which are primarily localized at the cell surface, and of the phosphoinositide phosphatase synaptojanin, which cleaves PI(4,5)P2 on endocytotic membranes (Kim et al., 2002; Stefan et al., 2002). Excess active ARF6—either because of GTPγS addition or because of mutation that inactivates its GTPase activity—may alter this balance and lead to an abnormal accumulation of PI(4,5)P2 on endosomes.

It seems particularly interesting that PIPKIγ is stimulated by ARF6, a protein previously implicated in regulating actin dynamics and membrane turnover (D’Souza-Schoeber et al., 1998; Randazzo et al., 2000; Schafer et al., 2000). Invaginations of the plasma membrane that resemble those found at synapses after prolonged stimulation (Heuser and Reese, 1973; Takei et al., 1996; Gad et al., 2000) have been detected in nonneuronal cells on expression of constitutively active ARF6 (D’Souza-Schoeber et al., 1998) or of an ARF6-specific exchange factor (Franco et al., 1999). ARF6 may recruit and activate PIPKIγ at the synapse, thus increasing the local PI(4,5)P2 concentration. This, in turn, would facilitate the formation of endocytotic structures like clathrin-coated pits and deeper membrane invaginations from which clathrin-coated vesicle budding can also occur. A number of observations suggest that clathrin-mediated endocytosis is highly interconnected to dynamics of the actin cytoskeleton (Lamaze et al., 1997). Accordingly, many accessory proteins of the clathrin pathway directly couple endocytotic coat formation to actin rearrangements (Qualmann et al., 2000; Schafer et al., 2000; Hussain et al., 2001; Lee and De Camilli, 2002; Orth et al., 2002). Endocytotic “hot spots” at synapses coincide with actin-rich zones (Kelly, 1999; Gad et al., 2000), and the accumulation of clathrin-coated vesicles induced in nerve terminals by the disruption of synaptojanin function correlates with the presence of a meshwork of actin around these vesicles (Cremona et al., 1999; Gad et al., 2000; Kim et al., 2002; Shupliakov et al., 2002). ARF6 may regulate actin dynamics through multiple cooperative mechanisms. Via the increase in PI(4,5)P2 production mediated by stimulation of PLD (Brown et al., 1993) and PIPKs (Honda et al., 1999; this paper), it enhances the recruitment and activation of actin regulatory proteins including N-WASP and small GTPases of the Rho family (Takenawa and Itoh, 2001). It can also directly regulate Rac via its binding to arfaptin 2/Par1 (Shin and Exton, 2001). Possibly through its effects on Rac and actin, ARF6 can stimulate formation of macro- pinosomes (Brown et al., 2001).

Thus, ARF6 appears to have a major regulatory role in endocytosis because it can control both clathrin-dependent and -independent endocytotic pathways. It will be critical to further elucidate the localization and regulation of ARF6-GEFs and the effect of synaptic activity on such regulation.

Materials and methods

Materials

DTSP, l-phosphatidylinositol 4-phosphate, and total brain lipid extracts were purchased from Sigma-Aldrich; γ[32P]ATP was purchased from Amer sham Biosciences. pAbs recognizing ARF6 were a gift of Dr. Julie Donaldson (National Institutes of Health, Bethesda, MD). 

Recombinant proteins

Wild-type or mutant ARF6s or ARF1 GST fusion proteins were purified from bacteria according to the manufacturer’s instructions (Amer sham Biosciences). For production of myristoylated mutants of ARF6s or ARF1, BL21 were cotransformed with pET-21b-ARF6 and pBB131 containing yeast myristoyl transferase (Duronio et al., 1990). Proteins from lysed cell extracts were adsorbed to His-bind resin (Boehringer) and eluted with 250 mM imidazole (pH 7.4) in 50% glycerol.
Recruitment experiments

Rat brain cytosol and LP2 membranes were prepared as described previously (Haucke and De Camilli, 1999). Membranes (1 mg/ml protein) were washed at 4°C in 0.1 M sodium carbonate, pH 9.5, for 15 min, recovered by centrifugation (89,000 g, for 15 min at 4°C), and resuspended in cytosolic buffer. Recruitment experiments were performed in a total volume of 400 μl cytosolic buffer containing 60 μg/ml LP2 membranes and 1.2 mg/ml rat brain cytosol. Nucleotides and recombinant myristoylated ARF6 were added in buffer (25 mM Hepes/KOH, pH 7.4, 320 mM sucrose, 2 mM MgCl2, 1% Triton X-100, 1 mM PMSF, 1 μg/ml leupeptin, 1 μg/ml aprotinin and 100 μg/ml Pefabloc for 4 h at 4°C. The beads were extensively washed and finally extracted twice with 100 μl Laemmli sample buffer. Alternatively, 0.15 mg/ml His6-tagged Arfaptin 2 or myristoylated ARF6(Q67L)-His6, or ARF1(Q71L)-His6 bound to Ni2+-NTA beads were rotated end over end with 2.5 mg/ml rat brain extract supplemented with 15% glycerol for 1 h at 4°C. The resin was washed and extracted twice with 120 μl sample buffer.

Pull-down experiments

For GST pull-downs, 0.5 mg/ml GST or GST-ARF6 bound to resin was supplemented with 1 mM GDP (GST-ARF6(T27N)) or 1 mM GTP (GST-ARF6(Q67L)) and incubated with 3 mg/ml mg rat brain extract in 20 mM Hepes/KOH, pH 7.4, 320 mM sucrose, 2 mM MgCl2, 1% Triton X-100, 1 mM PMSF, 1 μg/ml leupeptin, 1 μg/ml aprotinin and 100 μg/ml Pefabloc for 4 h at 4°C. The beads were extensively washed and finally extracted twice with 100 μl Laemmli sample buffer. Alternatively, 0.15 mg/ml His6-tagged Arfaptin 2 or myristoylated ARF6(Q67L)-His6, or ARF1(Q71L)-His6 bound to Ni2+-NTA beads were rotated end over end with 2.5 mg/ml rat brain extract supplemented with 15% glycerol for 1 h at 4°C. The resin was washed and extracted twice with 120 μl sample buffer.

Cross-linking experiments

1-mg LP2 membranes were incubated with 5 mg rat brain cytosol in the absence or presence of 200 μM myristoylated ARF6(T27N)- or ARF6(Q67L)-His6, 2 mM ATP, and 200 μM GDP or GTP in a final volume of 1.5 ml for 15 min at 37°C. Proteins were cross-linked with 0.5 mM DTSP for 1 h at 4°C. Samples were solubilized with 1% Triton X-100, centrifuged at 20,000 g (for 15 min at 4°C), and denatured in 6 M guanidinium hydrochloride for 1 h at 20°C. His6-tagged ARF6 and cross-linked partners were recovered by extracting twice with Ni2+-NTA beads in the presence of 10 mM imidazole. The collected beads were washed thoroughly and extracted with sample buffer.

Phosphoinositide kinase assays

For phosphoinositide kinase assays, liposomes (Fig. 7) or LP2 membranes (Fig. 7 D) were used. Large unilamellar liposomes were prepared for immunofluorescence microscopy. For phosphoinositide kinase assays, liposomes (Fig. 7, A–C) or LP2 membranes (Fig. 7 D) were used. Large unilamellar liposomes were prepared for immunofluorescence microscopy.
