I. INTRODUCTION

With the tremendous experimental progress in growing oxide heterostructures, new routes to engineer the dimensionality of materials have become available. A physical phenomenon particularly sensible to dimensionality is high-Tc superconductivity, which seems to find its ideal playground in quasi two–dimensional systems. Maybe not accidentally, in two dimensions also strong antiferromagnetic spin fluctuations prosper, without undergoing a phase transition to long-range order as in three dimensions.

Besides two dimensionality, the electronic structure of the most prominent class of unconventional superconductors, the cuprate family, is governed by a single Cu d_{x^2−y^2} orbital doped slightly away from half-filling. An important step towards a better understanding of cuprate superconductivity was taken by Pavarini et al. who found an empirical trend in the material dependence of the critical temperature, Tc, at optimal doping. In the proposed scenario the material dependent parameter is the energy difference between the planar Cu d_{x^2−y^2} orbital at the Fermi energy and an axial Cu 4s-like orbital at higher energy.

In a recent Letter, Chaloupka and Khaliullin proposed the artificial engineering of nickelate heterostructures with the aim of getting cuprate-like electronic structures and interplay between axial and planar orbitals. A possible realization are LaNiO$_3$/LaO-NiO$_2$ heterostructures and extend it by introducing an appropriate hopping in the z direction to describe the dimensional crossover to three dimensions. Using dynamical mean field theory, we study the effects of electronic correlations with increasing interaction strength along the crossover from 2D to 3D. Qualitatively, the effects of electronic correlations are surprisingly similar, albeit quantitatively larger interaction strengths are required in three dimensions for getting a Mott-Hubbard insulating state. The exchange parameters of an effective Kugel-Khomskii-like spin–orbital–model are also derived and reveal strong antiferromagnetic tendencies.

Reduced dimensionality and strong electronic correlations, which are among the most important ingredients for cuprate-like high-Tc superconductivity, characterize also the physics of nickelate based heterostructures. Starting from the local density approximation we arrive at a simple two-band model for quasi two-dimensional (2D) LaNiO$_3$/LaAlO$_3$ heterostructures and extend it by introducing an appropriate hopping in the z direction to describe the dimensional crossover to three dimensions (3D). Using dynamical mean field theory, we study the effects of electronic correlations with increasing interaction strength along the crossover from 2D to 3D. Qualitatively, the effects of electronic correlations are surprisingly similar, albeit quantitatively larger interaction strengths are required in three dimensions for getting a Mott-Hubbard insulating state. The exchange parameters of an effective Kugel-Khomskii-like spin–orbital–model are also derived and reveal strong antiferromagnetic tendencies.

For the purpose of this study, we simplify the local-density-approximation (LDA) bandstructure of Ni e_g orbitals by including merely the hopping between the first- and second-nearest neighbor Ni d(e_g) Wannier orbitals, in contrast to Ref. where the full LDA bandstructure was considered. This gives a quarter-filled two-band model for the e_g degrees of freedom, i.e., one electron in the two Ni e_g orbitals. We recall here that in transition metal oxides the transition metal ion is usually surrounded by an oxygen octahedron and, depending on the specific case, either f_{2g} (as, e.g., in vanadiumsesquioxide) states or e_g states (as in the nickelates and cuprates) play the most important role in determining the low energy excitations of the system. Hence, our study of an e_g–band model at quarter filling and the dimensional crossover from quasi–two– to three-dimensional systems if of interest also from a more general perspective. Moreover, since there are plenty of parameters governing the physics such as the bandwidth of the two bands, their crystal field splitting, the interband hybridization, the Coulomb interaction, and last but not least the dimensionality, it is of great importance to derive such models from realistic bandstructures.

This way we also make some contact to previous multi-
band model studies\textsuperscript{5,14} where features such as the orbital selective Mott transitions\textsuperscript{15,17} were analyzed. Many of these multi-band studies made approximations, such as neglecting the hybridization between the orbitals. This poses the question in how far the employed models are applicable to real world materials. Moreover, most of the aforementioned studies concentrated on half filling.

In Section II, we will briefly discuss the two-band model and how we derive its parameters. In Section III we discuss the evolution of the spectral function, self energy and double occupation with increasing Coulomb interaction strength. In Section IV we turn to the dimensional crossover, comparing the quasi two-dimensional system for a heterostructure and a more homogeneous 3D model. Finally, we discuss the issue of magnetic order at low temperatures and derive an effective spin-orbital superexchange model in Section V before we arrive at the conclusion in Section VI.

