ABSTRACT

Prior to ligation, each Okazaki fragment synthesized on the lagging strand in eukaryotes must be nucleolytically processed. Nuclease cleavage takes place in the context of 5′ flap structures generated via strand-displacement synthesis by DNA polymerase delta. At least three DNA nucleases: Rad27 (Fen1), Dna2 and Exo1, have been implicated in processing Okazaki fragment flaps. However, neither the contributions of individual nucleases to lagging-strand synthesis nor the structure of the DNA intermediates formed in their absence have been fully defined in vivo. By conditionally depleting lagging-strand nucleases and directly analyzing Okazaki fragments synthesized in vivo in Saccharomyces cerevisiae, we conduct a systematic evaluation of the impact of Rad27, Dna2 and Exo1 on lagging-strand synthesis. We find that Rad27 processes the majority of lagging-strand flaps, with a significant additional contribution from Exo1 but not from Dna2. When nuclease cleavage is impaired, we observe a reduction in strand-displacement synthesis as opposed to the widespread generation of long Okazaki fragment 5′ flaps, as predicted by some models. Further, using cell cycle-restricted constructs, we demonstrate that both the nucleolytic processing and the ligation of Okazaki fragments can be uncoupled from DNA replication and delayed until after synthesis of the majority of the genome is complete.

INTRODUCTION

The synthesis of each Okazaki fragment requires several distinct enzymatic activities (1). The primase component of the Pol α-prime complex synthesizes a short RNA primer, which is further extended by the error-prone DNA polymerase α (Pol α) (2,3). The high-fidelity, PCNA-associated polymerase δ (Pol δ) is subsequently loaded onto the 3′ terminus of the initiating fragment in a reaction catalyzed by the RFC clamp loader (4). Pol δ synthesizes DNA to the 5′ end of the preceding fragment and continues beyond this point (5), generating a 5′ flap structure. The displaced 5′ flap serves as a substrate for nucleases (6), which cleave to generate a nick between Okazaki fragment termini. Iterative rounds of extension, followed by flap cleavage or nick regeneration by the 3′-5′ exonuclease activity of Pol δ (5), maintain a ligatable nick that persists until it is sealed by DNA ligase I, encoded by the CDC9 gene in Saccharomyces cerevisiae (7). Nuclease cleavage during Okazaki fragment biogenesis represents an extremely abundant DNA transaction—one that must occur tens of thousands of times during each S-phase in S. cerevisiae and millions of times per human cell division.

The nucleases Rad27 and Dna2 have been proposed to cleave the majority of flaps during Okazaki fragment maturation. Genetic and biochemical work has given rise to a ‘two-nuclease’ model (1,8). According to this model, (9) iterative extension by Pol δ is followed by immediate cleavage of short DNA flaps by Rad27. If Pol δ extension outpaces Rad27 cleavage, Dna2 is required to process the resulting long flap. Rad27 and Dna2 show distinct substrate requirements in vitro. Rad27 readily cleaves short flaps; longer flaps are competent to bind RPA and thereby become refractory to Rad27 cleavage (10). Long, RPA-coated flaps are optimal substrates for Dna2 in vitro. Dna2 cleaves to leave a short flap such that RPA dissociates and Rad27 can cleave (11,12). However, recent reports indicate that Dna2 activity is sufficient to process 5′ flaps into ligatable nicks in vitro (13). Genetic data suggest additional redundancy in lagging-strand processing, and point to the likely involvement of Exo1 as a third Okazaki nuclease. In vivo in S. cerevisiae, neither RAD27 nor DNA2 is strictly essential for replication or viability because the lethality of dna2 null mutants can be suppressed by deletion of RAD9 (14,15). Furthermore, the temperature-sensitive phenotypes of both rad27 and dna2-1 can be suppressed by overexpression of EXO1 (16–18). Despite the apparent contribution of at least
three deoxyribonucleases to lagging-strand processing, the normal contribution of each nuclease has not been clearly defined \textit{in vivo}.

