Purpose: Modulation of the gut microbiota may lead to changes in pathological conditions. C-C chemokine motif ligand (CCL) 4 was upregulated in diabetes mellitus (DM) and was shown to play a significant role in pancreatic inflammation and glucose metabolism. The detailed in vivo mechanisms have not been well explored. This study aimed to investigate the hypothesis that direct CCL4 inhibition could modify gut microbiota and systemic metabolism in diet-induced DM mice.

Methods: C57BL/6 mice fed a high-fat diet (HFD) were used as a diet-induced DM model. CCL4 inhibition was conducted by anti-CCL4 neutralizing monoclonal antibodies. The gut microbiota was analyzed by high-throughput sequencing of the 16S rRNA. Fecal microbiota transplantation (FMT) was used to verify the effect of CCL4 deficiency on gut microbiota and the linkage between CCL4-modulated gut microbiota and HFD-induced DM.

Results: CCL4 inhibition stabilized glucose homeostasis, modulated lipid parameter, and decreased inflammatory markers in HFD-induced DM mice. Moreover, CCL4 inhibition reversed HFD-induced gut dysbiosis, evidenced by the decreased abundance of family Muribaculaceae and increased abundance of family Atopobiaceae when CCL4 antibodies were administrated. CCL4 inhibition led to a decrease in circulating trimethylamine N-oxide levels, a proinflammatory metabolite from gut microbiota. Taken together, CCL4 inhibition could modify gut microbiota profiles, suppress proinflammatory metabolites, reduce systemic inflammation, improve insulin resistance, and retard the progression of hyperglycemia in HFD-induced DM. Furthermore, FMT from CCL4 knockout mice rescued the glucose homeostasis in HFD-induced DM mice.

Conclusion: Our findings may not only provide a novel rationale to in vivo CCL4-based therapeutic approach in diet-induced DM but also indicate the significance of gut microbiota profile including the family Muribaculaceae and the family Atopobiaceae as a potential modifiable target for systemic metabolism.

Keywords: diabetes mellitus, gut microbiota, inflammation, chemokine, trimethylamine N-oxide

Introduction

The gut microbiota affects pathological conditions including obesity, diabetes mellitus (DM), and cardiovascular disease.1,2 Previous studies indicated that the gut microbiota may play a potential role in interfering with host metabolism, enhancing the risk factors of metabolic syndrome. Several micro-organism-derived metabolites, such as trimethylamine N-oxide.
trimethylamine N-oxide (TMAO), lipopolysaccharide (LPS), indoxyl sulfate, and p-cresol sulfate, could activate the inflammatory processes in metabolic syndrome.\(^3\) Systemic inflammation has been shown to be associated with the progression of hyperglycemia.\(^4,5\) Some diets could alter the gut microbiota, leading to changes in the lipid profile and accelerated systemic inflammation.\(^6,7\) Antidiabetic drugs and food supplementation could interfere with the gut microbiota to improve glucose tolerance and reduce inflammation in a high-fat diet (HFD)-induced diabetic mouse model,\(^8,9\) indicating the relationship between pathophysiological factors and the gut microbiota. More investigations of the role of the gut microbiota in diet-induced diabetes might provide new therapeutic approaches.

The levels of C-C chemokine motif ligand (CCL) 4 are similarly elevated in both type 1 and type 2 DM patients, implying that CCL4 might be related to systemic inflammation in different types of DM as well.\(^10,11\) In an HFD-induced diabetic mouse model, isoliquiritigenin-treated mice had higher plasma cholesterol and improved insulin resistance, with decreased CCL4 and proinflammatory levels of cytokines including interleukin (IL)-1β, IL-6, and monocyte chemoattractant protein-1.\(^12\) Furthermore, a diet including carotenoid-rich vegetables and fruits affects inflammation by decreasing CCL4 and tumor necrosis factor (TNF)-α levels in healthy individuals.\(^13\) Our previous study indicated that inhibition of CCL4 could control blood sugar levels, increase serum insulin levels, and decrease pancreatic IL-6 expression in streptozotocin-induced diabetic mice. Meanwhile, CCL4 inhibition could retard the progression of hyperglycemia, reduce serum tumor necrosis factor (TNF)-α and IL-6 levels, and improve insulin resistance in mice with type 2 DM or metabolic syndrome. These results suggested the critical role of CCL4-related inflammation in the progression of DM.\(^14\) However, the in vivo effects of CCL4 inhibition are complex and the potential mechanisms have not been completely elucidated. The evidence is still lacking regarding the potential effects of CCL4 on gut microbiota, which has been linked to the presence of systemic inflammation and insulin resistance in diet-induced diabetes.