II. LDA+DMFT

A. Effective two-band model

Density functional calculations were performed for the simplest, 1/1 unstrained superlattice LaNiO\(_2\)/LaAlO\(_3\) = LaO-NiO\(_2\)-LaO-AlO\(_2\) of which a detailed discussion can be found in Ref. [3]. Here we recall the most important facts relevant for the discussion of our model study. In the LaNiO\(_3\)/LaAlO\(_3\) heterostructure nickel is in a threevalent state Ni\(^{3+}\). The coordination polyhedron is an octahedron with a small tetragonal distortion due to the LaAlO\(_3\) layers along the c-axis. The cubic crystal field eigenstates of the Nickel d-electrons are the lower lying \(t\)\(_2g\) triplet and the higher lying \(e_g\) doublet. The cubic splitting is large enough so that the nominal filling in Ni\(^{3+}\) is \(t\)\(_{2g}\) (completely filled) and \(e_g\) (quarter filling). As a consequence we find two \(e_g\) bands at quarter filling around the Fermi energy to be the relevant degrees of freedom for the low energy excitations of the system\textsuperscript{3}. The insulating LaAlO\(_3\) layers give rise to the tetragonal distortion which splits the axial \(|3z^2-r^2\rangle\) orbital \(\approx 150\) meV above the \(|x^2-y^2\rangle\) orbital and, more importantly, strongly reduce the width of the axial \(|3z^2-r^2\rangle\) band by blocking the perpendicular hopping\textsuperscript{28}.

In order to obtain the model for our DMFT study we construct a basis of localized Ni \(e_g\) Wannier functions using the Nth-order muffin-tin orbital method (NMTO) like in Ref. [5] but now truncate the hoppings after those between second-nearest Ni neighbors. For our purposes of model calculations we prefer this simpler picture of the systems kinetics in real space and pay the price of a slightly less accurate representation of the dispersion of the LDA conduction bands. Let us remark that this simplification could affect the Fermi surface transition discussed in Ref. [5] but not the overall properties of the MIT and the 2D to 3D crossover.

![FIG. 1. (Color online) Orbitally projected DOS (spectral density) for each of the two \(e_g\) bands (thick lines). Neglecting the inter-orbital hybridization leads to the results shown as thin lines. The hybridization is seen to strongly enhance the width of the \(3z^2-r^2\) spectral density, leading to a remarkable itinerancy, despite the quasi two-dimensional nature of the LaNiO\(_3\)/LaAlO\(_3\) heterostructure.](image)

In the basis \(|x^2-y^2, 3z^2-r^2\rangle\) of the planar and axial \(e_g\) Bloch-summed orbitals, the one-electron part of the Hamiltonian is:

\[
\varepsilon_{2D}^2 = -2(\cos k_x + \cos k_y) \cdot \begin{pmatrix}
0.45 & 0 \\
0 & 0.17
\end{pmatrix}
\]

\[
+ 2(\cos k_x - \cos k_y) \cdot \begin{pmatrix}
0 & 0.28 \\
0.28 & 0
\end{pmatrix}
\]

\[
- 4(\cos k_x \cdot \cos k_y) \cdot \begin{pmatrix}
0.09 & 0 \\
0 & 0.03
\end{pmatrix} + \begin{pmatrix}
0 & 0 \\
0 & 0.15
\end{pmatrix}
\]

Here, energies are in eV. The first and second terms account for respectively the intra- and inter-orbital nearest-neighbor hoppings. We see that the hopping between the \(x^2-y^2\) orbitals is almost three times as large as the one between the \(3z^2-r^2\) orbitals and that the inter-orbital hopping is nearly the geometrical average of the intra-orbital hoppings. Thus, as well as the factor 3, is what one expects when the Ni-Ni hopping is exclusively via O, i.e., when \(t\)\(_{Ni-Ni}\) = \(t\)\(_{Ni-O}\) \(t\)\(_{O-Ni}\)/(\(\epsilon\)\(_{Ni}\) \(- \epsilon\)\(_{O}\)) and \(t\)\(_{Ni-O}\) follows the canonical rules\textsuperscript{28}, which in the present case yield: \(t\)\(_{x^2-y^2}\) = \(\sqrt{3}t\)\(_{3z^2-r^2}\) in \(x\)-, and \(y\)-direction. The third term in equation (1) is the second-nearest neighbor hopping, and the fourth is the on-site term, i.e., it gives the tetragonal crystal-field splitting. The last-mentioned terms do not mix the two orbitals. In real space, the Hamiltonian of our effective model reads:

\[
\hat{H}_{\text{mod.}} = \sum_{i,lj,\sigma} t_{iljm} c_{i\alpha l}^\dagger c_{jm\sigma} + \hat{H}_{\text{int.}},
\]

where \(l,m \in \{p,a\}\) label the planar and axial orbitals. The hopping amplitudes \(t_{iljm}\) are the matrices in Eq. (1) with \(l,m\) as the orbital index and \(i,j\) as site index of nearest or next nearest neighbors on the square lattice.

