(Dated: July 14, 2020)

We present a novel approach to understanding the extraordinary diversity of magnetic skyrmion solutions. Our approach combines a new classification scheme with efficient analytical and numerical methods. We introduce the concept of chiral kinks to account for regions of disfavoured chirality in spin textures, and classify two-dimensional magnetic skyrmions in terms of closed domain walls carrying such chiral kinks. In particular, we show that the topological charge of magnetic skyrmions can be expressed in terms of the constituent closed domain walls and chiral kinks. Guided by our classification scheme, we propose a method for creating hitherto unknown magnetic skyrmions which involves initial spin configurations formulated in terms of holomorphic functions and subsequent numerical energy minimization. We numerically study the stability of the resulting magnetic skyrmions for a range of external fields and anisotropy parameters, and provide quantitative estimates of the stability range for the whole variety of skyrmions with kinks. We show that the parameters limiting this range can be well described in terms of the relative energies of particular skyrmion solutions and isolated stripes with and without chiral kinks.

I. INTRODUCTION

Chiral magnets are special magnetic materials where the ground state is a homochiral spin spiral – a helical or cycloidal modulation of the normalised magnetisation, \( \mathbf{n}(r) = \mathbf{M}/|\mathbf{M}| \). The period of modulations is determined by the ratio of the coupling constants of the Heisenberg exchange interaction and the chiral Dzyaloshinskii-Moriya interaction (DMI) modelled by a term which we denote \( \psi_D(n) \). The presence of the potential energy term, \( U(n) \), in the Hamiltonian, \( \mathcal{E}(\mathbf{n}) \), allows for the existence of magnetic solitons, localized stable configurations possessing particle-like properties. Typical energy terms that contribute to \( U(\mathbf{n}) \) are the interaction with the external magnetic field and the magnetocrystalline anisotropy. Note, the latter can also be thought of as an approximation of dipole-dipole interaction in ultrathin films.

The solitons which arise in such materials can be classified by topological charges defined in terms of homotopy theory, and are therefore examples of topological solitons. In analogy with the topological solitons in the model of baryons proposed by T. H. R. Skyrme, it is now common to refer to the topological solitons in chiral magnets as chiral magnetic skyrmions, or more simply as chiral skyrmions.

The standard approach to finding skyrmion solutions is based on the general variational principle, \( \delta \mathcal{E}/\delta \mathbf{n}(\mathbf{r}) = 0 \), and direct energy minimization with respect to all possible configurations of the corresponding field \( \mathbf{n}(\mathbf{r}) \). Due to the complexity of the problem the diversity of the solutions for chiral skyrmions was underestimated for a long time. A variety of skyrmion solutions first were demonstrated by Bogdanov and Hubert in Ref. [9] where the authors studied so-called \( k\pi \)-skyrmions possessing two values of topological charge, \( Q = 0 \) and \( -1 \) for even and odd \( k \) respectively. Numerical evidence for the existence of chiral skyrmions with arbitrary topological charge has been provided only recently in Refs. [10] and [11]. Although the skyrmions with complex morphology predicted in Ref. [10] have not yet been observed experimentally in chiral magnets, the existence of similar textures has been proven by direct observation in liquid crystals.

According to the Hobart-Derrick theorem, the stability of magnetic skyrmions requires the negativity of the integral of the DMI energy term \( \psi_D(\mathbf{n}) \). However, this requirement does not rule out local variations in the sign of the integrand, and so the DMI energy density of stable skyrmion may be locally positive. In this paper we refer to regions where \( \psi_D(\mathbf{n}) < 0 \) as regions of favoured chirality and regions where \( \psi_D(\mathbf{n}) > 0 \) as regions of disfavoured chirality. The emergence of regions of disfavoured chirality is natural for instance in the skyrmion lattice where axial symmetry of individual skyrmions is slightly distorted due to inter-skyrmion interactions. On the other hand, the stability of an isolated skyrmion with locally disfavoured chirality is less obvious. For instance, isolated \( k\pi \)-skyrmions in perpendicular external field have negative DMI energy density in the whole space.

It was recently shown in Ref. [14] that skyrmions with locally disfavoured chirality remain stable in a finite range of the external magnetic field and anisotropy. Moreover, stable skyrmions with locally disfavoured chirality and arbitrary positive \( Q \) are discussed in Refs. [15] and [16] where exact analytical solutions are studied at a particular point of the phase diagram known as the Bogo- mol’nyi point. For our purposes it is important that the
exact solutions can be expressed in terms of a single complex function of one complex argument (the holomorphic function referred to in our title), which may be chosen arbitrarily. The presence of such locally disfavoured chirality significantly affects not only the stability of isolated skyrmions and their dynamics but also dramatically changes the character of inter-particle interactions from repulsive to attractive. We introduce the concept of chiral kinks to account for regions of disfavoured chirality in magnetic skyrmions like the ones discussed in Refs. We demonstrate the fruitfulness of this concept by using it in a new method for generating magnetic skyrmions with chiral kinks, and discuss the stability of the solutions thus obtained for a wide range of parameters.

Our concept of chiral kinks is a generalisation of what was called “domain wall skyrmions” in the paper. Both concepts describe a full rotation of the magnetisation vector along a domain wall in a two-dimensional spin texture. These were considered theoretically for infinite, straight domain walls, but we define chiral kinks of any winding number for domain walls of arbitrary geometry, and show that the topological charge of a spin texture can be expressed in terms of the number of kinks residing on domain walls in that spin texture. We prefer the term chiral kink to domain wall skyrmions because, as we shall show, chiral kinks on domain walls provide a description of a spin texture which is different from and in a certain sense dual to its interpretation in terms of skyrmions.

The work is organized as follows. In Section II we define the model and discuss our numerical method for direct energy minimization. In Section III we present our approach to the classification of magnetic skyrmions based on the observation that any configuration of a planar magnet defines a family of domain walls, and that the angle of the magnetisation along a wall relative to the tangent direction of the wall supports topological excitations which we call chiral kinks. We show that the topological charge of any magnetic skyrmions can be expressed in terms of number of kinks and domain walls, weighted with appropriate signs. We also show that our approach for soliton classification is consistent with the concept of so-called Bloch lines which is well established in the theory of magnetic bubble domains. In Section IV we recall the general exact form of magnetic skyrmions at the Bogomol’nyi point, and in Section V we use families of such exact solutions as initial states at other points in the phase diagram for the direct energy minimization by means of numerical methods. In Section V we analyse the energy dependence for different skyrmions as a function of the external field and determine the range of external fields for which the skyrmions with chiral kinks are the lowest energy state for Q ≠ −1. Combining analytical solutions and numerical analysis we discuss different classes of skyrmion solutions and estimate the range of their stability in Section VII. In Section VIII we provide estimates for the characteristic size of chiral kinks, and in Section IX we discuss the range of optimal parameter where most of the presented solutions may coexist. Our final section IX contains a brief discussion and concluding remarks.

II. MODEL DESCRIPTION

The micromagnetic energy density functional for the two-dimensional (2D) chiral magnet is given by

\[ E(n) = \int \left( n \cdot D \nabla n + U(n) \right) dx dy, \]

where \( n \cdot \) and \( D \) are micromagnetic constants of exchange interaction and DMI, respectively. The potential energy term \( U(n) = U_\text{s}(n) + U_\text{b}(n) \) includes uniaxial anisotropy, \( U_\text{s}(n) = K(1 - n_z^2) \), and interaction with the external magnetic field, \( U_\text{b}(n) = M_e B_\text{ext}(1 - n_z) \), applied perpendicularly to the plane along \( n_z \). The magnetic texture assumed to be homogeneous along the film thickness, \( t \).

The results presented in this work hold generally for a broad class of magnetic crystals of different symmetry irrespective of whether the DMI term favors Bloch or Néel type modulations. However, for definiteness, we consider the particular case of \( u_B(n) = n \cdot D \nabla n \) and \( D > 0 \), which favours right-handed Bloch-type modulations. This choice of symmetry also allows us to illustrate the consistency of our approach with the concept of Bloch lines which is well-established for magnetic bubble domain materials where Bloch type modulations are favored by dipole-dipole interactions.

The rescaling of spatial coordinates in units of equilibrium period of helical modulations, \( L_D = 4\pi AD^{-1} \), and the value of external magnetic field in units of saturation field, \( B_D = D^2/(2M_e A) \), allows one to write the functions in dimensionless form

\[ \mathcal{E}(n) = \int \left( \frac{\nabla n}{2} + 2\pi n \cdot \nabla \times n + U(n_x) \right) dx dy, \]

where the potential energy term is

\[ U(n_x) = 4\pi^2 h(1 - n_z) + 4\pi^2 u(1 - n_z^2). \]

The dimensionless magnetic field and anisotropy are \( h = B_\text{ext}/B_D \) and \( u = K/(M_e B_D) \), respectively. The energy is given in units of the energy of saturated state, \( E_0 = 2A t \). The magnetization vector \( n(r) \) can be parameterized by spherical angles \( \Theta(r) \) and \( \Phi(r) \) as \( n = (\sin \Theta \cos \Phi, \sin \Theta \sin \Phi, \cos \Theta) \).