This study aimed to investigate the hypothesis that direct CCL4 inhibition could modify gut microbiota and related systemic metabolism in diet-induced DM mice. In this study, the HFD-induced diabetic mouse model was used to investigate whether targeting on CCL4 inhibition could directly modify gut microbiota profile, reduce systemic inflammation, improve insulin resistance, and retard
the progression of hyperglycemia. Then, fecal microbiota transplantation (FMT) was performed to prove our concept that the gut microbiota mediated by CCL4 could rescue the pathology in diet-induced DM. Our findings may not only provide additional novel rationale to in vivo CCL4-based approach but also hopefully identify some specific gut microbiota related to metabolic control in diet-induced DM.

Materials and Methods

Animal Procedures
Six-week-old male C57BL/6 mice were purchased from the National Laboratory Animal Center (Taipei, Taiwan). LabDiet Rodent 5001 (23.9% protein, 5% fat (ether extract), 5% fat (acid hydrolysis); LabDiet, St. Louis, MO, USA) was used as a normal diet. C57BL/6 mice were fed a high-fat diet (23.6% protein, 34.9% fat, 25.9% carbohydrate, diet-induced obesity rodent-purified diet with 60% energy from fat-58Y1) for 14 weeks. Blood glucose was evaluated after the mice were fasted for 4 hours.

In another part of the experiments, CCL4 knockout (C57BL/6JNarl-Ccl4eml) mice were designed and generated via the CRISPR/Cas9 system by the National Laboratory Animal Center (Taipei, Taiwan). C57BL/6 mice were purchased from the National Laboratory Animal Center (Taipei, Taiwan) as the wild-type control group. The mice were sacrificed in deeply anesthesia induced via inhaled isofluorane. Animal experiments were conducted at National Yang Ming Chiao Tung University. Animals were raised according to the regulations of the Animal Care Committee of National Yang Ming Chiao Tung University. All animal-related work was performed under the Institutional Animal Care and Use Committee (IACUC) protocol approved by National Yang Ming Chiao Tung University (IACUC no. 1031275). Some diet-induced diabetic mice received an intraperitoneal injection of an anti-CCL4 neutralizing monoclonal antibody (MAB451, 100 μg; R&D Systems, Minneapolis, MN, USA) 3 times per week for 2 or 4 weeks. The rat IgG2a isotype (MAB006, 100 μg; R&D Systems) was administered as a control. Body weights and blood sugar concentrations were measured.

Fecal Microbiota Transplantation (FMT)
Antibiotic water containing ciprofloxacin 0.2 g/L were given before FMT for 2 days. FMT was conducted each weekday for 12 weeks. Feces were collected fresh from CCL4-deficient mice for daily FMT. Feces from CCL4-deficient mice were pooled by cage, and about 100 mg (about 5–6 fecal pellets) were re-suspended in 1 mL sterile saline. Feces and saline solution were mixed for 10 seconds, then centrifugation at 800 g for 3 minutes. The supernatants (about 500–600 μL) were collected and administered by oral gavage within 10 minutes to minimize the change in microbial content.

Oral Glucose Tolerance Tests (OGTTs) and Areas Under the Curves (AUCs)
Mice were fasted for 6 hours and orally administered glucose at a dose of 2 g/kg body weight. Blood samples were obtained at time 0 (just before glucose load) and at 15, 30, 60, 120, 150, and 180 minutes after glucose administration. The total and incremental AUCs for plasma glucose during the OGTT were determined by the trapezoidal method.

Homeostasis Model Assessment of Insulin Resistance (HOMA-IR)
Insulin resistance, insulin sensitivity, and steady-state β-cell function were determined by the homeostasis model assessment of insulin resistance (HOMA-IR) using fasting glucose and insulin levels. HOMA analysis is an accepted surrogate for measuring insulin resistance in rodents. The HOMA-IR index was calculated as (fasting insulin (μU/mL) × fasting glucose (mmol/L))/22.5.