The effects of the inter-orbital hybridization are clearly visible in Fig. 1 showing the noninteracting density

\[
\begin{pmatrix}
0.45 & 0 \\
0 & 0.17
\end{pmatrix}
\]

\[
+ 2(\cos k_x - \cos k_y) \cdot \begin{pmatrix}
0 & 0.28 \\
0.28 & 0
\end{pmatrix}
\]

\[
- 4(\cos k_x \cdot \cos k_y) \cdot \begin{pmatrix}
0.09 & 0 \\
0 & 0.03
\end{pmatrix} + \begin{pmatrix}
0 & 0 \\
0 & 0.15
\end{pmatrix}
\]
of states resulting from the noninteracting part of Hamiltonian \( \hat{H}_\text{int} \) of 2. A comparison to the case without hybridization (\( \Gamma_{\text{pa}} = 0 \)) plotted as a thin line shows a big difference especially for the 3\( z^2 - r^2 \)-projection. Its width is strongly enhanced if the hopping to the more mobile \( x^2 - y^2 \)-orbitals is properly taken into account. This effect is important since otherwise the reduced hopping in the \( z \)-direction would more severely reduce the itinerancy of electrons in the 3\( z^2 - r^2 \) orbital. That is, in the absence of the \( x^2 - y^2 \)-to-3\( z^2 - r^2 \) hybridization the 3\( z^2 - r^2 \) orbitals would localize too easily (even at a small Coulomb interaction strength). This scenario was originally proposed in Ref. 7 prior to realistic material calculations.

The Coulomb interaction terms read:

\[
\hat{H}_\text{int} = U \sum_{i,\sigma} n_{i\sigma}^+ n_{i\sigma} + \sum_{i > m, \sigma, \sigma'} (V - \delta_{\sigma, \sigma'} J) n_{i\sigma}^+ n_{m\sigma'}^-
\]

where \( n_{i\sigma}^+ = c_{i\sigma}^+ c_{i\sigma} \), \( \delta_{\sigma, \sigma'} \) denotes the Kronecker symbol, \( U \) and \( V \) represent the intra-orbital and inter-orbital repulsion, respectively, and \( J \) is the Hund exchange term.

For the solution of the impurity problem in the DMFT self consistency loop we use quantum Monte Carlo (QMC) simulations of the Hirsch and Fye type 25 which neither the pair hopping term (corresponding to highly excited states) nor the spin-flip term (which poses a severe sign problem in the numerical simulation) have been included. Presented results were obtained at \( \beta = 10 \text{eV}^{-1} \) except for the double occupancies shown in the right panel of Fig. 5. Further, convergence with respect to the value of the Trotter discretization \( \Delta \tau \) was validated. Afterwards, the maximum entropy method was employed to perform analytic continuation of the Green function to the real axis. Concerning the choice of the interaction parameter we perform a systematic analysis where \( U \) is varied in a regime of physically meaningful values in order to investigate the Mott–transition and its specific features. The Hund’s exchange term, on the other hand, has been fixed to \( J = 0.7 \text{eV} \), a reasonable value close to that of atomic Ni. Moreover, assuming the deviation from cubic symmetry to be negligible with respect to the Coulomb interaction parameters, we employ \( V = U - 2J \).

Before presenting our numerical results a comment about the applicability of DMFT to the finite dimensional system considered is due. While it has been shown that corrections arising from spatial correlations beyond DMFT 21,22 are generally small in 3D (except in the close proximity of a second order phase transition), stronger effects have to be expected for 2D systems. The strength of such correction with respect to DMFT is, however, decreasing with increasing temperatures 22,23 and therefore can be neglected as a first approximation in the temperature regime we are considering here. This corresponds to the assumption that we are well above any ordering temperature at \( \beta = 10 - 25 \text{eV}^{-1} \). Naturally a different treatment to include effects of spatial correlations is necessary in order to study the low temperature regime where spin fluctuations and, possibly, superconductivity emerge. For this reason we include in Sec. 1V a two-site calculation to estimate the size of non-local antiferromagnetic correlations for the system considered.

