Improving the Photocatalytic Reduction of CO₂ to CO through Immobilisation of a Molecular Re Catalyst on TiO₂

Christopher D. Windle, Ernest Pastor, Anna Reynal, Adrian C. Whitwood, Yana Vaynzof, James R. Durrant, Robin N. Perutz, and Erwin Reisner

Abstract: The photocatalytic activity of phosphonated Re complexes, [Re(2,2'-bipyridine-4,4'-bisphosphonic acid)(CO₂L)] (ReP; L = 3-picoline or bromide) immobilised on TiO₂ nanoparticles is reported. The heterogenised Re catalyst on the semiconductor, ReP–TiO₂ hybrid, displays an improvement in CO₂ reduction photocatalysis. A high turnover number (TON) of 48 mol CO mol⁻¹ Re is observed in DMF with the electron donor triethanolamine at l > 420 nm. ReP–TiO₂ compares favourably to previously reported homogeneous systems and is the highest TON reported to date for a CO₂-reducing Re photocatalyst under visible light irradiation. Photocatalytic CO₂ reduction is even observed with ReP–TiO₂ at wavelengths of l > 495 nm. Infrared and X-ray photoelectron spectroscopies confirm that an intact ReP catalyst is present on the TiO₂ surface before and during catalysis. Transient absorption spectroscopy suggests that the high activity upon heterogenisation is due to an increase in the lifetime of the immobilised anionic Re intermediate (l₁/₂ = 1 s for ReP–TiO₂ compared with l₁/₂ = 60 ms for ReP in solution) and immobilisation might also reduce the formation of inactive Re dimers. This study demonstrates that the activity of a homogeneous photocatalyst can be improved through immobilisation on a metal oxide surface by favourably modifying its photochemical kinetics.

Introduction

The efficient and selective reduction of CO₂ is the key challenge to access carbon capture and utilisation (CCU) technologies. The green conversion of CO₂ into the energy carrier CO is particularly attractive as it could be used, in combination with H₂, as an important chemical feedstock to form syngas, and replace the steam reforming of fossil fuels in the petrochemical industry. Sustainable syngas provides a direct route to a greener chemical industry sector and the generation of transport fuel through Fischer–Tropsch chemistry. Photoelectrocatalytic CO₂ reduction has been achieved on semiconductors, such as p-type Si, CdTe, InP, GaAs, GaP, Cu₂O and n-type TiO₂. However, semiconductor materials often suffer from poor selectivity, producing a range of carbon-based products as well as H₂. In contrast, enzymes display excellent selectivity and high turnover frequencies; synthetic molecular catalysts can be achieved through two main strategies: They can receive electrons from an excited photosensitiser with appropriate energy requirements. Rhenium catalysts...
for CO\textsubscript{2} reduction have been used in photocatalytic dyads of this type.\textsuperscript{[10]} A second approach consists of using molecular photocatalysts that can perform both the functions of light harvesting and chemical catalysis.\textsuperscript{[11]}

The rhenium tricarbonyl bipyridine complex with a defined leaving group L, [Re(bpy)(CO)\textsubscript{3}(L)], is one of very few mononuclear compounds that falls into this second category and acts as both a light absorber and a catalyst for the photo-reduction of CO\textsubscript{2} to CO.\textsuperscript{[11a-c]} However, the two major drawbacks of such Re catalysts are their inefficient absorption of solar radiation and their low photostability and turnover numbers to generate CO (TON\textsubscript{CO}). The highest TON\textsubscript{CO} reported to date for a Re complex acting as both light absorber and catalyst in solution in DMF/triethanolamine (TEOA) is 30, using \(\lambda > 400\) nm irradiation (L = Cl\textsuperscript{−}).\textsuperscript{[11a,12]} A Re derivative with a thiocyanate leaving group gave a TON\textsubscript{CO} of 26 (2 h, \(\lambda > 400\) nm)\textsuperscript{[39]} or a TON\textsubscript{CO} of 30 (25 h, \(\lambda = 365\) nm).\textsuperscript{[11]} A dinuclear system gave a TON\textsubscript{CO} per Re centre of 30 after one hour of irradiation (\(\lambda = 450\) nm, LED).\textsuperscript{[14]} Until recently, photocatalysis with Re complexes had only been performed in homogeneous solution. [Re(bpy)(CO)\textsubscript{3}L\textsubscript{1}] complexes have been immobilised in various environments, but few of these systems have been reported as CO\textsubscript{2} reduction photocatalysts.\textsuperscript{[15]} Emerging heterogeneous systems\textsuperscript{[16]} are advantageous as they facilitate catalyst recycling and increase the flexibility of solvents that may be used.\textsuperscript{[12,17]} However, heterogenised Re photocatalysts have to date shown only low efficiency, with a maximum reported TON\textsubscript{CO} of 7 in the absence of an additional dye.\textsuperscript{[12]}

Herein we report two novel phosphonated Re bipyridine photocatalysts (ReP) for selective CO\textsubscript{2} to CO reduction. Quantitative immobilisation of the ReP catalysts onto TiO\textsubscript{2} nanoparticles results in an improvement of the TON\textsubscript{CO} compared to previously reported homogeneous Re catalysts. To explain the nature of this enhanced photoactivity of ReP, the reaction mechanism and the kinetics of the catalytic intermediates were studied by time correlated–single photon counting and transient absorption spectroscopy. This spectroscopic study reveals an enhanced stability of the reaction intermediates when immobilising the ReP catalysts onto TiO\textsubscript{2} and provides evidence for a reduction in the concentration of inactive Re dimers formed during catalysis, resulting in a 26-fold increase in the CO\textsubscript{2} reduction yield for the heterogenised ReP on TiO\textsubscript{2} compared to homogeneous ReP.