To find a stable solution representing a local or global minimum for the functional we use a nonlinear conjugate gradient (NCG) method with a finite-difference discretization scheme of the fourth order defined on a regular square grid with periodical boundary conditions. To achieve high accuracy in the estimation of the energies and stability of the solutions, we use large simulated domains with the size \( \sim 5L_D \times 5L_D \) or even higher, when
necessary for a large size skyrmions. The mesh density \( \Delta l \) defined as a number of the mesh nodes per \( L_D \) can be controlled by the ratio \( A/D \). The typical values of \( \Delta l \) are 64, 128, or 256 depending on the purposes and particular type of the solution and always specified in figure captions and in the main text. We use various approaches to construct the initial spin-configuration followed by energy minimization with the GPU accelerated version of the NCG method implemented for the NVIDIA CUDA architecture (for details see Refs.\([10,19]\)).

III. DOMAIN WALLS AND CHIRAL KINKS

In the study of skyrmions - both in Skyrme’s original nuclear theory and in condensed matter physics - it is customary to interpret general field configurations in terms of constituent particle-like solitons, and to think of the topological degree as counting the number of such solitons. However, one of the key messages of this paper is that configurations of chiral magnets in the plane which minimise the energy \([2]\) are most naturally interpreted in terms of domain walls which may carry defects which we call chiral kinks. The latter effectively represent pairs of Bloch lines of equal sign. In this section we explain how the topological degree of an arbitrary configuration can be expressed as a sum of winding numbers associated to domain walls (which, in our two-dimensional setting, are of course one-dimensional) and obtain a relation between the winding number and the number of kinks on a domain wall.

Given a configuration \( \mathbf{n}(\mathbf{r}) \) in the plane, one can divide the plane into positive and negative domains according to whether \( \mathbf{n}(\mathbf{r}) \) takes values in the upper \( (n_x > 0) \) or lower \( (n_x < 0) \) hemisphere at \( \mathbf{r} \). These domains are separated by a region where \( \mathbf{n}(\mathbf{r}) \) takes values on the equator or, equivalently, \( \Theta(\mathbf{r}) = \frac{\pi}{2} \) [Fig. 1]. For smooth configurations and assuming maximal rank of the differential \( d\mathbf{n} \), this region is a 1-dimensional submanifold of the plane, and therefore a countable union of simple (i.e. non-selfintersecting) curves which are either closed or emerge from and tend to infinity. In the following, we will refer to these curves or contour lines as domain walls. We should stress that the precise value of \( \Theta \) on the contour does not matter for our purposes as long as \( 0 < \Theta < \pi \). In particular, if the differential \( d\mathbf{n} \) happens to be degenerate when \( \Theta = \frac{\pi}{2} \), Sard’s theorem assures that we can choose a value nearby where it is non-degenerate.

We index the domain walls and corresponding contours by a countable index set \( I \) and orient each contour so that it has a positive domain on the left and a negative domain on the right as illustrated in [Fig. 1].

Observing that the azimuthal angle \( \Phi(\mathbf{r}) \) is well-defined on a domain wall, we can therefore assign the winding numbers

\[
w(C_i) = \frac{1}{2\pi} \int_{C_i} \nabla \Phi \cdot d\mathbf{r}, \quad i \in I, \tag{4}\]

to each domain wall \( C_i \), with the direction of integration determined by the orientation of the domain wall. These numbers may be non-integer or even infinite for curves going off to infinity, however they are necessarily integers for closed curves.

Generally, the degree of a configuration \( \mathbf{n}(\mathbf{r}) \), which can be defined analytically as

\[
Q(\mathbf{n}) = \frac{1}{4\pi} \int \mathbf{n} \cdot (\partial_x \mathbf{n} \times \partial_y \mathbf{n}) \, dx dy, \tag{5}\]

can then be expressed in terms of the winding numbers of the domain walls as the sum

\[
Q(\mathbf{n}) = \sum_{i \in I} w(C_i). \tag{6}\]

Note that the topological charge, \( Q \), in \([5]\) and \([6]\) may be infinite or ill-defined in general. However, when finite, the expressions \([5]\) and \([6]\) agree. The proof of this result is provided in Appendix A.

The winding number \([3]\) counts the winding of the magnetization vector \( \mathbf{n} \) along a domain wall. The variation of \( \mathbf{n} \) relative to the tangent direction of the domain wall may lead to a variation of the chirality of the domain wall. For instance, domain walls with alternate chirality are known to appear in ferromagnetic films with perpendicular anisotropy and strong dipole-dipole interactions favoring Bloch type modulations within the do-
FIG. 2. Magnetic skyrmions with chiral kinks in 2D magnet with DMI supporting right-handed Bloch-type modulations. Each row illustrates the skyrmions of a particular topological charge, as indicated on the left. The first and the second columns illustrate schematically the orientation of the spins around the bubble domain core or skyrmion for $D \to 0$ and $D \neq 0$, respectively. The bluish and reddish regions in the schematic images indicate the negative and positive energy density of DMI respectively. The third column represents the spin texture of the corresponding skyrmion obtained by direct energy minimization. All images are given in the same scale. We used a standard color code: black and white denote up and down spins respectively while red-green-blue reflect azimuthal angle, $\Phi$, with respect to $x$-axis. The values of the external field, $h$, and uniaxial anisotropy, $u$, are indicated at the bottom of each image. The rightmost column contains the contour plots illustrating the distribution of scalar quantity $\mathbf{n} \cdot \nabla \times \mathbf{n}$ corresponding to the equilibrium spin-texture shown in the third column. This scalar field up to a positively defined constant corresponds to the energy density of DMI.

main walls. The transition regions with Néel like modulations which separate the regions of the Bloch domain wall with opposite chirality are known as Bloch lines. In this case, the position of the Bloch line on the domain wall is defined as the location where $\mathbf{n}$ is orthogonal to the tangent direction of the domain wall. Figure 1 illustrates a segment of the domain wall containing two Bloch lines at the points marked as A and B. Note that the Bloch lines in Fig. 1 have opposite handedness index, $\eta$, which is defined as a sign of the integrand in \[ f(r) = \int \frac{d^2 \mathbf{r}}{(2\pi)^2} \left( \mathbf{n} \cdot \nabla \times \mathbf{n} \right) \]

In the case of a chiral magnet, the position of the Bloch line can be defined as the point which separates the regions of favoured chirality ($w_D < 0$) from the region of disfavoured chirality ($w_D > 0$). This definition holds generally, for any type of DMI term.

In the case of closed domain walls, Bloch lines always appear in pairs otherwise the continuity of $\Phi(r)$ along the wall is broken. Pairs of Bloch lines with opposite signs for $\eta$, called unwind pairs, always annihilate, while the pairs of the same sign for $\eta$ can be stable. Such behaviour of Bloch lines can easily be explained by means of topological arguments. For instance, according to the topological charge of the texture depicted in Fig. 1 is zero, essentially because the integrand in changes

changes
sign at point C. Such a pair of Bloch lines represents an unstable configuration which we have included for illustrative purposes. On the other hand, for a pair of Bloch lines of the same handedness index, η, the contribution to the topological charge is ±1 because the angle of n relative to the tangent direction of the wall makes a 2π twist along the wall in this case while the sign of this contribution depends on the value of η of the Bloch lines or, in other words, on the direction of the twist. Examples for stable pairs of Bloch lines on the closed domain wall are shown in Fig. 2. In the absence of the DMI term, the Bloch lines tend to be equidistantly distributed along the closed domain wall [Figs. 2(e), (i) and (m)]. When the DMI term is nonzero, the system tends to reduce the distance between Bloch lines to minimize the area with disfavoured chirality and extend the area with favoured chirality [Figs. 2(f), (j) and (n)]. Thus, in chiral magnets, Bloch lines of the same sign ‘embrace’ the region of disfavoured chirality and tend to form coupled states. In the following, we will refer to such coupled Bloch lines in chiral magnets as chiral kinks.

The topological charge of spin textures which only comprise closed domain walls can be expressed as a sum of chiral kink numbers on the domain walls, and this will be useful for the following discussion. Closed domain walls can be distinguished according to whether their orientation, as defined above, agrees or disagrees with their usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive in the usual geometrical orientation (where the inside is always on the left), and we call the such walls positive.