Biochemical Indices
Serum levels of total cholesterol (TC), triglycerides (TG), and high-density lipoprotein (HDL) were determined after a 4 h fast using an automated clinical chemistry analyzer (FUJI DRI-CHEM 4000i). Blood glucose levels were measured by Optium Xceed.

Evaluation of TNF-α, IL-6 and Insulin Concentrations
Serum protein concentrations of TNF-α and IL-6 were determined by ELISA (R&D Systems) according to the manufacturer’s instructions. Serum concentrations of insulin were determined by ELISA (Millipore) according to the manufacturer’s instructions.

DNA Extraction and DNA Quality Control
We used a QIAamp® DNA Stool Mini Kit from QIAGEN (cat. no. 51504) to collect stool specimens. The quality and quantity of samples were checked by NanoPhotometer™ Pearl (Implen).
Library Construction and Sequencing for V3V4 Region of 16S Ribosomal DNA

16S metagenomics library was constructed using two rounds of PCR reactions. The PCR primers, forward (5'-TCGTCGGCAGCGTCAGATGTGTATAAGAGACAGG-CTACGGGNGGCWGCAG-3') and reverse (5'-GTCTCGTGGGCTCGGAGATGTGTATAAGAGACAGGGAC-TACHVGGGTWTCTAAT-3'), were designed to amplify the V3V4 domain of bacterial 16S ribosomal DNA and add adaptor sequences. Illumina index sequences were subsequently attached to the amplicons in the second PCR. PCR amplification was performed in a 50 μL reaction volume containing 25 μL 2X Phusion High-Fidelity PCR Master Mix (New England Biolabs), 0.2 μM of both the forward and reverse primer, and 100 ng DNA template. The reaction conditions consisted of an initial 98 °C for 30 seconds, followed by 30 cycles of 98 °C for 10 seconds, 55 °C for 30 seconds, 72 °C for 30 seconds, and 72 °C for 5 min. There were 10 cycles for the second PCR. Amplified products were then checked by 2% agarose gel electrophoresis and purified using the AMPure XP PCR Purification Kit (Agencourt). Quantification was performed using Qubit dsDNA HS Assay Kit (Thermo Fisher Scientific) on Qubit 2.0 Fluorometer (Thermo Fisher Scientific) and LightCycler 96 (Roche) according to the manufacturers’ instructions. The final purified libraries were applied for cluster generation and sequencing on the MiSeq using a V3 600 cycles kit.

Bioinformatics

Sequencing reads were first quality controlled using FASTX-Toolkit with the following parameters: fastq_quality_filter -Q33 -q 20 -p 70; and fastq_quality_trimmer -t 20 -l 200 -Q33. Then, UPARSE (https://www.drive5.com/uparse/) was employed for OTU clustering using the reads that passed quality control. Bowtie2 (http://bowtie-bio.sourceforge.net/bowtie2/index.shtml) was used for taxonomic assignment to align OTUs with the SILVA database (v132). The alignment identity was set as 97%. R package (v3.5.1) was employed to calculate relative abundance, abundance heatmap, alpha-diversity and beta-diversity.

Measurement of Serum Trimethylamine N-Oxide (TMAO)

For each sample, 50 μL of blood was obtained to measure the TMAO after fasting for 6 hours. After the blood sample was centrifuged (3000× g for 15 minutes at 4 °C), all serum samples were stored at –80 °C until the TMAO measurement. In detail, 50 μL of serum was mixed with 450 μL MeOH and TMAO-d9 isotopologues. After preparation, serum TMAO was analyzed by injection into a MicroSolv Cogent Diamond Hydride column (150 × 2.1 mm, 4.2 μm, MicroSolv, Eatontown, NJ, USA) interfaced with an Agilent 1290 UHPLC and coupled with an Agilent 6460 triple quadrupole mass spectrometer (Agilent Technologies, Santa Clara, CA). Precursor-product ion transitions occurred at m/z 76.1→58.1 and 76.1→59.1 (TMAO), m/z 85.1→66.3, and 85.1→68.3 (TMAO-d9). The results were represented as fold of the HFD group.