**Results and Discussion**

**Synthesis and characterisation of ReP**

Rhenium catalysts with phosphonated bipyridine ligands for immobilisation on metal oxides, three CO ligands in facial configuration and a 3-picoline (ReP\textsuperscript{pic}) or bromide (ReP\textsuperscript{Br}) leaving group were prepared (Figure 1). Heating [ReBr(CO)\textsubscript{5}] with tetraethyl 2,2′-bipyridine-4,4′-bisphosphonic acid in refluxing benzene gave \(^{19}\)ReP\textsuperscript{Br} in 92% yield. The bromide ligand in \(^{19}\)ReP\textsuperscript{Br} was replaced upon heating with AgPF\textsubscript{6} and 3-picoline in THF to yield \(^{31}\)ReP\textsuperscript{pic} in 77%. The ethyl ester groups were dealkylated with ISiMe\textsubscript{3} in CH\textsubscript{2}Cl\textsubscript{2} followed by methanol treatment to give ReP\textsuperscript{Br} in 39% yield. ReP\textsuperscript{Br} was synthesised by heating [ReBr(CO)\textsubscript{5}] with 2,2′-bipyridine-4,4′-bisphosphonic acid in a refluxing toluene/methanol mixture in 44% yield, or by reaction of ReP\textsuperscript{pic} with BrSiMe\textsubscript{3} in 62% yield.

The composition and purity of the ReP complexes were confirmed by \(^1\)H, \(^{31}\)C and \(^{31}\)P NMR, UV/Vis and FT-IR spectroscopies, mass spectrometry and elemental analysis (see Experimental Section and Figures S1–S8 in the Supporting Information). Single crystals of ReP\textsuperscript{pic} suitable for X-ray diffraction analysis were obtained from CH\textsubscript{3}Cl\textsubscript{2}/hexane and the crystal structure is shown in Figure 1 B. ReP\textsuperscript{pic} displayed a Re1–N1 bond length of 2.163(7) Å, a Re1–Br1 bond length of 2.6291(10) Å and a torsion angle for NCCN in the 2,2′-bipyridine of 6.3(1)°. In comparison [ReCl(4,4′-dimethyl-2,2′-bipyridine)(CO)\textsubscript{3}] showed a Re–N bond length of 2.172 Å, a Re–Cl bond length of 2.489 Å and a torsion angle in the bipyridine of 3.01°.\textsuperscript{[18]} ReP\textsuperscript{Br} was d;essed by ESI-MS as a doubly deprotonated species in the negative ion mode and is likely to exist in a singly deprotonated form as a zwitterionic, overall charge-neutral complex in solution. The absence of signals for the PF\textsubscript{6}– counter ion in the \(^{31}\)P NMR spectrum provided further evidence for a charge-neutral complex. Elemental analysis indicated that in ReP\textsuperscript{pic} the phosphonic acid groups are fully protonated and therefore that ReP\textsuperscript{Br} is also uncharged. ReP\textsuperscript{pic} and ReP\textsuperscript{Br} were both soluble in DMSO and H\textsubscript{2}O, but only ReP\textsuperscript{Br} in DMF.

**Assembly and characterisation of ReP–TiO\textsubscript{2} hybrid**

The quantitative immobilisation of ReP\textsuperscript{pic} on dispersed TiO\textsubscript{2} nanoparticles (NPs; Evonik Aeroxide P25; 21 nm diameter) at
sub-monolayer concentration was confirmed by UV/Vis spectrophotometry ($\lambda = 370$ nm assigned to MLCT band in RePpic). No RePpic remained in the supernatant after stirring RePpic (0.1 mmol) in aqueous solution with TiO$_2$ (5 mg) for 1 h and centrifugation of the RePpic-loaded TiO$_2$ NPs (see the Supporting Information, Figure S9). ReP was loaded in water due to the insolubility of RePpic in most common organic solvents and to avoid adsorption of a carbon containing solvent on the TiO$_2$ surface (to facilitate XPS analysis; see below). The maximum loading capacity was determined by UV/Vis spectrophotometry as 0.4 mmol per 5 mg TiO$_2$, which is comparable to the loading capacity of phosphonated cobaloxime and ruthenium tris(2,2'-bipyridine) complexes on TiO$_2$.[18]

Several techniques were subsequently used to characterise the RePpic–TiO$_2$ NP hybrid (Figure 2). An IR spectrum of RePpic in MeOH solution displayed CO stretching vibrations at 2037 and 1932 cm$^{-1}$ (Table 1), whereas an attenuated total reflectance (ATR) spectrum gave signals at 2025 and 1890 cm$^{-1}$. This difference in wavenumber is due to solid-state effects. Once loaded onto TiO$_2$ but before exposure to DMF/TEOA, the ATR spectrum gives wavenumbers of 2039 and 1931 cm$^{-1}$, which are very similar to the spectrum in MeOH solution. On the particle, the molecules of RePpic are dilute and experience no solid-state effects as they cannot interact with one another.