In Appendix A, we define the chiral kink number $N_{\text{kink}}(C)$ and show that is related to the winding number $w(C)$ of ϕ around C by

$$N_{\text{kink}}(C) = w(C) - \iota(C),$$

where $\iota(C)$ is the geometrical winding number of the wall. By Hopf’s Umlaufsatz, $\iota(C) = \pm 1$ for simple, closed walls, with the sign equal to the sign of the wall in our convention. Hence we have $N_{\text{kink}}(C) = w(C) - 1$ when such walls are positive and $N_{\text{kink}}(C) = w(C) + 1$ when they are negative. Note that the kink number on a domain wall is the sum of kinks on that wall weighted with their handedness index η, and therefore can be positive and negative. For a configuration n where all domain walls are closed, we split the index set I into a disjoint union of $I^+$ and $I^-$ so that $C_i$ is positive (negative) for $i \in I^+$ ($i \in I^-$). Then we can also express the topological charge for the whole spin texture in terms of the number of kinks hosted by the negative and positive domain walls as

$$Q(n) = \sum_{i \in I^+} (N_{\text{kink}}(C_i) + 1) + \sum_{i \in I^-} (N_{\text{kink}}(C_i) - 1).$$

This formula is the topological basis for our interpretation of topologically non-trivial configurations of chiral magnets in terms of chiral kinks on domain walls in the rest of the paper.

In contrast to bubble domains, which usually remain axially symmetric in the presence of Bloch lines [Figs. 2(e), (i) and (m)], the appearance of CKs in the structure of the chiral skyrmions leads to the violation of the axial symmetry of its spin texture. One of the reasons for such discrepancies between bubble domains and chiral skyrmions is that the diameter of the bubble domains is usually a few times larger than the width of the domain wall. Moreover, the dipole-dipole interaction responsible for the stability of bubble domains but not essential for chiral skyrmions is a long-range interaction. By contrast, the DMI is a short-range local interaction.

Equilibrium textures representing magnetic skyrmions with different numbers and signs of CKs and the corresponding topological charges $Q$ are shown in the third column of Fig. 2. These magnetic textures were obtained by direct energy minimization of functional (2) at $h$ and $u$ values indicated in the figures. The anti-skyrmion with $Q = +1$ in Fig. 2(k) was previously presented in Ref. 14 where we discussed the stability of chiral skyrmions in a tilted magnetic field. We note that, for the spin textures with CKs, all derivatives of the form $\partial n_i / \partial r_j$ ($i = x, y$) which enter the exchange term and DMI in (2) turn out to be bounded at all points of the simulated domain.

The rightmost column in Fig. 2 illustrates the distribution of the DMI energy density around the skyrmions. The key feature of the skyrmions which contain the CKs is the presence of regions with disfavoured chirality. As seen in the contour plots for the skyrmions with CK [Figs. 2(h), (l), and (p)] the emergence of red areas with disfavoured chirality is accompanied by the development of dark blue regions of strongly favoured chirality, i.e. regions where $w_D$ is more negative than for the skyrmion without CKs [Fig. 2(d)]. This reflects a sophisticated balance between different energy terms which is responsible for the stability of such solutions. One important consequence of the presence of the areas with disfavoured chirality is the possibility of attractive skyrmion interactions. It was observed in Ref. 14 that, in a tilted magnetic field ordinary solutions for π-skyrmions without CKs lose their axial symmetry and at the same time develop areas of disfavoured chirality, and that this in turn may lead to the formation of a stable bound pair of interacting skyrmions. Note also that a careful study of the asymptotic behavior of the solutions for skyrmions with positive CKs [see Figs. 2(k) and 2(l)] shows that regions of disfavoured chirality may extend to infinity. On the other hand in the case of negative CK [Figs. 2(o) and (p)] the region of disfavoured chirality is screened by a region with favoured chirality. Because of this screening effect, the skyrmions depicted in Fig. 2(o) are mutually repulsive, just like the axially symmetric π-skyrmions without kinks [Fig. 2(c)].

Before turning to the systematic investigation of a wide diversity of skyrmions with CKs in the next sections we look at Fig. 3 for a further illustration of the concept yielding the definition of topological charge in (6) and (8).
FIG. 3. Example of skyrmions with different topological charges (see the index in the left top corner) and the different number of chiral kinks. The images (a), (g), and (m) in the first column shows the host skyrmions with $Q = -1$, 0, and +1. Other images in each row show the skyrmions with a different number of kinks at different places of the host spin-texture. The solutions are obtained by direct energy minimization on the domain with the size of $L_x = L_y = 10L_D$ and the mesh density $\Delta l = 64$. For all cases the anisotropy, $u = 0$. For skyrmion in (d) the external field $h = 0.61$, for skyrmions in (a)-(c) and (e)-(f) $h = 0.62$, and for skyrmions in (g)-(r) $h = 0.64$.

The first column in Fig. 3 shows the skyrmions without kinks representing the host spin-textures for various skyrmions with CKs shown in the other columns. The Bloch walls lie in the coloured regions and, with our convention, should be traversed so that the black region lies on the left and the white region on the right. Comparing with the usual geometrical orientation, one finds, for example, that Fig. 3 (m) show one negative and two positive walls. There are no kinks in this configuration, so $Q = 2$ in agreement with (8). All the chiral kinks shown in Fig. 3 are positive, i.e. the handedness index, $\eta$, is positive when traversing the domain wall according to our convention. Therefore, again by (8), the charge $Q$ equals the number of chiral kinks plus the number of positive Bloch walls and minus the number of negative Bloch walls.

It is obvious from the pictures that the presence of chiral kinks deforms the Bloch wall on which they reside. Moreover, the positive chiral kinks shown in Fig. 3 produce an inward dent on positive walls and an outward dent on negative walls. As we show in a separate study, this can be understood in terms of a simple effective theory for the kink field.

Some of the observations we made about the skyrmions with single domain walls in Fig. 2 generalise to the more intricate skyrmions in Fig. 3, which are composed of several closed domain walls with a varying numbers of kinks. The skyrmions shown in Fig. 3 can be divided into those which have CKs on their outer walls and those that do not. We have found that this division affects the interaction of pairs of such skyrmions. The skyrmions with CKs on their outer Bloch walls have regions of disfavoured chirality stretching to spatial infinity. As for the antiskyrmion in Fig. 2 (l), this leads to such skyrmions being mutually attractive. By contrast, skyrmions with no CKs on their outer shells show the screening effect discussed above for the skyrmion with $Q = -2$ in Fig. 2 (o)-(p). In a perpendicular external field, such skyrmions always appear to repel each other.

IV. SKYRMIONS AT THE BOGOMOLOV'NYI POINT

One of remarkable properties of the chiral magnet model is that for parameters $h = 1$ and $u = -0.5$ – the Bogomol'nyi point, the model becomes exactly solvable. In this section, we review the key steps of Ref.15 and Ref.16 and introduce a few classes of analytical solutions for skyrmions which are used below as the initial state for direct energy minimization with numerical methods for $h$ and $u$ outside the Bogomol'nyi point.

As observed in Ref.16, the energy functional for chiral magnets with general type of DMI and potential term can be reinterpreted as that of a gauged sigma model with a non-abelian gauge field determined by the DMI term. For instance, for the DMI term, $w_D(n) = n \cdot \nabla \times n$, considered here, the required gauge field is $A_{x(y)} = -2\pi e_{x(y)}$. The field strength of this gauge field is $F_{xy} = \partial_x A_y - \partial_y A_x + A_x \times A_y$, so in our case, $F_{xy} = A_x \times A_y = 4\pi^2 e_z$. This gauge field encodes the twisting of spins favoured by the balance of DMI and symmetric exchange, which is directly related to the microscopic...
quantity $D_A^{-1}$. The energy of chiral magnets can be written in terms of the covariant derivative $D_{\xi(y)} n = \partial_{\xi(y)} n + A_{\xi(y)} \times n$, the field strength and potential energy terms. It takes a particularly simple form at a specific point in the phase diagram called the Bogomol’nyi point. For the energy [2] defining our model, the Bogomol’nyi point is at $h=1$ and $u=-0.5$, where the potential energy term [5] takes form

$$U(n) = 2\pi^2 (1-n_z)^2,$$

(9)

and the energy can be written as

$$E_c(n) = \int \left( \frac{1}{2} (D_x n)^2 + \frac{1}{2} (D_y n)^2 - n \cdot F_{xy} \right) \ dx \ dy.$$

(10)

Applying the usual Bogomol’nyi trick, this can be expressed as

$$E_c(n) = \frac{1}{2} \int (D_x n + n \times D_y n)^2 \ dx \ dy + 4\pi Q(n) + \Omega(n),$$

(11)

where

$$\Omega(n) = \int \left( \partial_x(n \cdot A_x) - \partial_y(n \cdot A_y) \right) \ dx \ dy = 2\pi \int \left( \partial_x n_y - \partial_y n_x \right) \ dx \ dy,$$

(12)

and $Q(n)$ is defined in [5].

