**ABSTRACT**

**Aims.** We derive the dense core structure and the water abundance in four massive star-forming regions in the hope of understanding the earliest stages of massive star formation.

**Methods.** We present Herschel/HIFI observations of the para- H2O 1 10 and the para- H18O 1 10 transitions. The envelope contribution to the line profiles is separated from contributions by outflows and foreground clouds. The envelope contribution is modeled with Monte-Carlo radiative transfer codes for dust and molecular lines (MC3D and RATRAN), and the water abundance and the turbulent velocity width as free parameters.

**Results.** While the outflows are mostly seen in emission in high-J lines, envelopes are seen in absorption in ground-state lines, which are almost saturated. The derived water abundances range from 5 × 10⁻⁵ to 4 × 10⁻⁴ in the outer envelopes. We detect cold clouds surrounding the protostar envelope, thanks to the very high quality of the Herschel/HIFI data and the unique ability of water to probe them. Several foreground clouds are also detected along the line of sight.

**Conclusions.** The low H2O abundances in massive dense cores are in accordance with the expectation that high densities and low temperatures lead to freeze-out of water on dust grains. The spread in abundance values is not clearly linked to physical properties of the sources.

**Key words.** dust, extinction – ISM: molecules – ISM: abundances

1. Introduction

Massive stars (≥ 10 M☉) play a major role in the interstellar energy budget and the shaping of the Galactic environment (Zinnecker & Yorke 2007). However, the formation of such high-mass stars is not well understood for several reasons: they have a short evolution time scale, are born deeply embedded, and are far from the solar system.

The main-sequence lifetime of massive stars is preceded by the accretion phase itself. Moreover, because the dust continuum is strong at the higher temperatures, water molecules can be seen in absorption, thus providing an alternative method probing different depths in the protostellar environment (Poelman & van der Tak 2007). Measurements of the abundance of water are therefore a step toward understanding the energy budget of star-forming regions, hence of the star formation process itself.

This paper presents water observations performed with the Heterodyne Instrument for the Far Infrared (HIFI; de Graauw & et al. 2010) onboard ESA’s Herschel Space Observatory (Pilbratt & et al. 2010). We use the p-H2O ground-state line and two lines that constrain the excitation and optical depth (Table 1), all three formed by warm gas-phase chemistry (Motte et al. 2003) and ultracompact H II regions (UCHII), which show large pockets of ionized gas confined to the star (Churchwell et al. 1990). A key question is to what extent these phases represent different levels of luminosity and/or age, and if all high-mass stars pass through all these phases.

The water molecule is thought to be a sensitive tracer of physical conditions in star-forming regions, which acts as a natural filter for warm gas because of its large abundance variations between hot and cold regions (van der Tak et al. 2006). Moreover, because the dust continuum is strong at the higher frequencies, water lines connecting with the lowest energy levels can be seen in absorption, thus providing an alternative method probing different depths in the protostellar environment (Poelman & van der Tak 2007). Measurements of the abundance of water are therefore a step toward understanding the energy budget of star-forming regions, hence of the star formation process itself.

This paper presents water observations performed with the Heterodyne Instrument for the Far Infrared (HIFI; de Graauw & et al. 2010) onboard ESA’s Herschel Space Observatory (Pilbratt & et al. 2010). We use the p-H2O ground-state line and two lines that constrain the excitation and optical depth (Table 1), all three

lying at similar frequencies and observed at similar resolution. The sources are four massive star-forming regions (Table 2): the HMCs G31.41+0.31 and G29.96–0.02 and the HMPOs W33A and W43-MM1. We compare our results with those for two other regions: the UCHII region DR21 (van der Tak et al. 2010) and G29.96–0.02 and W33A and nearly saturated for the other sources, which indicates abundances around ~10^{-8} for the outer cold parts of the massive dense cores (Poelman & van der Tak 2007).