Signals corresponding to phosphorus–oxygen bond stretches can be observed in the ATR spectra (Table 1). There is little difference between the P–O and P–OEt stretches for EtRePBr and EtRePpic despite the difference in charge between the complexes. The P–O stretch in RePpic shows a low wavenumber shift of 100 cm$^{-1}$ compared with EtRePBr and RePpic. There is little difference between the P–O signal for unbound RePpic and that when bound to TiO$_2$.

X-ray photoelectron spectroscopy (XPS) measurements of RePBr–TiO$_2$ confirmed the elemental composition upon immobilisation on TiO$_2$. RePBr was utilised for XPS studies due to the additional element, which provides a distinct handle for the bromide (as leaving group) compared to the picoline complex. XPS measurements showed a composition of 1.08 % Re, 0.49 % Br, 2.74 % P and 2.52 % N, in good agreement with the expected 1:1 ratio for P to N and 2:1 for N to Re (Figure 2, as well as Figure S11 and Table S1 in the Supporting Information). The low Br percentage suggests that the Br is rapidly substituted in the aqueous solution.[19]

Photocatalytic activity

The Re–TiO$_2$ system displays CO$_2$ photoreduction activity under UV-filtered simulated solar light (100 mW cm$^{-2}$, $\lambda > 420$ nm). Different amounts of RePpic on TiO$_2$ in 5:1 DMF/TEOA (4.5 mL) were studied to identify optimal conditions for the heterogenised Re catalyst; different filters and metal oxide nanoparticles were also used. The turnover number (TON) is defined as molecules of CO produced per molecule of ReP catalyst after the system had stopped producing CO and is a measure of stability of the Re catalyst in the system. RePpic loadings of 0.05, 0.1, 0.2, 0.3, 0.4, 0.5 mmol per 5 mg TiO$_2$ were tested and the highest TON (48) was achieved with a loading of 0.1 mmol RePpic on 5 mg TiO$_2$ under $\lambda > 420$ nm irradiation (see the Supporting Information, Table S2), which is hereafter denoted as the optimised system. RePpic–TiO$_2$ gives a Re-based turnover frequency (TOF$_{CO}$) of 8 h$^{-1}$ during the first 3 h irradiation and a TON$_{CO}$ of 48 after 1 day visible-light irradiation (Figure 3, Table 2). Control experiments, under comparable conditions but in the absence of either RePpic, TEOA, TiO$_2$, CO$_2$ or light, did not generate significant amounts of CO (Table S2).

**Table 1.** Functional group IR signals (cm$^{-1}$) for RePBr, RePpic (CH$_2$Cl$_2$ solution) and RePpic (MeOH solution). n.d. = not determined.

| Solution | RePBr | RePpic | RePpic | RePpic–TiO$_2$ | Assignment |
|----------|-------|--------|--------|---------------|------------|
| 2024     | 2036  | 2037   | n.d.   | CO            |
| 1930     | 1927  | 1932   | n.d.   | CO            |
| 1901     | —     | —      | n.d.   | CO            |

**ATR**

| ATR     | 1258  | 1153   | 1156   | P=O           |
|---------|-------|--------|--------|---------------|
| 1011    | 1014  | —      | —      | P–OEt         |
| 975     | 971   | —      | —      | P–OEt         |

Figure 2. A) ATR-IR spectrum of RePpic–TiO$_2$ before and after 24 h of $\lambda > 420$ nm irradiation in DMF/TEOA 5:1 under CO$_2$. Spectrum after 24 h normalised to the maximum of the 0 h spectrum. ; B) RePpic–TiO$_2$ XPS signals for Re before (circles, 1.08 %) and after (squares, 0.82 %) and for N before (circles, 2.74 %) and after (squares, 4.19 %) catalysis (2 h, $\lambda > 420$ nm in 5:1 DMF/TEOA, under CO$_2$).
For comparison, \( \lambda > 420 \) nm irradiation of homogeneous solutions of \([\text{ReCl(bpy)(CO)}_3]\), RePBr and \( ^{1}\text{RePBr} \) (0.022 mm; 0.1 \( \mu \)mol of catalyst in 4.5 mL DMF/TEOA 5:1) resulted in final TONCO values of 6, 2 and 0, respectively. The addition of 5 mg TiO\(_2\) did not alter the photoactivity of TiO\(_2\)-anchor-free \([\text{ReCl(bpy)(CO)}_3]\) or that of \( ^{1}\text{RePBr} \), demonstrating the importance of immobilisation of RePBr on TiO\(_2\) for photoactivity. Replacing TiO\(_2\) with other metal oxides had a detrimental effect on the activity; \( \lambda > 420 \) nm irradiation of RePBr–SrTiO\(_3\) gave a TON of 20, whereas RePBr–ZrO\(_2\) and RePBr–ZnO gave TON of 8 and 10, respectively. RePBr–CeO\(_2\) and RePBr–ITO were photo-inactive (Table S3). The choice of metal oxide particle is therefore critical for the activity of immobilised ReP.