Since the term $\Omega(n)$ does not contribute to the Euler-Lagrange equations (see Appendix) it can be subtracted from the $E_c(n)$

$$\tilde{E}_c(n) = E_c(n) - \Omega(n)$$

$$= \frac{1}{2} \int (D_x n + n \times D_y n)^2 \ dx \ dy + 4\pi Q(n).$$

(13)

The subtraction of $\Omega(n)$ ensures that the configuration $n$ representing a solution of the Euler-Lagrange equations is the stationary point of the energy (for details see Appendix).

As follows from [13], the energies of the soliton solutions are bounded from below

$$\tilde{E}_c(n) \geq 4\pi Q,$$

(14)

which is known as the Bogomol’nyi bound. The inequality [14] becomes equality when the first term in [13] vanishes:

$$D_x n + n \times D_y n = 0.$$ (15)

As shown in Ref[15] if a configuration satisfies this ‘Bogomol’nyi equation’, then it is also a solution to the full Euler-Lagrange equations for the functional (10).

In the following, instead of vectors $n = (n_x, n_y, n_z)$ and spatial coordinates $r = (x, y)$ given in Cartesian coordinates, it is convenient to use the stereographic projection of $n$ into the complex plane and complex coordinates for $r$ according to

$$w = \frac{n_x + in_y}{1-n_z}, \quad \zeta = x + iy.$$ (16)

In complex coordinates the Bogomol’nyi equation [15] has the following form:

$$\frac{\partial w}{\partial \zeta} = i\pi w^2 \Leftrightarrow \frac{\partial(1/w)}{\partial \zeta} = -i\pi.$$ (17)

The general solution for above equation is:

$$\frac{1}{w} = -i\pi \zeta + f(\zeta),$$ (18)

where $f$ is an arbitrary holomorphic function of the spatial coordinate $\zeta$. The solution $w(\zeta)$ which satisfies the equation [18] can be represented in terms of Cartesian vectors $n(r)$ by inverting the maps [16]:

$$n = \frac{1}{1 + |w|^2} \left( w + \bar{w}, -i(w - \bar{w}), 1 - |w|^2 \right),$$ (19)

$$r = \frac{1}{2} \left( \zeta + \bar{\zeta}, -i(\zeta - \bar{\zeta}) \right).$$ (20)

V. SKYRMIIONS BEYOND THE EXACT SOLVABLE MODEL

Now we consider some illustrative examples of the functions $f(\zeta)$ which can be used as an ansatz (initial configuration) for the numerical minimization of the energy functional [2]. First, we discuss a wide class of solutions composed of functions $f(\zeta)$ which are a ratio of two polynomials of order $m$ and $n$, respectively. The topological charge $Q$ of the corresponding configuration [20] is finite and can be computed as follows [22]. If $m > n + 1$, then $Q = m$. If $m < n + 1$, $Q = n - 1$. In the case where $m = n + 1$, the behaviour depends on the behaviour of $f(\zeta)$ as $\zeta$ becomes large:

$$Q = \begin{cases} 
  n + 1, & \lim_{\zeta \to \infty} f > \pi, \\
  n, & \lim_{\zeta \to \infty} f = \pi, \\
  n - 1, & \lim_{\zeta \to \infty} f < \pi.
\end{cases}$$ (21)

We can turn this around and ask for the number of degrees of freedom we have to construct a solution with a given $Q$. This is straightforward when $m \neq n + 1$. In the case $m = n + 1$, there are three possible general functions:

$$f(\zeta) = \frac{a_Q \zeta^Q + \ldots + a_0}{b_Q \zeta^{Q-1} + \ldots + b_0}, \quad |\frac{a_Q}{b_Q}| > \pi,$$ (22)

$$f(\zeta) = \pi e^{i\alpha} \zeta^{Q+1} + \ldots + a_0 \zeta^Q + \ldots + b_0,$$ (23)

$$f(\zeta) = \frac{a_Q+2 \zeta^{Q+2} + \ldots + a_0}{b_Q \zeta^{Q+1} + \ldots + b_0}, |\frac{a_Q+2}{b_Q+1}| < \pi.$$ (24)
where we assume that the leading coefficients of each polynomial is non-zero, and that numerator and denominator have no common factors.

We illustrate the general results with a family of configurations which play an important role in discussion of instabilities later in this paper, namely the configurations determined by

\[ f(\zeta) = \frac{a_2 \zeta^2 + a_0}{\zeta}. \]  

(25)

When \( a_0 = 0 \) and \( |a_2| > \pi \) the corresponding field is that of a single anti-skyrmion [Fig. 4 (a)], so \( Q = 1 \). Still keeping \( a_0 = 0 \) but taking the limit \( |a_2| \to \pi \), the anti-skyrmion elongates and, when \( |a_2| = \pi \), becomes an infinite isolated stripe (also called line defect \(^{15}\)). The direction of the isolated stripe depends on the phase of \( a_2 \).

Taking \( a_2 = -i\pi \) for definiteness we obtain a stripe parallel to the \( y \)-axis. The magnetization across the stripe is conveniently expressed in terms of the angles \( \Theta \) and \( \Phi \) which are related to the complex field \( v \) via

\[ \frac{1}{w} = \cot \frac{\Theta}{2} e^{-i\Phi}. \]  

(26)

Thus the solution \( 1/w = -i\pi(\zeta + \bar{\zeta}) = -2\pi i x \) can equivalently be written as

\[ \Theta(x) = 2 \arccot(2\pi |x|), \quad \Phi(x) = \begin{cases} \frac{\pi}{2} & \text{for } x > 0 \\ \frac{3\pi}{2} & \text{for } x < 0 \end{cases}. \]  

(27)

This reveals the geometrical shape of this solution: the magnetization vector \( \mathbf{n} \) performs a complete rotation in the plane orthogonal to the direction travel as one traverses the \( x \)-axis, beginning and ending in the vacuum \( \Theta = 0 \).

Finally switching on the coefficient \( a_0 \) in (25) while keeping \( a_2 = -i\pi \), we obtain a configuration of degree \( Q = 1 \) where an anti-skyrmion has been inserted at the origin, and broken the isolated stripe into two halves, both capped by half an anti-skyrmion [Fig. 4 (I)]. It turns out that the deformation of anti-skyrmions into an isolated stripe and the rupture of the stripe play an important role in our discussion of instabilities in Sect. VII.

We now turn to more general functions of the form (22)-(24) and use them to produce ansatz solutions away from the Bogomol’nyi point in the form

\[ \frac{1}{w} = -\frac{i\zeta}{l_1} + f \left( \frac{\zeta}{l_2} \right), \]  

(28)

where \( l_1 \) and \( l_2 \) are arbitrary scaling parameters chosen with respect to the size of simulated domain and the mesh density used in numerical scheme. The functions \( f(\zeta) \) depending on their analytical properties, e.g. number of zeros and poles, provide the solutions for different classes of skyrmions Fig. 4 – Fig. 7.

First, we consider an example when function \( f(\zeta) \) does not have poles, namely

\[ f(\zeta) = 2\zeta^p, \]  

(29)

where \( p \in \mathbb{Z}^+ \) – positive integer numbers. This ansatz describes axially symmetric skyrmions with \( p + 1 \) positive CKs equidistantly distributed over the perimeter of the skyrmion, see the images for the initial states in Fig. 4. The corresponding equilibrium configurations obtained after numerical energy minimization. The parameters of the system: \( h = 0.62 \) (f), \( h = 0.61 \) (g) and \( h = 0.65 \) for all others, \( u = 0 \) in all cases. The size of simulated domain \( 8L_D \times 8L_D \) the mesh density \( \Delta l = 128 \).

FIG. 4. The left image in each figure (a)-(e) is the initial magnetic textures which are described by (28) where \( f(\zeta) = 2\zeta^p \) and the scaling parameters are \( l_2 = 0.5 \) and \( l_1 = 1 \). The topological charge of these solutions is given by \( Q = p \). The right image is the equilibrium magnetization corresponding to a local minimum obtained after numerical energy minimization. The parameters of the system: \( h = 0.62 \) (f), \( h = 0.61 \) (g) and \( h = 0.65 \) for all others, \( u = 0 \) in all cases. The size of simulated domain \( 8L_D \times 8L_D \) the mesh density \( \Delta l = 128 \).
FIG. 5. The top image in each figure (a)-(e) is the initial magnetic textures which are described by \( f(\zeta) = 0.025 \sin(20\zeta) \) and the scaling parameters \( 2L_2 = L_1 = p/20 \). The bottom image is the equilibrium magnetization corresponding to a local minimum obtained after numerical energy minimization. The parameters of the system: domain size \( 16L_D \times 2L_D \), mesh density \( \Delta l = 128 \), \( h = 0.65 \), \( u = 0 \), the values of external magnetic field \( h \) and topological charge \( Q \) after full energy minimization are indicated in the images.