### B. Mott transition in two dimensions

**Spectral Function and Self Energy**

Fig. 2 shows the evolution of the \( k \)-integrated spectral functions \( A(\omega) \) for both orbitals with increasing \( U \). Let us first focus on the \( x^2 - y^2 \)-projected spectral density (black curve). Already at \( U = 4.4 \text{eV} \) \( (V = 3.0 \text{eV}; \) first panel), the spectrum is strongly renormalized with respect to the noninteracting case: A narrow quasiparticle peak at \( \varepsilon_F \) and Hubbard bands which are separated by an energy of the order of \( U \) are well visible. As the value of the interaction parameter is increased to \( U = 5.4 \text{eV} \) and \( U = 6.4 \text{eV} \) (second and third panels), such spectral features become even more pronounced as one observes a stronger renormalization of the quasiparticle peak and more pronounced Hubbard bands. However, at \( U = 7.4 \text{eV} \) (fourth panel) a qualitative change has occurred: the spectral weight at the Fermi level has vanished and a Mott-Hubbard gap has been formed. Hence, a Mott metal–insulator transition has taken place between \( U = 6.4 \) and \( 7.4 \text{eV} \).

Fig. 2 also indicates that the metal–insulator transition of the 3\( z^2 - r^2 \)-band (red curve) occurs for the same critical interaction of \( U \geq 6.4 \text{eV} \) as in the \( x^2 - y^2 \) band. It is, however, qualitatively different. For \( U \) increasing from \( 4.4 \text{eV} \), one observes that the 3\( z^2 - r^2 \) quasiparticle peak is shifted above that of the \( x^2 - y^2 \) peak, which is at the Fermi level. This is the Coulomb enhancement of the tetragonal crystal field which causes the Fermi surface to have only one, mostly \( x^2 - y^2 \)-like sheet as in the cuprates. For increasing \( U \), the 3\( z^2 - r^2 \) spectral weight shifts further and further above the Fermi level where for \( U = 7.4 \text{eV} \) it has completely disappeared.

The remaining spectral weight below the Fermi energy, corresponding to the lower Hubbard band, is entirely due to the hybridization with the lower \( x^2 - y^2 \)-like Hubbard band.

The different nature of the metal–insulator transition in the \( x^2 - y^2 \)- and the 3\( z^2 - r^2 \)-bands can be identified even more clearly from an analysis of the self energy. In Fig. 3 we show the evolution of the imaginary part of the self energy \( \text{Im}\Sigma_{x^2 - y^2}(\omega) \) with increasing interaction. Again, for the \( x^2 - y^2 \) band, the expected behavior of a standard Mott transition is found: The appearance of the insulating gap results from the divergence of \( \text{Im}\Sigma_{x^2 - y^2}(\omega) \) in the limit of zero frequency. In this limit the quasiparticle renormalization factor \( Z = (1 - \partial\text{Im}\Sigma_{x^2 - y^2}(\omega)|_{\omega = 0})^{-1} \) goes to zero as a further hallmark of the Mott character of the transition in the \( x^2 - y^2 \)-band (see black circles in the left panel of Fig. 3). At the same time, however, the insulating transition of the 3\( z^2 - r^2 \)-band is not associated to any qualitative change.
FIG. 2. (Color online) Evolution of the LDA+DMFT spectrum with increasing Coulomb interaction $U$ (with $J = 0.7\,\text{eV}$, $V = U - 2J$) at $\beta = 10\,\text{eV}^{-1}$. The black curves show the $x^2 - y^2$ and the red/gray ones the $3z^2 - r^2$-projected spectral density.

FIG. 3. (Color online) Evolution of the LDA+DMFT self energy (vs. negative Matsubara frequencies) with increasing $U$ at $\beta = 10\,\text{eV}^{-1}$. The black curves show the $x^2 - y^2$ and the red/gray ones the $3z^2 - r^2$ self energy. Via extrapolation of the imaginary and real part of the self energy to $\omega_n \rightarrow 0$ we can obtain the quasiparticle renormalization $Z$ and the “crystal–field” enhancement, respectively, shown in Fig. 4.

FIG. 4. (Color online) Left hand side: Effective chemical potential $\mu - \operatorname{Re}\Sigma(0)$ relative to the noninteracting chemical potential for the $x^2 - y^2$ (black) and $3z^2 - r^2$ (red/gray) orbital at $\beta = 10\,\text{eV}^{-1}$. At the Mott transition, the low frequency effective chemical potential of the $3z^2 - r^2$ orbital is strongly reduced so that it is shifted above the Fermi energy, i.e., the $3z^2 - r^2$ orbital becomes “band”–insulating. Right hand side: Quasiparticle weight $Z$ for the $x^2 - y^2$ (black) and $3z^2 - r^2$ (red) orbital (also at $\beta = 10\,\text{eV}^{-1}$). For the $x^2 - y^2$ orbital, we find $Z \rightarrow 0$, i.e., the (central) quasiparticle peak disappears and the $x^2 - y^2$ orbital becomes Mott–insulating.