The H$_2$O 2$_0$–1$_1$ line always appears in emission and shows a broad and a narrower velocity component (Fig. 1). In addition, the spectra of G31.41+0.31 and W43-MM1 show two well-defined self-absorption features that appear at the source velocity. With its high $E_{\text{up}}$, this transition mainly traces warm gas, and the presence of these absorption features in G31.41+0.31 and W43-MM1 suggests a higher water abundance in these sources than in G29.96–0.02 and W33A. The components seen in emission have Gaussian shapes, with one wider ($FWHM = 20–40$ km s$^{-1}$) than the other ($FWHM = 6.4–8.0$ km s$^{-1}$). We associate the broad component with high-velocity outflows associated with the protostar also seen in 1113 GHz and 988 GHz lines, the outflow components seen in emission have Gaussian iterative decompositions of the absorption profiles of the ground-state transition over the full velocity range, showing several velocity components thanks to the high resolution in velocity of the HIFI instrument. The absorptions at $V_{\text{LSR}}$ are saturated for G31.41+0.31 and W33A and nearly saturated for the other sources, which indicates abundances around ~10^{-8} for the outer cold parts of the massive dense cores (Poelman & van der Tak 2007).

### Table 3. Gaussian decomposition of the line profiles around $V_{\text{LSR}}$: Appendix A shows Gaussian iterative decompositions of the absorption profiles of the ground-state transition over the full velocity range, showing several velocity components thanks to the high resolution in velocity of the HIFI instrument. The absorptions at $V_{\text{LSR}}$ are saturated for G31.41+0.31 and W33A and nearly saturated for the other sources, which indicates abundances around ~10^{-8} for the outer cold parts of the massive dense cores (Poelman & van der Tak 2007).

### Table 2. List of sources.

| Name       | RA (J2000) | Dec (J2000) | $L$ (10$^4$ $L_\odot$) | $a^\circ$ | $V_{\text{LSR}}$ (km s$^{-1}$) |
|------------|-----------|------------|-------------------------|----------|-------------------------------|
| G31.41+0.31| 18$^h$47$^m$34.3$^s$ | -01$^d$12$^m$46.0$^s$ | 15 | 7.9 | +98.8 |
| G29.96–0.02| 18$^h$46$^m$03.8$^s$ | -03$^d$39$^m$22.0$^s$ | 20 | 7.4 | +98.7 |
| W33A       | 18$^h$14$^m$39.1$^s$ | -17$^d$52$^m$07.0$^s$ | 8.5 | 4.0 | +37.5 |
| W43-MM1    | 18$^h$47$^m$47.0$^s$ | -01$^d$54$^m$28.0$^s$ | 2.2 | 5.5 | +98.8 |

Notes: Values from Hatchell & van der Tak (2003), except W43-MM1 (Motte et al. 2003) and W33A (van der Tak et al. 2000).

3. Results

Observed water lines for the four studied regions are shown in Fig. 1. The H$_2$O 1$_1$–0$_0$ line shows an absorption at the systemic velocity ($V_{\text{LSR}}$) in all sources. In all cases except G31.41+0.31, outflow wings are detected close to the main absorption, with a maximal shift of 3 km s$^{-1}$. These wings are seen in emission, which indicates an origin in hot, low-density (10$^4$ cm$^{-3}$) gas (Poelman & van der Tak 2007). Absorption features are seen over a wide velocity range in G29.96–0.02, W33A, W43-MM1, and more weakly in G31.41+0.31. The absorptions at velocity offsets >4 km s$^{-1}$ likely originate in cold foreground clouds on the line of sight to the source. In contrast, the absorption features at lower velocity offsets are plausibly related to cold clouds surrounding the dense cores (which other studies call the protostellar envelopes), which are all part of large-scale molecular clouds (see Fig. 2).