One can also consider trigonometric or exponential functions. They have an infinite number of zeros in the plane, but finitely many in any finite region. Such functions therefore provide a useful ansatz for obtaining skyrmions with large \( Q \). Fig. 5 illustrates stretched skyrmions of high \( Q \) and large number of CKs obtained from

\[
f(\zeta) = \alpha \sin(p\zeta), \quad p \in \mathbb{Z}^+,
\]

where \( \alpha \) is arbitrary non-zero constant. The existence of such skyrmions also suggests the stability of the CKs in isolated domain walls and stripes, which will be discussed in the following sections.

Another class of solutions can be obtained with the function \( f(\zeta) \) that has poles but does not have zeros:

\[
f(\zeta) = 1/(2\zeta^p), \quad p \in \mathbb{Z}^+.
\]

This class of solutions represents \( 2\pi \)-skyrmions with \( p - 1 \) positive CKs (in our conventions) on its inner side. Fig. 6 shows initial configurations and corresponding equilibrium states obtained by direct energy minimization. In contrast to \( \ref{eq:29} \) this ansatz gives a satisfactory initial configuration for any value of \( p \).

Finally we consider the class of skyrmion ‘sacks’ with high \( Q \) discussed in Ref. \ref{10}. Such solutions can be obtained in our scheme by taking functions \( f(\zeta) \) which combine features of the previous two cases and which have poles and zeros of order \( p \) and \( p - 1 \) respectively:

\[
f(\zeta) = \zeta^{p-1}/(\zeta^p - 1), \quad p \in \mathbb{Z}^+.
\]

The initial states defined by \( \ref{eq:32} \) and the corresponding equilibrium configurations are shown in Fig. 7. The topological charge of this class of solutions is \( Q = p - 1 \). Among all skyrmions of this class only the skyrmion with \( Q = 0 \) [Fig. 7(a)] has a CK while the other skyrmions after energy minimization converge to the states free of CKs.

Like the ansatz \( \ref{eq:29} \), the ansatz \( \ref{eq:32} \) is only useful in a finite range of values for \( p \); for \( p > 10 \) it does not provide a good initial guess. To obtain configurations of this type but with higher \( Q \), one can use a more general class of functions \( f(\zeta) \) given in \( \ref{eq:22} - \ref{eq:24} \), and set the explicit distribution of zeros \( a_j \) and poles \( b_j \) of \( f(\zeta) \) via
FIG. 7. The left image in each figure (a)-(e) is the initial magnetic textures which are described by \( f(\zeta) = \zeta p - 1 / (\zeta p - 1) \), the topological charge of the solution \( Q = p - 1 \). The right image is the equilibrium magnetization corresponding to a local minimum obtained after numerical energy minimization. The parameters of the system: the size of simulated domain \( 8L_D \times 8L_D \), the mesh density \( \Delta l = 128 \), \( u = 0 \). For skyrmions in (a)-(e) the external field \( h = 0.65 \), for (f)-(j) \( h = 0.7 \).

The approach presented in this section for the construction of the initial states allows one to obtain a wide class of solutions, but it also has limitations. In particular, skyrmion sacks (skyrmion bags) representing a \( 2\pi \)-skyrmion shell with skyrmion cores inside (the simplest example is a \( 3\pi \)-skyrmion) can not be obtained using \( (28) \). There is an explanation for this: at the Bogomol’nyi point, the \( 2\pi \)-skyrmion solution has a zero mode corresponding to changing the size of the bag. In other words, the domain wall that forms the outside of the bag has no ‘tension’. Therefore if skyrmions are put inside it then the additional repulsive force will cause the bag to expand to infinity. One can also show that \( k\pi \)-skyrmions do not exist for \( k \geq 3 \) at the Bogomol’nyi point, and that the solutions described by \( (18) \) do not include solitons with \( Q \leq -2 \).

To construct initial configurations for skyrmions which are not covered by Eqs. \( (28) \), we either used piecewise functions based on these equations or crafted a texture by means of interactive tools implemented in our software \( \cite{24} \) (see also Supplemental Material in Ref. \( \cite{11} \)).

VI. ENERGIES OF SKYRMIONS WITH CHIRAL KINKS

FIG. 8. The self energy of skyrmions as function of the external field, \( h \), for the case of zero anisotropy, \( u = 0 \). Top, middle and bottom plots correspond to the skyrmions with \( Q = -1, 0, \) and \( +1 \), as indicated in the right top corner. The horizontal dashed line corresponds to \( E = 0 \) – the energy of field saturated state. The parameters of the system: the size of simulated domain \( 8L_D \times 8L_D \), the mesh density \( \Delta l = 64 \).
Since the presence of CKs indicates positive energy contributions of the DMI in some areas, one may guess that the skyrmions with CKs always have higher energies than skyrmions without them. In this section, we show that this is not the case and that solutions containing CKs may become energetically comparable or even favorable relative to skyrmions without CKs. In particular, we have calculated the energy dependencies for skyrmions with and without CKs as a function of the external field and group them with respect to their topological charge, $Q = -1, 0, 1$ [Fig. 8].

For any $Q$, at low magnetic fields, $h \lesssim 0.62$, the shown skyrmions are elliptically unstable. For high magnetic fields, the energy dependence curves in Fig. 8 end at the points which correspond to the collapse of the soliton. The only exception is the $\pi$-skyrmion with $Q = -1$. There is a strict mathematical proof that in the case of $u = 0$ the $\pi$-skyrmion remains stable for any $h$ above the elliptical instability and represents the lowest energy soliton solution in this topological sector. Moreover, for $h < 0.02$ the energy of the $\pi$-skyrmion is lower than the energy of ferromagnetic state (horizontal dashed line). The latter indicates the well-known fact that the lattice energy of ferromagnetic state is lower than skyrmions without CKs. In particular, we have calculated the energy dependencies for skyrmions with CK in Fig. 8 (c).

In the case of $Q = -1$ in Fig. 8 the $\pi$-skyrmion is the universal minimizer—the lowest energy state in the whole range of fields. The $3\pi$-skyrmion (b) has the second lowest energy but collapses at $h > 0.75$. At higher magnetic fields, the solution with CK Fig. 8 (c) has the second lowest energy among $Q = -1$ solutions. It is interesting that for $Q = -1$ the solutions without CKs [Fig. 8 (d), (e) and (h) for $Q = -1$] have higher energy and are stable in the narrower ranges of fields than the skyrmion with CK in Fig. 8 (c).

In contrast to the situation in the $Q = -1$ sector, there are no universal minimizers in the $Q = 0$ and $Q = 1$ sectors. In particular, for $Q = 0$ and a low magnetic field, the lowest energy state is the skyrmionum [Fig. 8 (a)]. However, in the range of $0.65 \lesssim h \lesssim 0.67$ the lowest energy state is the skyrmion with one CK [Fig. 8 (b)]. Note that the skyrmion with one CK in Fig. 8 (b) is identical to that shown in Fig. 2 (g). For $h > 0.67$ this skyrmion is unstable and skyrmionum becomes the lowest energy state again. Above the skyrmionum collapse field the lowest energy state corresponds to the skyrmion solution with CKs: the skyrmion in (c) in range of $0.71 \leq h \leq 0.74$ and the skyrmion in (f) for $0.74 \lesssim h \lesssim 0.79$, see Fig. 8 for $Q = 0$.

For the case of $Q = 1$, the behavior of the solutions is very similar to that for $Q = 0$. The lowest energy state alternates between states (a) and (b) and when the skyrmion in (a) collapses the lowest energy state corresponds to state (c) in the range of fields $0.71 \leq h \leq 0.74$ and skyrmion in (f) in the range of fields $0.74 \lesssim h \lesssim 0.78$, see Fig. 8 for $Q = 1$. The skyrmions with $|Q| > 1$ show nearly the same behaviour but because of the complex morphology and large diversity of the solutions with large $Q$ they are not discussed here.

It is worth emphasizing that the range of the existence for skyrmions which are shown in Fig. 8 may increase when a more precise numerical scheme is used. Nevertheless, Fig. 8 clearly illustrates that the energies of skyrmions with and without CKs are comparable. Thereby the solutions containing CKs cannot be excluded from consideration. Besides that one can conclude the more complicated morphology of skyrmions leads to the higher stability of the solutions at strong magnetic fields. Because the energy of skyrmions with CKs possess a few times higher energies than the energy of $\pi$-skyrmion such skyrmions cannot become the ground state of the system.