It is currently unclear whether impaired lagging-strand processing \textit{in vivo} would predominantly give rise to reduced nick translation by Pol $\delta$ and associated nucleases, or to residual Okazaki fragment 5' flaps resulting from ongoing strand-displacement synthesis by Pol $\delta$ without coupled nuclease cleavage. \textit{In vitro} data suggests that strand-displacement synthesis by Pol $\delta$ should be dramatically reduced by a failure to cleave Okazaki fragment termini; instead, idling by Pol $\delta$ should maintain genomic nicks after limited strand displacement (5, 19). However, electron microscopy analysis of DNA purified from \textit{Schizosaccharomyces pombe} with lagging-strand processing defects detected the accumulation of long flap structures at $\sim$1-2% of Okazaki fragment termini (20); because shorter flaps would be undetectable by electron microscopy, the extent of residual flap formation in lagging-strand processing mutants is unclear. Furthermore, the ability of the replisome to bypass damage \textit{in vivo} (21, 22) and \textit{in vitro} (23) suggests that DNA repair can occur after bulk DNA synthesis. This model is supported by additional \textit{in vivo} evidence – for example the ability of \textit{S. cerevisiae} to defer post-replication repair to G2/M (24). Lagging-strand synthesis must inevitably occur at the same time as the leading strand, but the extent to which Okazaki fragment processing must be coupled to ongoing replication has not been determined.

Here, we conduct a systematic analysis of lagging-strand processing in \textit{S. cerevisiae} while depleting the lagging-strand nucleases Rad27, Dna2 and Exo1 in all possible combinations. In all cases, we co-deplete DNA ligase and therefore analyze mature lagging-strand products, which we refer to as Okazaki fragments. Our data are consistent with a model whereby the extent of strand-displacement by Pol $\delta$ is severely reduced in the absence of nuclease cleavage. Rad27 cleaves most lagging-strand flaps, Exo1 serves as a redundant processing factor when Rad27 is absent, and the contribution of Dna2 to lagging-strand processing in the uniquely mappable regions of the \textit{S. cerevisiae} genome is limited. Further, we show that cells remain viable when Okazaki fragment ligation is deferred until after bulk DNA synthesis in each cell cycle; nucleolytic processing of the lagging strand can be similarly deferred, but only if the accumulation of single-stranded DNA is mitigated during S-phase.

**MATERIALS AND METHODS**

**Yeast strains, cell growth and spot tests**

Yeast strains were all W303 RAD5+. The wild type strain genotype is \textit{MATa, tor1-1::HIS3, fpr1::NatMX4, RPL13A-2xFKBP12::TRP1, CDC9-FRB::KanMX6}. Additional FRB tagging, gene deletions, Cbr2 promoter insertion and myc tagging were performed by PCR-mediated replacement, and introduced into the parent strain by crossing. At least two independent replicates of each strain were selected after tetrad dissection.

For \textit{GAL1-SSB} strains, the pRS405 integrating vector containing a codon-optimized open reading frame encoding \textit{E. coli} SSB under the control of the \textit{GAL1} promoter was integrated at the \textit{LEU2} locus. Stains were grown at 30°C in YPD unless otherwise specified. Rapamycin was added to a final concentration of 1 g/ml in liquid media or 2 g/ml in solid media. For spot tests, cells were washed and diluted to an OD of 1. Cells were plated at a 1:10 dilution series and grown overnight at 30 or 37°C as specified.

**Cell-cycle synchronization and western blotting**

200 ml of exponential phase cell cultures at OD 0.3–0.4 was synchronized in G1 using 5 g/ml alpha factor. Cells were released into S-phase and harvested at different time points. Growth was immediately stopped by addition of ice cold water and cells were centrifuged at 4°C. Cells were resuspended for 5 min in 2 M lithium acetate at 4°C, pelleted, resuspended for 5 min in 400 mM sodium acetate at 4°C, pelleted again and finally resuspended in 1× Laemmli buffer plus 5% beta-mercaptoethanol. After 5 min of boiling at 100°C, the lysates were centrifuged for 5 min at top speed and transferred to new tubes prior to loading on a 10% SDS-PAGE gel. After migration at 100 V, samples were transferred to a PVDF membrane, blocked with 5% milk in TBS–0.1% Tween and probed with a C-Myc antibody (Genescript A00173-100). Loading controls were done by Coomassie staining of gels loaded with identical amounts of sample and run alongside gels for Western blots.