### Table 1. List of lines.

| Molecule | Transition | $\nu$ (GHz) | $E_{\text{up}}$ (K) | $n_{\text{crit}}$ (cm$^{-3}$) | $\sigma_{\text{rad}}$ (mK) |
|----------|------------|-------------|---------------------|--------------------------|--------------------------|
| H$_2$O   | 1$_1$–0$_0$| 1113.343    | 53.4                | 1.7×10$^6$               | 40                       |
| H$_2$O   | 2$_0$–1$_1$| 987.927     | 100.8               | 2.1×10$^6$               | 50                       |
| H$_2$O   | 1$_1$–0$_0$| 1101.698    | 53.4                | 1.7×10$^6$               | 40                       |

Notes: Values at 20 K from collision rates of Grosjean et al. (2003).

The data were simultaneously taken with the acousto-optical wide band spectrometer (WBS) and the correlator-based high-resolution spectrometer (HRS), in both horizontal and vertical polarizations. This paper focuses on data from the WBS, which covers 1140 MHz bandwidth at 1.1 MHz spectral resolution (~0.3 km s$^{-1}$) (Roelfsema et al. 2010). System temperatures range between 350 K around 1113 GHz and 450 K around 988 GHz; receiver 4a in V polarization shows particularly high values. Integration times (ON+OFF) were 193 s for the 1113 GHz and the 1102 GHz lines and 206 s for the 988 GHz line for each source, and the rms noise levels reached are 40–50 mK (Table 1). Observations were reduced with the Herschel interactive processing environment$^1$ (HIPE) version 2.8. The intensity scale is converted to $T_{\text{mb}}$ using main beam efficiencies of 0.74. The double-sideband continuum level was divided by 2 to make its brightness directly comparable to that of the lines, which are measured in single sideband.

### 4. Discussion and conclusions

To derive the water abundance in the four massive dense cores, we removed features related to outflows and foreground clouds from the spectrum before any line modeling. The high spectral resolution of HIFI is essential in this process, in particular for

Notes.  (*) Absorption lines are indicated in $T_{\text{mb}}/T_{\text{continuum}}$ scales.
the absorbers with velocities close to that of the central source. Studying the H$_2$O $1_{11}$$-0_{00}$ transition prior to the others also facilitates disentangling the envelope contribution, since this line is not saturated because it has a lower optical depth than the main H$_2$O isotope.

Once the main contribution is extracted, we model its profile according to the method described in Marseille et al. (2008); first, the dust emission from the massive dense core is reproduced with the MC3D radiative transfer code (Wolf et al. 1999), including total luminosity and density profile from the literature (power-law index $p = -1.5$); second, the temperature profile obtained is used to model the line emission with the RATRAN code (Hogerheijde & van der Tak 2000). The free parameters are $X_{H_2O}$, the molecular abundance relative to $H_2$, and $v_{turb}$, the turbulent velocity width.

Good fits are obtained for the H$_2$O $1_{11}$$-0_{00}$ transition, which is not saturated, unlike the H$_2$O lines. The fitting considers both the line strength (area and width) and the profile shapes. We have computed a grid of $X_{H_2O}$ and $v_{turb}$ values, adapting step by step the grid around the best $\chi^2$. Using a $^{16}O/^{18}O$ ratio of 500, we proceed to model the main isotopic water lines. The H$_2$O abundance is kept constant in our models. We tried models with an abundance increase in the inner region where $T > 100$ K, but the current data do not favor those models above the constant-abundance models.

We estimate the absolute uncertainty in the retrieved H$_2$O abundance to be a factor of 10. Since we use the same modeling strategy as in the studies by van der Tak et al. (2010) and Chavarría et al. (2010), the abundances obtained should be comparable to better than a factor of 3. Our observed spread in abundances of a factor of ~100 is much greater than this uncertainty. The same range of abundances is found in other HIFI-based studies of high-mass star-forming regions (van der Tak et al. 2010; Chavarría et al. 2010), and also in previous work with ISO (Boonman et al. 2003) and from the ground (van der Tak et al. 2006).