in $\operatorname{Im}\Sigma_{3z^2-r^2}(\omega)$. For all interactions a “metallic”–like bending can be observed in $\operatorname{Im}\Sigma_{3z^2-r^2}(\omega)$ at low frequencies. As a consequence of this, the renormalization factor $Z$ stays always finite (red crosses in the right panel of Fig. 4). The disappearance of spectral weight at the Fermi energy in this case is determined by a large relative shift of the orbitals induced by the Coulomb interaction. This shift $\Delta_{\text{eff}}$, is a consequence of the strong variation of the real part of the self energies at zero frequency shown in the left panel of Fig. 4. More specifically, while the effective chemical potential of the $x^2 - y^2$-band (defined as $\mu - \operatorname{Re}\Sigma_{x^2-y^2}(0)$) remains close to the noninteracting value up to $U = 6.4\,\text{eV}$, its value for the $3z^2 - r^2$-band is clearly decreasing with increasing $U$. As a result, the metal insulator transition of the $3z^2 - r^2$-band occurs for a value of $U \gtrsim 6.4\,\text{eV}$, when the low energy spectral weight of this band is shifted above the Fermi energy.

A key feature in the physics we have observed here is the interplay between the two orbitals stemming from the fairly large hybridization in equation (1) proportional to $\cos k_x - \cos k_y$. An evident sign of such interplay is the concomitance of the metal insulator transition in both orbitals. For understanding the underlying physics it is instructive to consider the different possible scenarios for the MIT in a two band system with hybridization.

Increasing the Coulomb interaction has basically two effects (see also Refs. 24, 25 and in particular Ref. 14): Double occupancy of a site becomes more expensive and on-site energies of the two orbitals are shifted with respect to each other. This gives rise to three possible transition scenarios. (i) If the shift between the bands is increasing slowly with interaction, double occupancy becomes practically forbidden for a value of $V$ where both bands are still partially filled. As a result, a simultaneous Mott transition occurs with $Z \rightarrow 0$ for both bands. If, instead, the shift is increasing more rapidly with interaction, at a certain point one of the bands will empty, leav-
ing the other one half filled. The nature of the transition then depends on the value of \( U \) for which this happens. There are two possibilities: (ii) If \( U \) is strong enough to forbid double occupancy in the half-filled band, this band will become insulating abruptly. Such a situation is reflected in simultaneous, but qualitatively different, metal–insulator transitions for both bands. This is what we observe in Figs. 2 and 3. (iii) The other possibility is that \( U \) is not yet strong enough to prevent the double occupancies in the half-filled band. The Mott transition in this band – differently from our case – would then not take place simultaneously with the depletion of the other band. This case is different from the one considered in Figs. 2 and 3 and the only one in which the metal–insulator transition can be fully described in terms of an effective single-band model.

The initial lifting of the orbital degeneracy (the LDA crystal-field splitting) is expected to push the system in the direction of situation (ii), which we observed for our model with an initial crystal field splitting of \( \varepsilon_{3z^2-r^2} - \varepsilon_{x^2-y^2} = 150 \text{ meV} \). The inter-orbital hybridization also gives rise to two effects. The first one, which can be understood intuitively, is an effective broadening of the more narrow band (see Fig. 4 for the noninteracting case). This leads to a more metallic behavior of the \( 3z^2 - r^2 \)-electrons. The second effect is more intrinsic in the sense that the hybridization makes the bands more similar, obviously pushing the system towards situation (i). It is important to notice that both effects work against the effective crystal-field splitting. As mentioned above, the fingerprints of the hybridization can clearly be seen also in Fig. 2. Although the narrow \( 3z^2 - r^2 \)-like band is shifted above the Fermi energy, at the metal–insulator transition some residual \( 3z^2 - r^2 \) weight remains in the region of the lower \( x^2 - y^2 \)-like–Hubbard band.

**Double occupancy**

As in the case of the half-filled Hubbard model, complementary information about the metal–insulator transition can be extracted from analysis of the double occupancy \( d \), which is the derivative of the free energy with respect to the interaction parameter \( U \) and is a good indicator for the Mott metal–insulator transition.\(^{20}\) However, such an analysis for a two-band model is more complicated since it involves not only the orbital-diagonal double occupations (\( d_{mm} = \langle n_{m\uparrow} n_{m\downarrow} \rangle \)) but also the orbital-offdiagonal parts with parallel (\( d_{pp}^{\parallel} = \langle n_{p\uparrow} n_{p\downarrow} \rangle \)) and antiparallel spin orientations (\( d_{pp}^{\perp} = \langle n_{p\uparrow} n_{a\downarrow} \rangle \)).