Measurements with different neutral density filters and therefore reduced light intensity showed little effect on catalytic rate for RePBr–TiO\(_2\) (0.1 \( \mu \)mol on 5 mg; see the Supporting Information, Figure S12), demonstrating that light harvesting was not performance-limiting under optimised conditions. Employing a 300, 400 or 420 nm cut-off filter resulted in comparable results (Table 2). Unexpectedly, a high TONCO of 39 and 16 was observed with ReP–TiO\(_2\) with a \( \lambda > 455 \) filter and a \( \lambda > 495 \) nm filter, respectively (Table 2). To our knowledge, catalytic CO production by Re complexes with wavelengths as long as 495 nm has not been previously reported.

After 24 h of irradiating RePBr–TiO\(_2\) (0.5 \( \mu \)mol on 5 mg), the nanoparticles were separated by centrifugation from the reaction solution, dried under vacuum and investigated with ATR-IR spectroscopy. Two metal carbonyl signals were clearly detected at \( \nu = 217 \) and 1885 cm\(^{-1}\), indicating that a significant quantity of the Re catalyst remains intact on the TiO\(_2\) particles (Figure 2A and Figures S13 and S14 in the Supporting Information). The FT-IR spectrum suggests that the \([\text{Re(bpy)}(\text{CO})_3(L)] \) (\( L = \) labile ligand) symmetry is retained and vibrations display a substantial low frequency shift with respect to fresh ReP–TiO\(_2\), indicating that the Re centre has changed from cationic to neutral. This is due to coordination of an anionic species, probably deprotonated TEOA. The post-catalysis vibrations are comparable in wavenumber to those reported for a solution spectrum of the \([\text{Re(bpy)}(\text{CO})_3(OCH}_2\text{CH}_2\text{N(CH}_2\text{CH}_2\text{OH})_2]) \) complex (2006, 1897 and 1881 cm\(^{-1}\)), but show only one low-wavenumber band.\(^{204}\) The CO stretches after catalysis are broader than beforehand, suggesting that they are probably compound peaks from multiple species. Proposed deactivation products for homogeneous Re systems include dimerisation during electrocatalysis\(^{221}\) and formation of Re formate complexes.\(^{23}\) It is likely that dimer formation would be less favourable due to immobilisation of the catalyst on TiO\(_2\).

The catalytic ReP–TiO\(_2\) system was characterised after 2 h of photocatalysis using XPS to investigate the stability of the molecular Re catalyst on the TiO\(_2\) surface (Figure 2B, as well as Figure S15 and Table S1 in the Supporting Information). The percentage composition was Re 0.82 %, Br 0.42 %, P 1.99 % and N 4.19 %. The values for Re, Br and P are in a comparable ratio to the pre-catalysis measurements (see above), whereas the nitrogen content has increased. This observation can be explained by coordination of DMF and/or TEOA to the Re, as in known photocatalytic intermediates for comparable Re complexes.\(^{220}\) In addition, the three hydroxy groups in TEOA can also bind to TiO\(_2\) and surface bound TEOA would result in a higher post-catalysis N content. The N 1 s signal at 400.3 eV, present before and after catalysis, has a very similar binding energy to signals previously assigned to the N in a Ru complex of 4,4’-dicarboxylic acid-2,2’-bipyridine adsorbed on TiO\(_2\) (400 eV).\(^{211}\) The additional signal after catalysis at 402.2 eV is assigned to contributions from DMF and/or TEOA. The XPS results are consistent with FT-IR measurements, which indicate that a significant quantity of the molecular catalyst is present on the surface during catalysis.

**Spectroscopic characterisation**

CO\(_2\) photoreduction is significantly more efficient for ReP catalysts anchored onto TiO\(_2\) compared with analogous conc-
entrances in solution. ReP–TiO₂ is also more efficient than an optimised homogeneous [ReCl(bpy)(CO)₃] system (0.871 mm in DMF/TEOA) under simulated solar light. To understand the difference in efficiency between homogeneous and TiO₂ immobilised catalysis, the ReP catalysts were investigated on TiO₂ and in solution by time correlated–single photon counting (TC-SPC) and transient absorption spectroscopy (TAS). The catalytic mechanism of ReP for the reduction of CO₂ was found to be independent of the nature of the labile ligand (Br or picoline).

The irradiation of [Re(bpy)(CO)₃(L)] complexes (ReP) with visible light causes an MLCT transition generating a triplet state (ReP*) that emits at 600 nm with a characteristic broad signal (see the Supporting Information, Figure S16). ReP displays a blue-shifted emission signal with respect to ReP*. This feature of ReP is characteristic of a cation, despite the zwitterionic feature of ReP in the homogeneous system (Figure S16). Both in solution and when immobilised onto TiO₂, the luminescence of ReP decays within t₅₀% = 20 ns. In good agreement with previous reports, TEOA was observed to quench approximately 90% of the emission within t₅₀% = 10 ns due to the reductive electron transfer to ReP (see the Supporting Information, Figure S17). The luminescence intensity of ReP immobilised onto TiO₂ is very similar to that of an analogous Al₂O₃ film functionalised with ReP (see the Supporting Information, Figure S18). Since Al₂O₃ is a semiconductor with a conduction band that does not allow for electron injection (−4.2 V vs. NHE), these results indicate that electron injection from the photocatalyst to TiO₂ does not take place.