**Fluorescence-activated cell sorter (FACS) analysis**

150 µl of cells were harvested during the S-phase release at different timepoints and 350µl of 100% ethanol was added to fix the cells overnight at 4°C. Cells were pelleted, resuspended in 50 mM sodium citrate plus Rnase A and incubated at 50°C for 1 h. After addition of protease K and another hour of incubation, cells were labeled with SYTOX green and stored at 4°C before analysis using a Becton Dickinson Accuri.

**Okazaki fragment analysis**

Okazaki fragments were purified and end-labeled essentially as described (25). Briefly, DNA concentration was normalized by Qubit. 650 ng of DNA per lane was treated with Klenow (exo-) (NEB) and $\alpha$-32P dCTP for 30 min at 37°C in NEBuffer 2. Unlabeled nucleotides were removed using Illustra G50 columns (GE Healthcare) and samples were separated for 5 h at 77 V in 1.3% alkaline agarose gels. DNA was transferred to a Nylon membrane overnight and visualized using a phosphorimagor.

For \textit{in vitro} ligation experiments, samples were incubated in 1× DNA ligase buffer (NEB). 2 µl of T4 DNA ligase (NEB) was added and samples were incubated for 90 min at room temperature before phenol extraction and end-labeling. Okazaki fragment purification and sequencing was carried out as previously described (25). Paired-end sequencing (2 × 75 bp) was carried out on an Illumina Next-seq 500 platform.
RESULTS

Systematic depletion of Okazaki nucleases and analysis of lagging-strand products

DNA2 is an essential gene in checkpoint-proficient *S. cerevisiae* (14), and rad27Δ mutants have several undesirable phenotypes including slow growth and elevated mutation rate (26). In addition, genetic interactions between lagging-strand nucleases render double- and triple-mutant strains inviable or extremely sick (17). Therefore, we used the anchor away conditional nuclear depletion strategy to analyze lagging-strand processing in the absence of Rad27 and Dna2. Anchor away depletion is mediated by dimerization of FRB-tagged nuclear proteins with FKBP-tagged ribosomal subunits, and rapidly depletes proteins from the nucleus (27). We constructed a panel of *S. cerevisiae* strains carrying all possible combinations of *exo1Δ*, *RAD27-FRB* and *DNA2-FRB*, in combination with an FRB-tagged allele of *CDC9* for simultaneous co-depletion of DNA ligase. All proteins were tagged at the C-terminus. Two biological replicates of each strain were obtained via sporulation with redundant genetic backgrounds. In wild-type *S. cerevisiae*, Okazaki fragment 5' and 3' termini are normally enriched at nucleosome dyads; a shift in this distribution towards the replication-fork-proximal edge of the nucleosome is indicative of nick translation by Pol δ and associated nucleases (25,28). Therefore, when Rad27 is absent, nick translation would leave juxtaposed termini, whereas extensive strand displacement would generate 5' and 3' ends that peak at different points in the nucleosome. To directly investigate the extent of strand-displacement synthesis by Pol δ and nucleolytic lagging-strand processing in nucleosomal DNA, we purified and sequenced Okazaki fragments from asynchronous cultures of strains depleted for one or both Okazaki nucleases for 1h. Distributions of Okazaki fragment termini around nucleosome dyads are shown in Figure 2. All data were highly reproducible across two biological replicates. Data from the second replicate corresponding to Figures 2 and 3 are shown in Supplementary Figure S1. For each sample, data were normalized to the maximum signal in the range to facilitate comparison between samples.

Okazaki fragment processing of nucleosomal DNA *in vivo*

In wild-type *S. cerevisiae*, Okazaki fragment 5' and 3' termini are normally enriched at nucleosome dyads; a shift in this distribution towards the replication-fork-proximal edge of the nucleosome indicates reduced nick translation by Pol δ and associated nucleases (25,28). It is further possible to distinguish reduced nick translation from ongoing strand-displacement synthesis in the absence of nucleosome cleavage by comparing the locations of the 5' and 3' ends of mature Okazaki fragments: reduced nick translation would leave juxtaposed termini, whereas extensive strand displacement would generate 5' and 3' ends that peak at different points in the nucleosome. To directly investigate the extent of strand-displacement synthesis by Pol δ and nucleolytic lagging-strand processing in nucleosomal DNA, we purified and sequenced Okazaki fragments from asynchronous cultures (25) after co-depletion of Cdc9 and all combinations of nucleases for 1h. Distributions of Okazaki fragment termini around nucleosome dyads are shown in Figure 2. All data were highly reproducible across two biological replicates. Data from the second replicate corresponding to Figures 2 and 3 are shown in Supplementary Figure S1. For each sample, data were normalized to the maximum signal in the range to facilitate comparison between samples.