VII. STABILITY UPPER BOUND FOR SKYRMIONS WITH CHIRAL KINKS

To estimate the range of stability for the skyrmions containing CKs, we consider the limiting case of a large skyrmion sack with $Q \ll -1$. An example of such a skyrmion with one CK in the outer side of its shell is shown in Fig. 9 (a). We found that the skyrmions of this type are the most stable among all skyrmions possessing CKs. At high magnetic fields, such skyrmions collapse via a rupture of the shell at the position where the CK was placed [Fig. 9 (b)-(d)]. Such a rupture changes the number of kinks and walls, but maintains the overall charge $Q$ as the magnetization field is changing smoothly. The ruptured shell of the skyrmion in Figs. 9 (b)-(d) is identical to the elongated skyrmion depicted in Fig. 2 (k), which in this case will then collapse. The larger the size of the skyrmion, the higher the external field required for its collapse. Thereby, to estimate the stability of such solutions from the top we consider the limiting case of the isolated stripe with CK [Fig. 9 (e)]. The blue line, $h_c$, in Fig. 9 represents the collapse field for an isolated stripe with CK, estimated numerically with high accuracy.

In order to provide estimates for the lower limiting field for skyrmions with CK we do the following. We consider the anti-skyrmion as a stripe capped by two chiral kinks. For the functional (2) one can find the solution of the variational problem for an isolated stripe along the $y$-axis and thus calculate its energy per unit length, $E_{KS}(h,u)$. When $E_{KS}(h,u) < 0$, the stripe has negative energy per unit length, so it will extend, and therefore so will an anti-skyrmion [Fig. 9 (h)]. When $E_{KS}(h,u) > 0$, the stripe has positive energy per unit length so will tend to be as short as possible, giving a stable shape for the anti-skyrmion [Fig. 9 (g)]. Along the curve $E_{KS}(h,u) = 0$ the extension of the anti-skyrmion into the stripe is a zero mode. The criterion $E_{KS}(h,u) = 0$ gives a good estimation of the elliptic instability of the anti-skyrmion which can be understood by taking into account its elongated shape [Fig. 9 (g)]. Higher $Q$ configurations can also be considered as stripes with several kinks attached, although this is a worse approximation.

The solution for the isolated stripe can be written as
follows\textsuperscript{27,28}:

$$\Theta(x) = 2 \arccot \left( \frac{\sqrt{h}}{k} | \sinh (2\pi k x) | \right),$$

$$\Phi(x) = \begin{cases} \frac{3\pi}{2} & \text{for } x > 0 \\ \frac{3\pi}{4} & \text{for } x < 0 \end{cases}. \quad (33)$$

where $k = \sqrt{h + 2u}$. Taking the limit $k \to 0$ gives back the solution \textsuperscript{27} at the Bogomol’nyi point.

After integration over $x$, the energy per unit length of the isolated stripe is\textsuperscript{29}

$$E_{IS} = -4\pi^2 + 8\pi k + \frac{2\pi \sqrt{2h}}{\sqrt{u}} \log \frac{k + \sqrt{2u}}{k - \sqrt{2u}}. \quad (34)$$

As follows from (34) the solution for the isolated stripe for $h \geq 0$ remains stable under the condition $h + 2u \geq 0$. The energy of the isolated stripe increases gradually with increasing $h$ and $u$. The asymptotic behavior of the energy of the solution (34) for $h$ and $u$ independently approaching infinity are

$$E_{IS}(u) = 16\pi^2 u - 4\sqrt{2\pi^3 \sqrt{u}} + O(\sqrt{u}), \; u \gg 1, \quad (35)$$

for any fixed $h \geq 0$, and

$$E_{IS}(h) = 16\pi^2 h - 4\pi^3 \sqrt{h} + O(\sqrt{h}), \; h \gg 1, \quad (36)$$

for fixed values of $u$.

The red solid line, $h_c$, in Fig. 9 corresponds to $E_{IS}(h, u) = 0$, while black dots are the elliptic instability field for anti-skyrmion estimated numerically [Figs. 9(g)-9(h)].

The elliptic instability field, $h_c$ and the collapse field $h_e$ meet at Bogomol’nyi point ($h = 1$, $u = -0.5$). Thereby the stability of skyrmions with CKs is limited by the strong easy-plane anisotropy, $u = -0.5$. On the other hand, there is no limiting value for strong easy-axis anisotropy above which the solutions for chiral skyrmions with CK would be unstable. The latter statements can be proven as follows.

Let us consider an isolated straight stripe with one CK. The energy of such a solution can be bounded above by an ansatz where $\Theta(x)$ is as in (33), and $\Phi$ depends on $y$ for $x > 0$. Minimizing the energy within this ansatz gives:

$$\Phi_a(x, y) = \begin{cases} \frac{3\pi}{2} & x < 0 \\ 4 \arctan(e^{my}) + \frac{\pi}{2} & x > 0 \end{cases}, \quad (37)$$

where the functional dependence of $m$ on $h$ and $u$ is given in Appendix (C). The corresponding energy of the solution can be written as follows

$$E_{IS+CK} = E_{IS} + E_{CK}, \quad (38)$$

where self energy of isolated stripe $E_{IS}$ is defined in (34) and the energy of the CK is

$$E_{CK} = \sqrt{\frac{k\pi}{u} - \frac{h\pi}{2\sqrt{2u}} \ln \frac{k + \sqrt{2u}}{k - \sqrt{2u}}}. \quad (39)$$

As $u \to \infty$ for fixed $h$, this chiral kink energy upper bound goes to $0$, $E_{CK} \to u^{-1/4}$, so we expect the chiral kink on a stripe to remain stable for large $u$.

![FIG. 9. $h$-$u$ diagram of stability of magnetic skyrmions with CKs. (a) is an example of a large skyrmion with the negative CK in outer side of the shell at $h = 1$, $u = 1$. (b)-(d) are the snapshots of the system at different time after a rupture of the shell with increasing the external field up to $h = 1.05$. The collapse field, $h_c$ (blue solid line) corresponds to the field at which the isolated stripe with the negative CK is ruptured (e)-(f). The elliptic instability field, $h_e$ (red solid line) are defined by the criteria that the energy of isolated stripe in (34) equals zero, $E_{IS} = 0$. The black dots lying very close to red line corresponds to numerically estimated elliptic instability of the anti-skyrmion (g). For $h < h_e$ the anti-skyrmion starts to elongate abruptly as indicated by wight arrows in (h).](image)

It is worth emphasizing that the diagram for skyrmion stability in Fig. 9 should be understood as an estimation for the upper bound range for the stability of skyrmions with CKs. At any point inside the range bound by the $h_c$ and $h_e$, there is an exponentially localized solution for chiral skyrmion with CKs, but this does not guarantee that such a solution will be stable everywhere inside the shaded region. As a final note, we point out that solutions with indefinite chirality may also exist outside the shaded area, for instance, so-called in-plane skyrmions at very strong easy-plane anisotropy. However, according to the arguments provided in Ref. [14] such solutions should be considered as a distinct class of soliton-like solutions composed of coupled vortices and antivortices. A
distinguishing feature of these solutions is that the saturated ferromagnetic state representing the vacuum for such vortex-like solutions has a nonzero in-plane component of magnetization. The energy of that state is degenerate with respect to the rotation around the plane normal.

VIII. CHARACTERISTIC SIZE OF CHIRAL KINKS

Since the typical soliton solutions are exponentially localized, there is not a unique approach to measuring their size, but there are a few conventional approaches to estimating it. The same is true for CKs which in addition represent only an element of the spin-texture and cannot be treated as isolated objects. To estimate the characteristic sizes of CKs we suggest an approach based on the analysis of the interaction between them. Fig. 10 shows the numerically calculated potential energy dependence of two negative CKs located on one side of the isolated stripe. The interaction energy, $E_{\text{int}}$, is defined as follows

$$E_{\text{int}}(R) = E_{\text{tot}}(R) - 2E_{\text{CK}} - E_{\text{IS}},$$

where $E_{\text{tot}}(R)$ is the total energy of the state composed of two negative CKs, see for instance the equilibrium states depicted in Fig. 10 (a)-(d), $E_{\text{CK}} = E_{\text{IS}+\text{CK}} - E_{\text{IS}}$ is the self energy of an isolated negative CK on the isolated stripe [Fig. 10 (e)], and $E_{\text{IS}}$ is the self energy of an isolated stripe without CK [Fig. 10 (f)]. The distance $R$ is the distance between two points A and B with fixed spins:

$$R = |\mathbf{r}_A - \mathbf{r}_B|,$$

where $\mathbf{r}_A = (x_0, -R/2)$ and $\mathbf{r}_B = (x_0, R/2)$ are the position vectors in two-dimensional plane, $x_0$ may have any arbitrary chosen value. The two pinned spins at points $\mathbf{r}_A$ and $\mathbf{r}_B$ are lying in plane of the film, $\Theta = \pi/2$, while $\Phi_A = 3\pi/4$ and $\Phi_B = \pi/4$ (so $\mathbf{n}(\mathbf{r}_A) = (1/\sqrt{2}, 1/\sqrt{2}, 0)$ and $\mathbf{n}(\mathbf{r}_B) = (1/\sqrt{2}, 1/\sqrt{2}, 0)$). An equilibrium position of all other spins is defined via the direct energy minimization scheme.