Photoexcitation of homogeneous ReP and ReP immobi-

lised on TiO₂ (λₘₐₓ = 415 nm) in the presence of TEOA results in two characteristic transient absorption features; a peak centred at λₘₐₓ = 500 nm and a broad transient signal in the near-IR region of the spectrum (800–900 nm). The latter band shows a smaller signal amplitude relative to the 500 nm peak, with this difference being more pronounced for ReP immobi-

lised on TiO₂ than for the homogeneous system (see the Supporting Information, Figure S19). These signals are not detected in the absence of an electron donor. As reported previously for analogous [Re(bpy)(CO)₃(L)]-type catalysts, we have assigned the λₘₐₓ = 500 nm transient absorption peak to the reduced catalytic species ReP*, an important reaction intermediate in the CO₂ photoreduction formed upon the reductive quenching of ReP* by TEOA along with the loss of the labile ligand (L). This reaction intermediate was detected independently of the nature of the labile ligand (picoline or Br). It has previously been suggested that the catalytic mechanism of Re-based complexes involves the replacement of these ligands by DMF or TEOA. However, the transient absorption in the near-IR has been previously assigned to the formation of catalytically inactive Re-dimers. This assignment implies that the lower signal amplitude for ReP–TiO₂ compared to homogeneous samples results from the formation of dimeric species, this being less favourable when the molecules are immobilised onto the surface of a metal oxide.

The kinetics of ReP in solution and anchored on TiO₂ were also monitored by transient absorption spectroscopy in the millisecond to second timescales (Figure 4). The measurements were performed under either an N₂ or a CO₂ atmosphere, using TEOA (1 mm in DMF) as sacrificial electron donor. In all cases, the decays were probed at 500 nm, corresponding to λₘₐₓ of the reduced catalytic intermediate ReP*. Under N₂, the lifetime of ReP is more than one order of magnitude longer when the catalyst is immobilised onto TiO₂ than in solution (t₀% > 1 s for ReP–TiO₂ and t₀% = 60 ms for ReP in homogeneous solution). The addition of CO₂ in ReP–TiO₂ samples shortens the lifetime of the transient absorption decay assigned to ReP to t₀% = 400 ms. The decay of ReP in solution, in the presence of CO₂, has a strong biphasic behaviour, with a fast component in the 1–10 ms timescale and a slow phase in the 100 ms–1 s timescale, indicative of a multiple step process. The effect of the lifetime of the reaction intermediates on the CO₂ reduction photocatalysis is further discussed below.

The increase in lifetime of the reduced reaction intermediate observed when the catalyst is immobilised on TiO₂ suggests that the scaffolding provided by the metal oxide enhances the stability of this intermediate. Thus, the longer-lived catalytically
active Re\(^{3+}\) species formed in ReP\(_{\text{pic}}\)-TiO\(_2\) samples have a greater probability of encountering and consequently reacting with CO\(_2\) as well as of undergoing the second reduction necessary for the release of CO. This is consistent with our catalytic measurements showing a better performance of the ReP–TiO\(_2\) system. Our results are also in good agreement with a recent publication showing improved CO\(_2\) reduction yields in a TiO\(_2\) system loaded with a phosphonated Re catalyst and a molecular dye.\(^{[17]}\) However, in this previous study the Re catalyst acted solely as an electrocatalyst with the dye acting as photosensitiser, whereas in our work ReP was employed as a photocatalyst without requiring an additional dye.

The transient absorption signal of ReP\(_{\text{pic}}\)-TiO\(_2\) decays approximately one order of magnitude more rapidly when adding CO\(_2\) compared with the analogous system under N\(_2\). This faster decay can be most obviously assigned to the disappearance of ReP\(^{3+}\) species upon reaction with CO\(_2\) in the 100 ms to 1 s timescale. Further evidence of the timescale of the interaction between ReP\(^{3+}\) and CO\(_2\) is provided by comparing the kinetics of ReP\(_{\text{pic}}\) in solution and when immobilised on TiO\(_2\). From the biphasic transient absorption decay under CO\(_2\) of ReP\(_{\text{pic}}\) in solution, the kinetics of the slow phase are very similar to those of ReP\(_{\text{pic}}\)-TiO\(_2\) (Figure 4B, inset), suggesting that they involve the same process. Theoretical calculations supported the hypothesis that rhenium photocatalysts covalently attached to TiO\(_2\) show an optimum orientation for maximum reduction capacity.\(^{[18]}\) Thus, the lack of steric hindrance when immobilising ReP onto TiO\(_2\) suggests that the interaction of ReP\(^{3+}\) with CO\(_2\) is expected to be comparable to a homogeneous system. We hypothesise that the fast phase of ReP\(_{\text{pic}}\) in solution is due to the formation of a reaction intermediate involved in the deactivation pathway of CO\(_2\) reduction, likely to correspond to the formation of the Re dimer.\(^{[22]}\) The detailed nature of these catalytic and deactivation pathways are currently under investigation. We also note that the reduction of CO\(_2\) to CO requires two electron transfers. It has been previously hypothesised that this second reduction can take place through the interaction of two singly reduced ReP\(^{3+}\) catalysts, or via the reaction of the carbon radical formed upon the deprotonation of [TEOA]\(^{+}\) species with ReP\(^{3+}\).\(^{[13,20,25]}\) The kinetics of this second reduction, represented by dashed grey lines in Scheme 1, have not been observed in our transient absorption spectroscopy measurements. However, the higher CO\(_2\) reduction yields observed when ReP is immobilised onto TiO\(_2\) compared to homogeneous solution suggests that, in our system, the second electron transfer may occur through the sacrificial electron donor, as the immobilisation of ReP would hamper electron transfer between two Re molecules. The results of our kinetic studies are summarised in Scheme 1.