Statistics

Results are presented as the mean ± standard error of the mean (SEM). Statistical analyses were performed using unpaired Student’s t-tests or analysis of variance, followed by Scheffe’s multiple-comparison post-hoc test. SPSS software (version 14; SPSS, Chicago, IL, USA) was used to analyze data. A p-value <0.05 was considered statistically significant.

Results

CCL4 Inhibition Provided Beneficial Effects on Glucose Homeostasis

C57BL/6 mice were fed a high-fat diet to mimic the clinical development of diet-induced DM. The body weights were increased in the HFD-induced DM mice compared to those fed a normal diet. CCL4 antibody injections did not affect the body weight of HFD-induced DM mice (Figure 1A). The blood sugar levels were increased in HFD-induced DM mice compared to mice fed a normal diet. Blood sugar levels were decreased in the HFD-induced DM mice that received the CCL4 antibody injection for 4 weeks (Figure 1B). In the OGTT test, blood sugar levels were lower in the CCL4 antibody-treated group at 15, 30, 60 and 120 minutes than in the untreated HFD-induced DM group (Figure 1C). The CCL4 inhibition group also had lower levels of HOMA-IR than the HFD-induced DM group (Figure 1D). These results suggested that CCL4 inhibition had beneficial effects on glucose homeostasis in HFD-induced DM mice.

CCL4 Inhibition Modulated Lipid Parameter and Inflammation in HFD-Induced DM Mice

Due to the close relationship between diet-induced obesity and dyslipidemia, we also investigated the serum lipid profile in mice. HFD-induced DM mice showed...
dyslipidemia symptoms, as evidenced by the increased total cholesterol (TC), triglycerides (TG), and non-high-density lipoprotein (HDL) levels compared to mice fed a normal diet. The CCL4 inhibition group exhibited decreased serum TC, TG, and non-HDL levels compared to the untreated HFD-induced DM group (Figure 2A–C). Moreover, obesity was characterized by systemic and tissue inflammation.\(^\text{17}\) The serum TNF-\(\alpha\) and IL-6 levels were enhanced in the HFD-induced DM group compared to those fed a normal diet. The enhanced inflammatory markers were both reversed after CCL4 antibody injection for 4 weeks (Figure 2D and E). These results indicated that CCL4 inhibition was able to modulate the lipid profile and reduce systemic inflammation in HFD-induced DM mice.

**CCL4 Inhibition Changed the Structure of Gut Microbiota in HFD-Induced DM Mice**

We hypothesized that CCL4 inhibition plays a critical role in programming host–microbe metabolic interactions and...
Figure 2. The effect of CCL4 inhibition on lipid parameter and systemic inflammation in HFD-induced DM mice. has beneficial effects on glucose homeostasis, the lipid profile, and inflammation. We therefore investigated whether CCL4 inhibition led to specific alterations in the gut microbiota structure. The stool samples were analyzed for the microbial structure. The CCL4 inhibition group had a significant influence on the α-diversity of the intestinal microbiota (Figure 3A). Mice that received CCL4 antibody for 4 weeks showed a distinct clustering of microbiota composition using principal coordinate analysis (PCoA) of β-diversity, which indicated that the composition of gut microbiota changed in response to CCL4 inhibition in HFD-induced DM mice (Figure 3B). In addition, the unweighted UniFrac distance analysis revealed that the differences in microbiota between groups were significant (Figure 3C).

The relative abundance of the predominant taxa examined by sequencing was analyzed to profile the specific changes in the gut microbiota (Figure 4). Taxon-based analysis revealed significant differences in gut microbial composition after CCL4 inhibition. The overall community patterns in the stool samples were altered after CCL4 inhibition at the phylum and family levels (Figure 4A and B). A significant increase of phylum Actinobacteria was observed in the CCL4 inhibition group (Figure 4A). At the family level, the relative abundance of Muribaculaceae was lower in the CCL4 inhibition group, while the relative abundance of Atopobiaceae was apparently higher in the CCL4 inhibition group than in untreated HFD-induced DM mice (Figure 4B). The ANCOM results indicated that the CCL4 inhibition group had a remarkable reduction of Muribaculaceae compared to the untreated HFD-induced DM mice (Figure 4C). These results showed that CCL4 inhibition could modulate the gut microbiota of HFD-fed mice, which may have caused the beneficial effects against HFD-induced obesity and DM.