The evolution of these four quantities is shown in Fig. 5 for two different temperatures. In both cases we observe the same trend for all double occupations which are decreasing with increasing interaction. Starting the analysis with the \( x^2 - y^2 \)-orbital, which undergoes a Mott-Hubbard transition when getting half filled, we observe that its double occupation decreases around \( U = 6.4 \text{ eV} \), i.e., near the critical value of the interaction that we can estimate form the spectral function in Fig. 2. At \( kT = 1/10 \text{ eV} \) (Fig. 5 left panel), however, this behavior is thermally smeared out. The Mott-Hubbard transition occurs in form of a very smooth crossover. A better estimate can be made by going down in temperature to \( kT = 1/25 \text{ eV} \) (Fig. 5 right panel), where we can see a very steep drop of \( d_{pp} \) marking the transition point at \( U \approx 7.0 \text{ eV} \) where we also found \( Z \to 0 \) for the \( x^2 - y^2 \) band.

At a first glance the behavior of the other three double occupancies \( d_{aa} \), \( d_{pa}^{\parallel} \), and \( d_{pa}^{\perp} \) appear to be more difficult to interpret: One could have expected that \( d_{pp}^{\parallel} \) and \( d_{pa}^{\perp} \) should be the largest ones because they are energetically less expensive \( (V, V - J) \) in comparison with the \( d_{mm} \) \( (U) \). What we observe, however, is a crossing of \( d_{pa}^{\parallel} \) with \( d_{pp} \) at \( U \approx 5.4 \text{ eV} \) and \( U \approx 4.2 \text{ eV} \) for \( \beta = 10 \) and \( \beta = 25 \text{ eV} \) respectively. Moreover, \( d_{pa}^{\perp} \) is lower than \( d_{pp} \) for all interaction values. This situation can be properly understood considering also the depletion of the \( 3z^2 - r^2 \)-band: The low values of \( d_{aa} \), \( d_{pa}^{\parallel} \), and \( d_{pa}^{\perp} \) reflect the low \( 3z^2 - r^2 \)-electron density. In order to disentangle these effects we have plotted the double occupancies normalized by the respective density in the inset of the left panel of Fig. 5 \( (\delta_{mm} = d_{mm}/\langle n_m \rangle^2 \), \( \delta_{pa}^{\parallel} = d_{pa}^{\parallel}/\langle n_p \rangle \langle n_a \rangle \), and \( \delta_{pa}^{\perp} = d_{pa}^{\perp}/\langle n_p \rangle \langle n_a \rangle \)). In this way the hierarchy of the energetic consideration is restored and all renormalized double occupancies behave in a similar way. On the other hand, the crossing observed in the unrenormalized data can be also interpreted as a clear signal that we are far from the situation (i) described above, that is, a simultaneous Mott-Hubbard transition in both bands.

**FIG. 5.** (Color online) Double occupancy vs. Coulomb interaction \( U \) for two values of \( \beta \) (left: \( 10 \text{ eV}^{-1} \); right: \( 25 \text{ eV}^{-1} \)). Shown are the double occupation of the \( x^2 - y^2 \) orbital (\( d_{pp}^{\parallel} \)), of the \( 3z^2 - r^2 \) orbital (\( d_{aa} \)) as well as the double occupation of both orbitals with parallel (\( d_{pa}^{\parallel} \)) and antiparallel spin (\( d_{pa}^{\perp} \)). Inset: double occupancies normalized by the respective density (\( \delta_{mm} \) see text).

**III. FROM 2D TO 3D**

Having discussed in detail the results for the two-dimensional model for the LaAlO\(_3\)/LaNiO\(_3\) superlattice, we now present results for a 3D model for bulk LaNiO\(_3\),

![Diagram](https://via.placeholder.com/150)
and compare with the 2D case. Specifically, we no longer restrict the hopping of the axial \(3z^2 - r^2\) band to the \(xy\)-plane, but allow for hopping along the \(z\)-axis by adding the term

\[\mathbf{t}_z \cdot \mathbf{r} \cdot \cos(k_z) \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix}\]

to the kinetic part of our Hamiltonian (1). We choose \(t_z = 0.6\) eV, i.e., \(4/3\) times the 0.45 eV in equation (1), as it should be in cubic symmetry according to the Slater-Koster tables22 and Ref. 28. Our 3D model is not completely cubic because from equation (1) we kept the tetragonal crystal-field splitting (last term in Eq. (1)) as well as the second–nearest neighbor hoppings in \(xy\)-plane, without including them in the \(xz\)- and \(yz\)-planes.

Moreover, this 3D model is not to be seen as a true LDA+DMFT analysis of pseudo–cubic LaNiO\(_3\), albeit the link to this compound is a motivation for the analysis of the modified model.