Conclusions

We have synthesised two novel phosphonated rhenium bipyridine complexes, which bind quantitatively to TiO\(_2\) nanoparticles. The ReP–TiO\(_2\) hybrids can photoreduce CO\(_2\) to CO with high wavelength light (λ > 495 nm), show good stability and show higher TONs than previously reported Re catalysts in the absence of dye as far as we are aware. The molecular structure is retained when the complex is immobilised onto the surface of the metal oxide before and during catalysis, although there are changes in the axial ligand, L. The unexpected enhancement in photocatalysis with ReP–TiO\(_2\) is explained by the significantly longer lifetime of the reduced catalytic Re species on TiO\(_2\), an important intermediate in the photoreduction mechanism, formed upon reductive quenching by the sacrificial electron donor. The near-IR region of the transient absorption spectra provide evidence that a reduced amount of inactive Re dimers is being formed in the catalytic cycle, which may also contribute to the higher activity of the ReP–TiO\(_2\) assembly. We have therefore shown that modification of the photochemical kinetics through photocatalyst immobilisation on metal oxide surfaces is a viable route to enhanced catalytic activity.

Experimental Section.

Materials and Methods

Chemicals were obtained from the following suppliers: BrSiMe\(_3\), Et\(_3\)N, triethanolamine, anhydrous DMF, SiMe\(_3\), CeO\(_2\) particles (< 25 nm), SrTiO\(_3\) particles (< 100 nm), AgPF\(_6\) [Pd(PPh\(_3\))\(_4\)], PPh\(_3\), P(OEt\(_3\)) (Aldrich); 3-picoline (BDH Chemicals); 4,4’-dibromo-2,2’-bipyridine (BOC Sciences); CO\(_2\)/CH\(_4\) (BOC); silica 60 (Fluka); [Re(CO)\(_5\)] (Strem Chemicals). [ReBr(CO)\(_5\)], [ReCl(bpy)(CO)\(_3\)], \(^{[8a]}\) tetraethyl 2,2’-bipyridine-4,4’-bisphosphonic acid\(^{[26]}\) and 2,2’-bipyridine-4,4’-bisphosphonic acid\(^{[26]}\) were prepared according to literature procedures. All solvents were dried before use in the synthetic part of the work. TiO\(_2\) nanoparticles (Aeroxide TiO\(_2\), P25 particles; anatase/rutile (8:2) mixture, average particle size 21 nm, BET 50 m\(^2\) g\(^{-1}\)) and ZnO nanoparticles were a gift from Evonik Industries, ZrO\(_2\) nanoparticles were obtained from Skyspring Nanomaterials Inc. and CeO\(_2\), SrTiO\(_3\) and ITO from Sigma Aldrich.

Physical measurements

\(^1\)H and \(^{31}\)P NMR spectra were recorded either on a Bruker AVIII HD Smart Probe (400 MHz), a Bruker AVIII HD (400 MHz) or a Bruker ECS400 (400 MHz) spectrometer. \(^1\)H NMR spectra were referenced to the solvent residual peaks as an internal reference,\(^{[29]}\) and \(^{31}\)P NMR spectra were referenced to an external standard (85% H\(_3\)PO\(_4\) in D\(_2\)O). UV/Vis spectra were recorded on a Varian Cary 50 UV/Vis spectrophotometer using quartz glass cuvettes. Electrospray ionisation mass spectra (ESI-MS) were recorded on a Quattro LC...
spectrometer, Bruker Esquire 6000 or a Bruker microTOF instrument (for high-resolution (HR) ESI-MS measurements) and the theoretical and experimental isotope distributions were compared. m/z values are quoted for $^{64}$Zn, $^{185}$Re and $^{79}$Br. Elemental analysis was carried out by the microanalysis service of the Department of Chemistry, University of Cambridge. IR spectra were recorded on a Mattson RS FTIR instrument, averaging 64 scans at resolution 2 cm$^{-1}$ or on a Thermo Scientific Nicolet 1500 FT-IR spectrometer. ATR spectra of the particles were recorded with an average of 256 scans. IR spectra of the KBr discs of the particles were taken with a PerkinElmer RX I instrument. ATR-IR spectra of particles before and after catalysis were run with 0.5 $\mu$m RePBr on 5 mg TiO$_2$ to obtain the strongest possible signals. X-ray photoelectron spectroscopy (XPS) measurements were carried out using an XRF monochromator Al$_{\text{K}}\alpha$. X-ray source (hv = 1486.6 eV) with a 900 mm spot size in an ultra-high vacuum chamber (ESCALAB 250Xi). The pass energy was 20 eV. RePBr was chosen over RePBr$_2$ (see below) for XPS due to the additional measurable element (Br). The sample after catalysis was washed with DMF, and dried under vacuum, followed by exposure to the XPS operating vacuum.