The family tree and heatmap illustrated the presence of a different bacterial environment in the gut between the untreated HFD-induced DM group and CCL4 inhibition group (Figure 5A and B). Most importantly, CCL4 inhibition led to specific alterations in the gut microbiota structure.
inhibition could decrease the TMAO levels in HFD-induced DM mice (Figure 5C). In summary, CCL4 inhibition led to lower abundance of Muribaculaceae and higher abundance of Atopobiaceae at the family level, as well as a decreased concentration of TMAO.

HFD-Induced DM Mice Received FMT from CCL4 Knockout Mice Had Improved Glucose Homeostasis

CCL4 knockout mice were used to further confirm the pathological role of CCL4 in diet-induced DM. In the OGTT test, blood sugar levels were lower in the CCL4 knockout mice fed an HFD at 15 and 30 minutes than in the wild-type mice fed an HFD (Figure 6A). The AUCs of the OGTT were significantly lower in the CCL4 knockout mice fed an HFD than those in the wild-type mice fed an HFD (Figure 6B). The knockout mice fed an HFD also had lower levels of HOMA-IR than the wild-type mice fed an HFD (Figure 6C). These results indicated that CCL4 deficiency could truly improve glucose homeostasis in HFD-induced DM mice.

In another part of the study, we used FMT to verify the effect of CCL4 inhibition on gut microbiota and the linkage between CCL4-modulated gut microbiota and HFD-induced DM. In the OGTT test, blood sugar levels were lower in the wild-type mice fed an HFD with FMT from CCL4 knockout mice at 15 and 150 minutes than in those without FMT (Figure 6D). The AUCs of the OGTT were markedly lower in the wild-type mice fed an HFD with FMT from CCL4 knockout mice (Figure 6E). Moreover, the wild-type mice fed an HFD with FMT from CCL4 knockout mice had lower levels of HOMA-IR than those without FMT (Figure 6F). The above results definitely enhanced the causal relationship between CCL4 and the microbiota in the treatment of HFD-induced DM.
Discussion

In this study, it was shown that CCL4 inhibition may alter the gut microbiota, and improve glucose metabolism, the lipid profile, and systemic inflammation in HFD-induced DM mice. Potential factors that may have contributed to the beneficial effects caused by CCL4 inhibition that we identified include a decreased relative abundance of family Muribaculaceae and an increased relative abundance of family Atopobiaceae in the gut microbiota, as well as a reduced circulating TMAO concentration. Given the suggested role of TMAO in systemic inflammation, these results indicated the potential association between the compositional changes in the gut microbiota and CCL4 inhibition-related indices in HFD-induced DM mice. More interestingly, FMT from CCL4-deficient donor could lead to protective efficacy on glucose homeostasis in HFD-induced DM, which support the potential effects of CCL4 on gut microbiota for in vivo metabolic control. Given the limited number of experiment animals, the data may be preliminary. Future studies are indicated to investigate the complex role of gut microbiota, such as family Muribaculaceae and family Atopobiaceae in systemic inflammation as well as metabolic disorder.

There have been few previous studies related to the family Atopobiaceae, but there was a recently sequencing and cultivation study of the family Muribaculaceae.18 While the systemic role of the family Atopobiaceae is rarely known, the diverse impacts of the family Muribaculaceae was shown in different animal experiments.