The interaction energy between two CKs in Fig. 10 has two local minima at $R \approx 0.2L_D$ and $R \approx 0.9L_D$ and global minimum at $R \to \infty$. The equilibrium configurations corresponding to local minima obtained without spins pinning are shown in Fig. 10 (a) and (b). The minimum corresponding to the smallest distance $R$ can be thought of as a reasonable estimate for the characteristic size of the CK.

The presence of two local minima indicates the presence of two characteristic scales of inhomogeneities in the system, which is not typical for the majority of magnetic systems and represents an intriguing feature of chiral magnets. The latter also allows classifying the different types of solutions according to the inherent scale of inhomogeneities. For instance, the solutions free of CKs such as spin-spirals, $k\pi$-skyrmions and a variety of skyrmion sacks discussed in Ref. 10 one may attribute to the class of the solutions with inhomogeneities at the large scale. The characteristic scale of inhomogeneities for this class of solutions is of the order of the equilibrium pitch of the helical spiral, $L_D$. Accordingly, the skyrmions with CKs presented in this paper can be attributed to the class of solutions with magnetic inhomogeneities at small scale – about an order of magnitude lower than $L_D$.

![FIG. 10. The interaction energy between two negative CKs at different distance, $R$. The points A and B indicate the position of fixed spins with $\Theta = \pi/2$ and $\Phi_A = 3\pi/4$ and $\Phi_B = \pi/4$, respectively. (a) and (b) are zoomed images of (c) and (d), respectively. (e) and (f) are isolated stripe with one negative CK and the stripe without kinks, respectively. The parameters of the system: $h = 0.65$, $u = 0$, domain size $3L_D \times 6L_D$, mesh density $\Delta l = 128$.](image)

An important consequence of the above is that for numerical analysis of functional $\Pi$ one has to use the finite difference scheme with an appropriate mesh density.

IX. SKYRMIONS WITH NEGATIVE CHIRAL KINKS

Up to now, we have considered a variety of skyrmions with positive CKs while for skyrmions with negative CKs we found only a few solutions. The stability range of these solutions is smaller than for skyrmions with positive CKs while for skyrmions with negative CKs we have estimated the range of existence for the most stable solution with $Q = -2$ [Fig. 11]. The stability region of this solution is bounded by three distinct critical lines, which correspond to three different mechanisms of collapse. In the inverted magnetic field, $h < 0$, the skyrmion blows up at the so-called bursting field, $h_b$. On the other hand for $h > 0$ the skyrmion with negative CK may either
converge to two $\pi$-skyrmions at $h > h_d$ via a duplication mechanism, or may transform into a single $\pi$-skyrmion $h > h_b$. For the chosen value of mesh density ($\Delta l = 64$) the two critical fields $h_d$ and $h_b$ meet at $u = 1.287$. However, when increasing the accuracy of the calculations by increasing the mesh density and thereby approaching the continuum limit, the critical field $h_b$ converges to the values depicted as a dashed (red) line. Moreover, with increasing $\Delta l$, the whole curve $h_b$ quickly shifts to the right, towards higher $u$. For instance, for $\Delta l > 128$, we did not find any evidence for a corresponding field instability for any reasonable $u$. Therefore, in the continuum limit the stability range for a skyrmion with one negative CK similar to the one shown in Fig. 9 is limited only by two critical fields $h_b$ and $h_d$ (dashed red line).

An important aspect of the diagram shown in Fig. 11 is that within the stability range for the $Q = -2$ skyrmion all the solutions for chiral skyrmions with positive CKs presented in this paper are also stable. A good candidate for a point where all possible solutions may coexist is the point $h = 0.01$, $u = 1.25$. In this point and its narrow environment, we succeeded in stabilizing the most exotic skyrmion solution for $Q = -1$ containing one negative CK and one positive CK [Fig. 11(g)].

**CONCLUSION**

In this paper, we showed that the structure of 2D chiral skyrmions can be understood and classified in terms of their constituent domain walls with or without chiral kinks. Since chiral kinks produce regions of energetically disfavoured chirality which contribute positively to the total energy, one might expect spin textures containing chiral kinks to be unstable. Our results show that this expectation is naive, and that a wide range of isolated skyrmions containing chiral kinks is in fact stable.

Remarkably, we found that the topology of domain walls and chiral kinks in our initial configuration does not change during energy minimisation in a large portion of the phase diagram. Thus we were able to exploit the simplicity of solutions at the Bogomol’nyi point to pick configuration with an interesting domain wall and kink structure and obtain metastable configurations with the same structure at other points in the phase diagram by numerical minimization. The combination of our ansatz in terms of a holomorphic function and subsequent numerical minimisation thus allowed us to obtain many previously unknown types of chiral skyrmions.

We estimated the region of stability for skyrmions with chiral kinks as a function of the external magnetic field $h$ and the anisotropy parameter $u$. In particular, we showed that for any fixed $u > -0.5$ there is a critical magnetic field, $h_c$, above which these solutions collapse. On the other hand, for any $0 < h < h_c$ one can find a skyrmion with a chiral kink at any sufficiently big anisotropy $u \gg 0$.

In this paper, we also took the first steps in studying the structure and interactions of chiral kinks. For chiral kinks on a single straight stripe we analysed the profile of a single kink and studied the interactions of two kinks. In a forthcoming paper we also study chiral kinks on curved domain walls, and look at the interplay between the curvature of the domain wall and the chiral kinks on it.

The use of holomorphic data for initial configurations provides a versatile and powerful tool but it has also certain limitations. For example, the presented approach does not provide an ansatz for skyrmion bags of negative topological charge. Since the skyrmion bag is a closed $2\pi$-domain wall that contains the skyrmions in it, the repulsion of the skyrmions on the inside must be balanced by the tension (tendency to shrink) of the domain wall. While closed circular $2\pi$-domain walls are possible at the Bogomol’nyi point, they have an arbitrary size which results in zero tension that cannot balance the repulsive forces of $Q = -1$ skyrmions.

We end with a brief outlook on the interaction of several localised chiral skyrmions. Based on our preliminary numerical results we conjecture that configurations with
chiral kinks on an outer domain wall will generally attract while chiral skyrmions without kinks on their outer domain wall to repel. It would clearly be interesting to test this conjecture with further numerical analysis or to prove it analytically. We leave this as a challenge for future work.

Experimental observations of domain walls with chiral kinks were recently reported in Pt/Co/Ni/Ir multilayers. One may therefore expect that tuning the parameters of such a system will also allow experimental observations of some of the skyrmions presented in this work.

Appendix A: Winding numbers of the domain wall

To prove the formula (6) for the degree of a configuration \( n \), we note that, in terms of the vector field

\[
g = \sin \Theta \nabla \Theta \times \nabla \Phi, \tag{A1}
\]

the integrand of (5) can be written as

\[
n \cdot (\partial_x n \times \partial_y n) = e_x \cdot g, \tag{A2}
\]

and so the degree may also be viewed as the total flux through the plane of the emergent field \( g \). This field is not generally globally a curl (otherwise its flux would be zero) but it can be written as the curl of Dirac’s monopole vector potentials \( a_+ \) and \( a_- \) in the positive and negative domains, respectively:

\[
g = \nabla \times a_{\pm}, \quad a_{\pm} = (\pm 1 - \cos \Theta) \nabla \Phi. \tag{A3}
\]

Splitting the integral (5), with the integrand written according to (A2), as a sum of integrals over positive and negative domains, applying Stokes’s theorem in each domain and keeping track of the orientation of bounding Bloch walls then yields (6).

We define the kink field as the azimuthal angle \( \Phi(s) \) relative to the angle \( \varphi(s) \) which the tangent vector to the curve makes with the \( x \)-axis, i.e. \( \Psi(s) = \Phi(s) - \varphi(s) \).