Synthesis and Characterisation

**[Re(Br(tetraethyl 2,2'-bipyridine-4,4'-bisphosphonic acid)](CO)$_3$]**

(RePBr): To a flame-dried two-neck 50 mL round bottom flask fitted with a reflux condenser was added tetraethyl 2,2'-bipyridine-4,4'-bisphosphonic acid (50 mg, 117 $\mu$mol) followed by [ReBr(CO)$_5$] (47 mg, 117 $\mu$mol). The solids were subsequently suspended in anhydrous benzene (15 mL) and the reaction mixture heated to 65 °C. The reaction was monitored by IR spectroscopy ($\nu_{\text{CO}}$) showing completion after approximately 20 h. The solvent was removed under reduced pressure and the crude product redissolved in CH$_2$Cl$_2$, followed by precipitation of an orange solid upon addition of hexane. Yield: 84 mg, 92%. Single crystals suitable for X-ray diffraction analysis were obtained by layering a CH$_2$Cl$_2$ solution of RePBr$_3$ with hexane. $^1$H NMR (400 MHz, CDCl$_3$): $\delta$ = 1.41 (td, 2.70 and 7.09 Hz, 12H; CH$_2$CH$_3$), 4.26 (m, 8H; CH$_2$CH$_3$), 7.84 (qd, 1.09, 5.41 Hz, 2H; 5-bpy), 8.63 (d, 13.41 Hz, 2H; 3-bpy), 9.19 ppm (t, 4.81 Hz, 2H; 6-bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CDCl$_3$): $\delta$ = 16.58 (CH$_3$CH$_3$), 63.88 (CH$_2$CH$_3$), 125.75 (bpy), 129.15 (bpy), 140.88 (bpy), 142.75 (bpy), 153.50 (bpy), 155.34 (CO), 196.21 ppm (CO); $^{31}$P NMR (109 MHz, CD$_3$OD): $\delta$ = 8.25 (1H, ppm; CH$_2$CH$_3$), 8.77 (1H, ppm; CH$_2$CH$_3$), 7.25 (dd, 5.71 and 8.08 Hz, 1 H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2 H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s; 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2 H; bpy); $^{31}$P NMR (109 MHz, CD$_3$OD): $\delta$ = 10.14 ppm (s; 1H, ppm; CH$_2$CH$_3$), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{31}$P NMR (109 MHz, CD$_3$OD): $\delta$ = 6.68 ppm (s; IR (ATR): $\nu$ = 2025 (s), 1890 (s, broad; $\nu_{\text{CO}}$), 1153 cm$^{-1}$; IR (CH$_3$OH): $\nu$ = 3273 (s), 993 cm$^{-1}$ (s, broad; $\nu_{\text{CO}}$); ESI-MS (negative): m/z(%): 676.4 (48; $\nu_{\text{CO}}$), 583.4 (48; $\nu_{\text{CO}}$), C$_{23}$H$_{27}$N$_3$O$_9$P$_2$Re requires 582.9.

**[Re(3-picolinate)(2,2'-bipyridine-4,4'-bisphosphonic acid)](CO)$_3$**

(RePBr$_2$): A Schlenk tube was charged with RePBr$_3$ (179 mg, 191 $\mu$mol) and dried under reduced pressure at 40 °C overnight, followed by cooling to 0 °C. A solution of ISiMe$_3$ in CHCl$_3$ (1 mL) was prepared in the glovebox, cooled to 0 °C and added by cannula (1.09 mL, 7.64 mmol of ISiMe$_3$) to the reaction mixture. The red solution was stirred at 0 °C for 5 min and then evaporated to dryness and dried under vacuum for 72 h. The solid was redissolved in dry chloroform (1 mL), followed by the addition of methanol (1 mL). The solution was stirred at 0 °C for 10 min, allowed to warm to room temperature under stirring, and then evaporated to dryness and dried under vacuum for 24 h. The solid was precipitated from methanol with diethyl ether. Yield: 50 mg, 39%. $^1$H NMR (400 MHz, CD$_2$CO): $\delta$ = 2.22 (2H, s; 3H-picolinic acid), 7.25 (dd, 5.71 and 8.08 Hz, 1H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s, 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CD$_2$CO): $\delta$ = 16.53 (CH$_3$CH$_3$), 64.16 (C$_2$H$_5$), 7.25 (dd, 5.71 and 8.08 Hz, 1H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s, 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CD$_2$CO): $\delta$ = 16.53 ppm (CH$_3$CH$_3$), 64.16 (C$_2$H$_5$), 7.25 (dd, 5.71 and 8.08 Hz, 1H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s, 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CD$_2$CO): $\delta$ = 16.53 ppm (CH$_3$CH$_3$), 64.16 (C$_2$H$_5$), 7.25 (dd, 5.71 and 8.08 Hz, 1H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s, 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CD$_2$CO): $\delta$ = 16.53 ppm (CH$_3$CH$_3$), 64.16 (C$_2$H$_5$), 7.25 (dd, 5.71 and 8.08 Hz, 1H; picoline), 7.75 (d, 8.04 Hz, 1H; picoline), 8.12 (q, 5.44 Hz, 2H; bpy), 8.17 (d, 5.55 Hz, 1H; picoline), 8.25 (s, 1H; picoline), 8.77 (d, 12.70 Hz, 2H, bpy), 9.44 ppm (dd, 3.22, 5.63 Hz, 2H, bpy); $^{13}$C($^1$H) NMR (100.6 MHz, CD$_2$CO): $\delta$ = 16.53 ppm (CH$_3$CH$_3$), 64.16 (C$_2$H$_5$).
Single crystal X-ray diffraction studies