Several types of animal models have been used in the experiments of gut microbiota for systemic metabolism. First, dietary supplements are usually used in this type of study, which may theoretically generate local intestinal

effects followed by systemic metabolic impacts. The oral administration of capsaicin was shown to reduce metabolic endotoxemia and chronic inflammation, which were associated with the anti-obesity effect and decreased abundance of the gut Muribaculaceae/S24-7 family. It was also shown that a polyphenol-rich extract of Dendrobium loddigesii could decrease the blood glucose, body weight, and low-density lipoprotein cholesterol levels, and increase the insulin levels in type 2 obese diabetic mice with decreased relative abundance of the family Muribaculaceae/S24-7. Another study showed that a raspberry extract, which may improve the severity of obesity-related symptoms, led to a decreased abundance of the flower of Edgeworthia gardneri, a Chinese traditional medicine, could decrease the blood glucose level and ameliorate insulin resistance and lipid metabolism impairment in diabetic mice, as well as increase the family Muribaculaceae/S24-7 in the gut microbiota. Casein glycomacropeptide hydrolysates treatments reduced the concentration of LPS and pro-inflammatory cytokines in serum with enhanced abundance of gut Muribaculaceae/S24-7 in streptozotocin-induced DM mice. Given the controversial findings in the dietary supplement animal models, other types of approach are required to clarify the specific role of Muribaculaceae/S24-7 in systemic metabolism.

Genetic modified mice may be another type of animal model that could be used for gut microbiota study. Recently, glutaredoxin 1-deficient mice was shown to exert upregulated lipid homeostasis biomarkers and Nrf2/Kearp1 expression, as well as antioxidant defense genes with a lower abundance of Muribaculaceae/S24-7, which may suggest the association of suppressed family Muribaculaceae/S24-7 with favorable metabolic status. In such case, both systemic inflammation and gut microbiota might be modified individually and simultaneously due to the general genetic background.

In the present study, systemic CCL4 inhibition, another novel experiment approach, improves glucose metabolism and lipid profiles with the downregulation of family Muribaculaceae and upregulation of family Atopobiaceae in the gut microbiota of HFD-induced DM mice. It has been indicated that inflammatory mediators including TNF-α and IL-6 are increased with insulin resistance and play an important role in deregulating glucose homeostasis in metabolic disorders. While TNF-α and IL-6 were used as the major markers in the current study, other inflammatory biomarkers such as IL-1β, MCP1, and so on may be also examined for a more comprehensive inflammatory profile of CCL4 inhibition in the future study. In the present study, both inflammatory proteins such as TNF-α and IL-6 and circulating TMAO level as a pro-inflammatory metabolite from gut microbiota were reduced by direct CCL4 inhibition. It seems that the systemic effects of CCL4 inhibition might alter the gut microbiota via a unique pathway, which may then improve the microbiota profiles for a less inflammatory status evident by the reduced circulating TMAO level. Furthermore, the lipid profiles were also improved by CCL4 antibodies in HFD-induced DM mice in the current study. Accordingly, the lipid profiles of CCL4 knockout mice and HFD-induced DM mice receiving FMT from CCL4 knockout mice should be interesting. While the lipid profiles were not examined in DM mice receiving FMT from CCL4 knockout mice in the current study, future studies may be required to further elucidate the detailed mechanisms of CCL4-related inflammation in systemic metabolism of both glucose and lipids.

TMAO is a metabolite that has attracted attention because of its close association with several chronic inflammatory diseases such as type 2 DM, atherosclerosis, and chronic kidney disease. The production of TMAO results from the conversion by the gut microbiota of dietary nutrients. Specifically, choline and carnitine can be transformed to trimethylamine and converted into TMAO in the liver by flavin-containing monoxygenase 1 and 3. Studies have shown that nutrients and bioactive compounds from food can modulate the gut microbiota to reduce TMAO production. HFD-induced obese NLRP3-deficient mice had an altered composition of gut microbiota associated with reduced levels of TMAO and LPS, attenuated systemic inflammation, and improved lipid metabolism. Given that higher levels of circulating TMAO could be associated with a higher risk of DM, it is then important to develop the novel interventional strategy that manipulates the production of TMAO. Interestingly, in the present study, we did observe that CCL4 inhibition could reduce the levels of TMAO with a significant and probably favorable alteration of the gut microbiota.