The signed curvature of a domain wall is given by

\[
\frac{d\varphi}{ds} = \kappa(s). \tag{A4}
\]

we use (A4) to deduce

\[
\Psi'(s) = \Phi'(s) - \kappa(s). \tag{A5}
\]

Defining the winding number of the kink field as

\[
N_{\text{kink}} = \frac{1}{2\pi} \int_C \nabla \Psi \cdot dr, \tag{A6}
\]

where we again assume our chosen orientation of \( C \), we integrate (A5) to deduce

\[
N_{\text{kink}} = w(C) - \iota(C), \tag{A7}
\]

where \( \iota(C) \) is the winding number of the wall. For simple and closed curves \( C \), \( \iota(C) = \pm 1 \) by Hopf’s Umlaufsatz. Specifically, \( \iota(C) = 1 \) if the orientation of \( C \) agrees with its geometrical orientation and \( \iota(C) = -1 \) otherwise.

Appendix B: Modification of the chiral magnet energy by a boundary term

For most values of the phase diagram parameters \((h, u)\), skyrmion solutions are exponentially localised. In this appendix we explain why the standard expression [1] for the energy of chiral magnets should be modified along a critical line in the phase diagram where solutions are only localised according to a power law. This line includes the Bogomol’nyi point, and the modification at that point was addressed in Ref. 15 and more generally in Ref. 16. The modification was first introduced for analytical reasons in an earlier paper [23]. Here we illustrate the consequences of the modification concretely for axially symmetric configurations.

We consider a family of energy expressions of the form [1], depending on a parameter \( \mu \):

\[
\mathcal{E}(n) = \int \left( \frac{1}{2} (\nabla n)^2 + 2\pi n \cdot \nabla \times n + \frac{\mu^2}{2} (1 - n_x)^2 \right) \, dx \, dy. \tag{B1}
\]

In the phase diagram parametrised by \( h \) and \( u \), this family constitutes a line along which the potential changes from having a unique minimum, favouring a ferromagnetic phase, to having a circle of minima, favouring a symmetry-breaking tilted ferromagnetic phase. The value \( \mu = 2\pi \) defines the Bogomol’nyi point.

With this energy one can find [15,25] an exact hedgehog solution \( \Phi = \phi + \pi/2 \) to the Euler-Lagrange equations with profile

\[
\Theta(r) = 2 \arctan \left( \frac{4\pi}{\mu^2 r} \right). \tag{B2}
\]

At the Bogomol’nyi point \( \mu = 2\pi \), this reduces to the solution [18] with vanishing holomorphic part \( f(\zeta) = 0 \).

However, although (B2) solves the Euler-Lagrange equations it is not a stationary point of the energy with respect to scaling of the solution. This can be seen by the usual Derrick argument. Writing \( \mathcal{H}, \mathcal{W}_D \) and \( \mathcal{U} \) for the integrated exchange energy, DMI energy and potential energy, the total energy of a rescaled configuration \( n_\lambda(r) = n(\lambda r) \) is

\[
\mathcal{E}(n_\lambda) = \mathcal{H}(n) + \frac{1}{\lambda} \mathcal{W}_D(n) + \frac{1}{\lambda^2} \mathcal{U}(n). \tag{B3}
\]
If we want our configuration to be a stationary point with respect to this scaling, we require:

$$\frac{\partial}{\partial \lambda} \mathcal{E}(n)|_{\lambda=1} = -\frac{1}{\lambda^2} W_{DP}(n) - \frac{2}{\lambda^3} U(n) = 0,$$  \hspace{1cm} (B4)

so the contribution to the energy from the DMI must be $-2$ times the contribution from the potential. These arguments are common for a general form of the potential\cite{39}. However, if we evaluate the various terms for our exact hedgehog solution, we instead find $W_{DP} = -U$, showing that it cannot be a stationary point of the energy under scaling. So, even though the hedgehog \textbf{[B2]} solves the Euler-Lagrange equations, it cannot be a stable minimum of the energy.

This problem arises because the hedgehog configuration \textbf{[B2]} falls off like $1/r$ at infinity, and therefore re-scaling is a variation which also falls of like $1/r$. While the solution \textbf{[B2]} is a stationary point of the energy with respect to variation with vanish rapidly at infinity, it is not a stationary point with respect to variations which decay like $1/r$. One can fix this problem by modifying the energy functional by subtracting the total vorticity\cite{10,10}:

$$\tilde{\mathcal{E}}(n) = \mathcal{E}(n) - 2\pi \int (\partial_x n_y - \partial_y n_x) =$$

$$\int \left( \frac{1}{2}(\nabla n)^2 + 2\pi (n - e_x) \cdot (\nabla \times n) + 4\pi^2 \frac{\mu^2}{2} (1 - n_z)^2 \right) dx dy$$  \hspace{1cm} (B5)

The modified energy functional only differs from the original energy functional for configuration which decay like $1/r$ at infinity. For faster decays it does not change the total energy.

With this correction, we solve the problem above: now any finite-energy solution of the Euler-Lagrange equations is a stationary point of the energy. And in particular, the exact solutions we have, for arbitrary $\mu$ and in particular at the Bogomol’nyi point, are minima of the energy with respect to any variation. This means that the energy of a configuration is simply bounded below by its degree. At the Bogomol’nyi point, one finds that the skyrmion ($Q = -1$) and anti-skyrmion ($Q = 1$) solutions have energy $-4\pi$ and $+4\pi$, while without the correction they were degenerate in energy. This is the ordering we expect physically, and so provides another justification for working with the modified energy expression. Finally, with this correction the energy of the domain wall solution \textbf{[27]} is well-defined and equal to zero at the Bogomol’nyi point.

**Appendix C: Chiral kink ansatz**

For describing the profile of the stripe with a kink we use the ansatz functions method and let $\Theta = \Theta(x)$ as in \textbf{[27]} and let $\Phi$ depend on $y$ for $x > 0$ only. Substituting this into energy functional \textbf{(2)} and deciding that a single kink energy $\mathcal{E}_{CK} = \mathcal{E}_{IS+CK} - \mathcal{E}_{IS}$ we have

$$\mathcal{E}_{CK} = \int_{-\infty}^{\infty} \left( \frac{I}{2} \left( \frac{d\Phi}{dy} \right)^2 + 2\pi^2 (1 - \sin \Phi) \right) dy,$$  \hspace{1cm} (C1)

where $I = \int_0^\infty \sin^2 \Theta dx$. $I$ can be written in the form

$$I = \frac{k}{2\pi u} - \frac{h}{4\sqrt{2}\pi u^{3/2}} \ln \left( \frac{k + \sqrt{2u}}{k - \sqrt{2u}} \right).$$  \hspace{1cm} (C2)

Treating the profile of $\Theta(x)$ as fixed, we can minimize the energy with respect to $\Phi(y)$ to get $\Phi(y) = 4\arctan(e^{my}) + \pi/2$, where $m = \sqrt{3/2}\pi$ and $\mathcal{E}_{CK}^a = 8\sqrt{27}\pi$. Note that in this calculation, the contribution for the DMI has acted like a potential for the function $\Phi$ along the domain wall. Extending this observation to allow for a wall that changes shape in response to $\Phi$ is the subject of a future paper\cite{21}. This value for the energy is shown on Fig\textbf{[12]}

![Graph showing energy dependency of a kink energy $E_{CK}$ as a function of anisotropy, $u$, for two fixed values of magnetic fields $h = 0.3$ and $h = 0.65$. Solid lines correspond to $E_{CK}$, dashed lines are result of numerical minimization. For simulations mesh densities $\Delta t = 256, 512$ are used.](image)

**FIG. 12.** Energy dependency of a kink energy $\mathcal{E}_{CK} = \mathcal{E}_{IS+CK} - \mathcal{E}_{IS}$ as a function of anisotropy, $u$, for two fixed values of magnetic fields $h = 0.3$ and $h = 0.65$. Solid lines correspond to $\mathcal{E}_{CK}$, dashed lines are result of numerical minimization. For simulations mesh densities $\Delta t = 256, 512$ are used.

We consider the limiting case $u \rightarrow \infty$ in formula \textbf{(C2)}. In this case we obtain $I \rightarrow \frac{1}{\pi\sqrt{2u}} \left( 1 + \frac{h \ln u}{u} \right)$ and the corresponding kink energy decreases as $\mathcal{E}_{CK}^a \rightarrow \frac{8\sqrt{27}}{(20)^{1/4}} \left( 1 + \frac{3}{4} \frac{\ln u}{u} \right)$. The analytic expression for the exact kink energy (see numerical curve on Fig\textbf{[12]}) is unknown but the inequality $\mathcal{E}_{CK} \leq \mathcal{E}_{CK}^a$ holds for any ansatz functions. Therefore the exact kink energy is bounded: $\mathcal{E}_{CK} \leq \frac{8\sqrt{27}}{(20)^{1/4}} \left( \frac{\ln u}{u^{3/4}} \right).$ The fact that the energy of
the ansatz goes to 0 at high $u$ suggests that this is a good approximation to the exact kink solution at high $u$. This fits with the observation that at high $u$, the wall is ‘stiff’ and does not bend much in response to the kink.