Diffraction data were collected at 110 K on an Oxford Diffraction SuperNova diffractometer with MoKα radiation (λ = 0.71073 Å) using a EOS CCD camera. The crystal of 4-RePph was cooled with an Oxford Instruments Cryojet. Diffractometer control, data collection, initial unit cell determination, frame integration and unit-cell refinement was carried out with “CrysAlisPro”. Face-indexed absorption corrections were applied using spherical harmonics, implemented in SCALE3 ABSPACK scaling algorithm. OLEX2 was used for overall structure solution, refinement and preparation of computer graphics and publication data. Within OLEX2, the algorithm used for structure solution was “charge-flipping” using the superflip program. Refinement by full-matrix least-squares used the SHELXL-97 algorithm within OLEX2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed using a “riding model” and included in the refinement at calculated positions. Crystal data and structure refinement details (see the Supporting Information, Table S4), selected bond distances and angles (Table S5) and details about the X-ray crystal structure refinement are given in the Supporting Information.

Assembly of colloidal ReP–TiO2 hybrid system

ReP was pre-loaded onto the TiO2 nanoparticles by stirring ReP with dispersed TiO2, in H2O for one hour protected from light. The particles were separated by centrifugation and removal of the supernatant, followed by drying under high vacuum at room temperature overnight. In a typical procedure, a solution of ReP-Ph (1.36 mg) in H2O (10 mL) was added dropwise to a sonicated suspension of TiO2 (100 mg) in H2O (20 mL) with stirring. The mixture was stirred for 1 h, centrifuged, the supernatant removed and the ReP-Ph-modified TiO2 powder dried by high vacuum at room temperature overnight.

Photocatalytic studies

A reaction mixture of DMF/TEOA 5:1 (4.5 mL) and the catalyst were prepared by dissolving the photocatalyst (0.1 mmol) in H2O for one hour protected from light. The mixture was subjected to centrifugation and removal of the supernatant, followed by drying under high vacuum at room temperature overnight. In a typical procedure, a solution of ReP-Ph (1.36 mg) in H2O (10 mL) was added dropwise to a sonicated suspension of TiO2 (100 mg) in H2O (20 mL) with stirring. The mixture was stirred for 1 h, centrifuged, the supernatant removed and the ReP-Ph-modified TiO2 powder dried by high vacuum at room temperature overnight.

Spectroscopic measurements

Homogeneous samples for spectroscopic measurements were prepared by dissolving the photocatalyst (0.1 mmol) in a water/DMF mixture (1:2). When required, TEOA was added to the solution to give a concentration of 1 mmol L−1. Anatase TiO2 films were employed for spectroscopic measurements, because their smaller particle size and decreased scattering effect offer an enhanced optical transparency compared to that of P25 analogues. Anatase TiO2 films (8 μm thick, area 1 cm × 1.5 cm) were prepared from a colloidal paste as reported previously and Al2O3 was prepared as reported previously, and deposited onto microscopic slides by Doctor blading. The films were functionalised by dipping the TiO2 slides into a 0.3 mm aqueous solution of ReP during 48 h in the dark, to avoid degradation of the catalyst. The samples were then dried under vacuum for approximately 1 h to remove any traces of water. The samples were kept in the dark before and in between the measurements. The millisecond to second transient absorption measurements were performed using a home built system as reported previously. The samples were excited with a 415 nm laser pulse (∼300 μJ cm−2, 0.5 Hz rep. rate, 6 ns pulse width) and, unless otherwise stated, transient absorption decays were monitored at 500 nm. The decays observed were the average between 500 and 1000 laser pulses. N2 was used to purge the samples (∼15 min) before each measurement, unless otherwise stated.

Time correlated–single photon counting measurements were performed using a Horiba Jobin Yvon TBX Fluorocube system. As excitation source, a pulsed laser with 404 nm nominal wavelength at a repetition rate of 100 kHz was used. The photoluminescence of a 0.1 mm ReP solution in N2-purged water, and a ReP–TiO2 film in air was monitored at 600 nm for a fixed period of time (300 s). The instrument response was measured at the full width half maximum, showing typically a 200–250 ps value.