Accordingly, our findings might support the potential pathogenic role of family Muribaculaceae suggested by previous studies. While the bio-effects of family Atopobiaceae are scanty known, family Muribaculaceae/S24-7 is found as an LPS-producing bacterium related to LPS biosynthesis. It has been shown that in HFD-fed
mice, the modulation of gut microbiota was linked to an increased intestinal permeability and LPS absorption that amplified the development of inflammation and metabolic disorders. A previous study found that the bacterium-associated LPS could bind to toll-like receptor-4 and led to increased levels of proinflammatory cytokines. In mice fed a high-fat diet, an enhanced abundance of the Gram-negative S24-7 family was observed, and chronic low-grade inflammation was prevented with lower levels of the family S24-7. Decreased levels of Muribaculaceae/S24-7 in the gut microbiota were also associated with anti-inflammatory effects from decreasing the expression of TNF-α and IL-6 in diabetic db/db mice. In this study, we further showed that in a high-fat diet-induced diabetic mouse model, direct systemic CCL4 inhibition could result in suppressed gut microbiota Muribaculaceae/S24-7, decreased circulating TMAO level, and reduced systemic inflammatory proteins, such as TNF-α and IL-6. Taken together, one may speculate the complex effects of direct CCL4 inhibition in vivo. In addition to modulating circulating inflammatory cells and pancreatic inflammation by direct inhibition on CCL4, there might be a novel local mechanism of CCL4 inhibition to modulate gut microbiota particularly family Muribaculaceae/S24-7 and family Atopobiaceae, which then reduce LPS related, toll-like receptor-4 and Nrf2/Keap1-mediated production of inflammatory proteins. While our findings support the hypothesis that direct CCL4 inhibition could modify gut microbiota and related systemic metabolism in diet-induced DM mice, further investigations are required to elucidate the CCL4-related signaling pathways in gut.

On the other hand, though less likely, it is possible that direct inhibition on CCL4 may alter systemic inflammation that leads to changes in gut microbiota. In such case, gut microbiota profiles, similar to circulating C-reactive protein levels, may be just a mirror to the status of systemic inflammation. While the family Muribaculaceae has been suggested pathogenic and linked to systemic inflammation and metabolic disorder, our findings of the modulation on family Muribaculaceae by direct CCL4 inhibition seem meaningful. More interestingly, the specific pathology of HFD-induced DM could be potentially rescued by CCL4-mediated gut microbiota through the FMT experiments.

There are some concerns about the current study that should be further indicated. In our study, an FMT mouse model with CCL4 knockout mice was used to validate the beneficial effects of CCL4 inhibition in HFD-induced DM. While the fecal from CCL4 knockout mice would not be equal to the mouse fecal after CCL4 antibody treatment, a sequencing of stool from CCL4 antibody treatment, a sequencing of stool from CCL4 knockout mice might be needed for further evaluation. On the other hand, a previous study compared the depletion of gut microbes by administering a single broad-spectrum antibiotic and indicated that each option individually elicited unique taxonomic changes. In the current study, antibiotic water containing ciprofloxacin was used to create a control environment in gut for FMT. While a combination of antibiotics was frequently used in previous FMT experiments, it is interesting to see if our current observations may be validated in another FMT model with the antibiotic cocktail. Finally, for advanced mechanistic insight, further studies are ongoing to elucidate the direct impact of gut microbiota including family Muribaculaceae and family Atopobiaceae on systemic inflammation that related to in vivo glucose metabolism.

**Conclusion**

Direct CCL4 inhibition altered gut microbiota profiles, with reduced abundance of family Muribaculaceae, enhanced abundance of family Atopobiaceae, and decreased TMAO production in vivo. The above changes were associated with the reduction of systemic inflammation and the improvements of glucose as well as lipid metabolism in HFD-induced DM mice. In line with the inflammatory theory of glucose metabolic disorders, our findings highlight the significant impacts of CCL4 on both systemic inflammation, metabolism, and gut microbiota. Furthermore, FMT from CCL4 knockout mice could potentially rescue the glucose homeostasis in HFD-induced DM mice. Given the established role of gut microbiota in systemic inflammation and metabolism, our findings could provide a novel and important rationale to CCL4-based approach in diet-induced DM. Theoretically, they may have potential clinical impacts, particularly in chronic systemic inflammation with elevated CCL4 levels such as type 2 DM and atherosclerosis disease. While the current findings might be observational, additional studies are ongoing to investigate the direct role of family Muribaculaceae and family Atopobiaceae as the potential modifiable targets for metabolic control in either experimental or clinical DM.