The noninteracting density of states for this 3D model is shown in Fig. 6. The main difference from the 2D model in Fig. 1 is obviously, a much broader \(3z^2 - r^2\)-band caused by the additional hopping in the 3rd direction. As a result of this broadening the two different bands are much more similar than in the 2D case. In the truly cubic case the \(x^2 - y^2\) and \(3z^2 - r^2\) spectral densities would have been identical.

In Fig. 7 we show the spectral functions and self energies of the interacting 3D system. On the left hand (right hand) side the data for a metallic (insulating) solution are plotted. They refer to \(U = 7.4\) eV and \(U = 9.9\) eV, respectively. This indicates that the metal–insulator transition occurs for considerably larger values of the interaction than in the 2D system, as might be expected. Another difference to the 2D case is the enhanced spectral weight of the \(3z^2 - r^2\)-band below the Fermi energy. However, the metal–insulator transitions for the two bands are qualitatively similar to those of the 2D case as is clearly demonstrated by the behavior of the imaginary part of the selfenergy shown in the bottom panels of Fig. 7.

The evolution of the self energies qualitatively resembles the one shown in Fig. 6 displaying the same “metallic” down–bending. The only (quantitative) difference to be noticed w.r.t. the 2D case is a larger imaginary part of the \(3z^2 - r^2\)-selfenergy at low-frequencies. This can be understood as a natural consequence of the closer resemblance of the bands in the noninteracting density of states. In terms of our precedent discussion we thus observe again the situation (ii) of section 2B i.e., a simultaneous albeit quantitatively different Mott transition. However, we are now slightly closer to the case (i) of a simultaneous double Mott transition for both bands than for the layered model. In other words, the Mott transition is qualitatively the same for the 3D as the 2D case, but quantitatively the Mott transition is shifted to much higher values of the interaction strength. Such large values can hardly be realized in experiment.

It must however be emphasized that for a truly cubic 3D model, the two \(e_g\) orbitals remain identical (for all strengths of the interaction) so that the Mott transition will occur simultaneously for both bands and for a value of \(U\) which is about \(\sqrt{2}\) larger than for the single-band case28. That a small symmetry breaking at the LDA level, as exhibited by our 3D \(e_g\) model, can drastically change the nature of the Mott transition in the paramagnetic state has previously been found in DMFT calculations for 3D \(t^2\) systems29,30 and \(t^3\) systems31, as well as for the \(e_g\) system LaMnO\(_3\).
IV. PREDOMINATING SPIN FLUCTUATIONS AND EFFECTIVE SUPEREXCHANGE MODEL

Predominating spin fluctuations

The model calculations discussed in the previous sections were performed for the paramagnetic phase. However, one expects the system to display magnetic and/or orbital order at sufficiently low temperatures. The treatment of such complex ordered phases is particularly difficult in LDA+DMFT. An insight into this physics can be obtained however by diagonalizing a “two-site version” of Hamiltonian (2) (with open boundary conditions, i.e., a diatomic molecule directed along the x-axis). The analysis of the corresponding energy levels for this two-electron system allows to infer the relevant fluctuations which dominate the low temperature physics. On the left-hand side of Fig. 8 we show the calculated energy level diagrams as a function of U for the same set of parameters that we have used for the LDA+DMFT 2D crystal calculation discussed in previous sections.

For the values of U considered, the mixing of the lowest energy levels with the energy-costly double-occupied states is very small, i.e., these states are already above the energy window which we plot in Fig. 8. More interestingly, our results show that the ground state of the two-electron system allows to infer the relevant fluctuations which dominate the low temperature physics. On the left-hand side of Fig. 8 we show the calculated energy levels with the energy-costly double-occupied crystal calculation discussed in previous sections.

Neglecting the charge transfer part of Hamiltonian (4) allows for a comparison with our two-site calculation, albeit only for $\Delta_{CF} = 0.15\text{eV}$ (dashed line in the plot on the right-hand side). Right hand side (reproduced from Ref. 5): Same diagram as a function of $\Delta_{CF}$ for $U = 4.5\text{eV}$ (dashed line in the plot on the left-hand side). The color of the points indicates the character of orbital ordering ($SF$: orbital ferro; $OAF$: orbital antiferro).

Effective superexchange model

A first analysis of the magnetic and orbital ordered phases in the La$_2$NiAlO$_6$ heterostructure was carried out in Ref. 4 considering the following superexchange Hamiltonian, defined for a bond $ij \parallel \gamma$ in the NiO$_2$ plane:

$$H_{ij}^{(\gamma)} = (R_{\gamma,\pm,\pm} + R_{\gamma,\pm,-})(1/2 \pm \tilde{z}_i^{(\gamma)})(1/2 \pm \tilde{z}_j^{(\gamma)})\hat{P}_{\sigma,ij} \quad (4)$$

with an implied sum over $\sigma = 0, 1$ and all combinations of $\pm, \pm$. $\hat{P}_{\sigma,ij}$ represents the projector to a singlet and a triplet state of two Ni$^{3+}$ $S = \frac{1}{2}$ spins while $\frac{1}{2} \pm \tilde{z}_j^{(\gamma)}$ selects the planar orbital in the plane perpendicular to the $\gamma$ axis and the directional orbital along this axis.