In conclusion, for the massive-star forming regions described in this letter, we clearly detect the contribution of the envelope within the dense core. It is limited to a strong self-absorbed feature mainly seen in the ground-state line. To evaluate it, we first have to remove emission from outflow shocks and absorption by foreground clouds along the line of sight. The velocities of the absorbers indicate that some are part of the close environment of the source, while others are physically unrelated. The derived massive dense core abundances suggest a strong freeze-out of water on dust grains, and imply that water plays only a minor role in the thermal balance of the gas.

The H$_2$O line profiles do not seem to depend on the supposed evolutionary stage of the source. For example, the two "hot molecular cores" G31.41 and G29.96 show very different line profiles, and also their H$_2$O abundances differ by a factor of ~100. Also, the abundance variations that we have found do not seem related to the luminosity of the sources, their temperature or their turbulent velocity field. However, there are not enough cases treated for a statistical treatment. Future studies following the same procedure with more sources should resolve this issue. Within our sample, the highest H$_2$O abundances are derived for G31.41 and W43-MM1, which show self-absorbed $2_{02}$$-1_{11}$ line profiles (Fig. 1). As these sources are not the most luminous, hot, or active ones in our sample, the origin of such a high abundance is unclear.

Firm conclusions about a link between water emission behavior and the evolutionary stage of the source are limited by the small number of sources. Our data show that water is a useful tool for understanding the gas dynamics in and around massive star-forming regions. Future multiline studies of larger samples are highly promising for answering key questions about the formation of massive stars.

Acknowledgements. HIFI has been designed and built by a consortium of institutes and university departments from across Europe, Canada, and the United States under the leadership of SRON Netherlands Institute for Space Research, Groningen, The Netherlands, and with major contributions from Germany, France, and the US. Consortium members are: Canada: CSA, U.Waterloo; France: CESR, LAB, LERMA, IRAM; Germany: KOSMA, MPIfR, MPS; Ireland, NUI Maynooth; Italy: ASI, IFSI-INAF, Osservatorio Astrofisico di Arcetri- INAF; Netherlands: SRON, TUD; Poland: CAMK, CBK, Spain: Observatorio Astronómico Nacional (IGN), Centro de Astrobiología (CSIC-INIA). Sweden: Chalmers University of Technology – MC2, RSS & GARD; Otsala Space Observatory; Swedish National Space Board, Stockholm University – Stockholm Observatory; Switzerland: ETH Zurich, FHNW; USA: Caltech, JPL, NHSC.

HIFI is a joint development by the Herschel Science Ground Segment Consortium, consisting of ESA, the NASA Herschel Science Center, and the HIFI, PACS, and SPIRE consortia.

Appendix A: Massive dense core component extraction

The velocity profiles of the H$_2$O $1_{11}−0_{00}$ line show absorption features at several velocities. These absorption features arise in foreground clouds along the line of sight or in cold clouds in the neighborhood of the massive dense core, and are not saturated unlike the absorption from the massive envelope. In addition to these absorptions, some sources show H$_2$O emission from protostellar outflows.

This appendix presents our procedure for removing these features in order to extract the contribution from the envelope to the line profile. In contrast to others, absorption from this part of the object is saturated. We are then able to remove other features by iterative Gaussian fits. This process is helped by the high resolution in velocity provided by the Herschel/HIFI instrument, showing accurate and “bumpy” profiles in absorptions. Assuming that each bump corresponds to a velocity component, they are removed using the Gaussian fitting tool available in the HIPE software. Starting from the component with the lowest velocity, they are extracted one by one, using the residual of the previous removal to fit the next one. This way of fitting insures a very good extraction of velocity component, giving a quasi-unique final decomposition of the absorption features. Results of this process are given in Figs. 2, A.1, A.2, A.3 and Tables A.1, A.2, A.3, and A.4.

Table A.1. Gaussian fit parameters for the full extraction of the saturated absorptions of para-H$_2$O $1_{11}−0_{00}$ line in W43-MM1.