Neglecting the charge transfer part of Hamiltonian (4) allows for a comparison with our two-site calculation, albeit only for $\Delta_{CF} = 0.15\text{eV}$ (dashed line in the plot on the right-hand side). Right hand side (reproduced from Ref. 5): Same diagram as a function of $\Delta_{CF}$ for $U = 4.5\text{eV}$ (dashed line in the plot on the left-hand side). The color of the points indicates the character of orbital ordering ($SF$: orbital ferro; $OAF$: orbital antiferro).

Finally, in the right panel we show the effect of turning on the crystal field splitting $\Delta_{CF}$, disregarding some (here still small) terms which admix the orbitals in Hamiltonian (4). The changes in the color clearly indicates a rapid demixing of the eigenstates, since the $x^2 - y^2$ and $3z^2 - r^2$ orbitals are eigenfunctions of the crystal field operator. This limits the applicability of Hamiltonian (4) to the cases of small crystal field splittings.

As for the magnetic fluctuations, the Kugel–Khomskii-type Hamiltonian (4) clearly favors an antiferromagnetic spin–alignment along each pair. Depending on the crystal–field splitting, the preferred orbital orientation is along the bond or—for larger crystal field—a ferro–orbital occupation of the $x^2 - y^2$ orbital.

FIG. 8. (Color online) Left hand side: Energy level diagram of the two site model as a function of the Coulomb repulsion $U$ for $\Delta_{CF} = 0.15\text{eV}$ (dashed line in the plot on the right-hand side). Right hand side (reproduced from Ref. 5): Same diagram as a function of $\Delta_{CF}$ for $U = 4.5\text{eV}$ (dashed line in the plot on the left-hand side). The color of the points indicates the character of orbital ordering ($SF$: orbital ferro; $OAF$: orbital antiferro).
neglected the effect of interband-hybridization. This hybridization turned out to be most important for the itinerancy of the $3z^2−r^2$ band and for a simultaneous, albeit different Mott transition in both orbitals.

For realistic $U$ values we find that LaNiO$_3$/LaAlO$_3$ is a metal with an $(x^2−y^2)$–like quasiparticle peak at the Fermi level and a $(3z^2−r^2)$–like peak slightly above. At larger values of the Coulomb interaction, the $3z^2−r^2$ spectral density is shifted above the Fermi as in a metal to band–insulator transition for this band, while the $x^2−y^2$–like band undergoes a genuine Mott transition with divergent effective mass $(1/Z)$. Due to the hybridization between both orbitals, there is however still spectral weight in the $3z^2−r^2$ channel at the position of the predominantly $x^2−y^2$ lower Hubbard band.

If LaAlO$_3$/LaNiO$_3$ is grown on a substrate, stress can further enhance the initial (LDA) orbital splitting so that one could obtain a situation which is more single-band-like. This is expected to reduce the critical Coulomb interaction strength for the Mott transition.

Studying the two-site version of the model, which also includes second order processes in the nearest-neighbor hopping, we made contact with an effective Kugel-Khomskii-Hamiltonian, indicating predominant antiferromagnetic spin fluctuations, an essential ingredient for a prospective superconductor. Antiferromagnetic long-range order is hence also possible and might enhance the tendencies towards an insulating ground state.

We thank G. Khaliullin for valuable discussions and for initiating our interest in this system. This work was supported in part by the Austrian Science Fund (FWF) through SFB F41 (ViCoM), WK004 and Research unit FOR 1346 as well as the EU-Indian network MONAMI and the National Science Foundation under Grant No. PHY05-51164 (KITP). Calculations have been performed on the Vienna Scientific Cluster.

V. CONCLUSION

We have analyzed in detail the Mott transition in the high-temperature, paramagnetic state of LaAlO$_3$/LaNiO$_3$ heterostructures, including the dimensional crossover from the two-dimensional layered heterostructure to the three dimensional bulk system. The LDA bandstructure was NMTO-downfolded to the Ni $e_g$ orbitals and, in order to concentrate on the essentials of the Mott physics, we included merely the hoppings between first and second-nearest Ni neighbors. This realistic model also allowed us to contribute to the intensive discussion on the orbital-selective Mott transition\cite{14}, a discussion which with a few exceptions\cite{12} has hitherto