Consistent with a global reduction in strand-displacement synthesis by Pol δ when processing nucleases are depleted, fragment 5' (Figure 2A) and 3' (Figure 2B) termini showed similar distributions within each sample. If strand displacement were occurring in the absence of nucleosome cleavage, 3' ends would show a wild-type distribution with respect to nucleosomes, while 5' ends would shift to more upstream locations. Depletion of Rad27 led to a pronounced shift in both 5' and 3' termini towards the replication-fork proximal edge of the nucleosome. Therefore, when Rad27 is absent, nick translation is substantially impaired even though most Okazaki termini are apparently not precisely juxtaposed (Figure 1B and C). Deletion of *EXO1* produced a lesser shift in the same direction, while depletion of Dna2 did not significantly impact Okazaki fragment terminus location. Additional deletion of Dna2 did not dramatically alter the location of termini in *RAD27-FRB* or *exo1Δ* strains. However, cells lacking both Exo1 and Rad27 activity showed an additional shift compared to each single mutant, consistent with redundancy between the two nucleases. Okazaki fragment distributions in the *RAD27-FRB DNA2-FRB exo1Δ* strain were similar to those in *RAD27-FRB exo1* (Figure 2A and B). Taken together, this suggests that depletion of Dna2 to levels that do not support viability does not have a significant impact on nucleosomal Okazaki fragment processing throughout most of the genome, even when one or both of the other Okazaki nucleases are absent. The distribution of Okazaki fragment termini supports a model whereby Rad27 processes the majority of 5' flaps, with a minor contribution from Exo1 and an extremely limited role for Dna2.
Figure 1. Enrichment of ligation-competent Okazaki fragments from strains lacking both lagging-strand nucleases and DNA ligase I. (A) Spot tests of indicated strains on YPD ± 2 μg/ml rapamycin at 30 or 37 °C, as indicated, for single and double mutant strains analyzed in this study. Addition of rapamycin depletes FRB-tagged proteins from the nucleus. (B) End-labeled Okazaki fragments obtained after 1 h rapamycin treatment to deplete DNA ligase I and FRB-tagged nucleases. Where indicated, DNA was treated with T4 DNA ligase after purification but before labeling to assess the proportion of Okazaki fragments poised for ligation. WT denotes an otherwise wild-type CDC9-FRB strain. The percentage of signal lost upon ligase treatment, calculated from three replicates and shown graphically in (C), is indicated under each pair of lanes. In both (B) and (C), P values for differences between paired samples with and without ligase were calculated by t-test. *** denotes P < 0.001, ** denotes P < 0.01, n/s denotes P > 0.05. (C) Quantification of Okazaki fragment end-labeling signal from (B). The cumulative signal from the region corresponding to sizes <1000 nt was calculated for three replicate experiments, of which (B) is a representative example. Mean ± SD is plotted and P values are as in (B).

Okazaki fragment processing of non-nucleosomal DNA in vivo

In nucleosome-free regions, Okazaki fragment termini are normally enriched immediately upstream of binding sites for the transcription factors Abf1, Reb1 and Rap1. These transcription factors re-associate quickly following DNA replication, and appear to represent ‘hard’ barriers to Pol δ in contrast to the ‘soft’ barrier activity of nucleosomes (25). We analyzed the distribution of Okazaki fragment termini around these transcription factor binding sites, as a means to investigate strand-displacement and processing on non-nucleosomal templates (Figure 3). Data were normalized to the median signal within the range in order to assess the propensity of Pol δ to terminate specifically at transcription-factor binding sites as opposed to nearby sequences.

In both wild-type and single nuclease depletions, we observed a prominent peak of Okazaki fragment 5′ and 3′ termini immediately upstream of a meta-binding site for Abf1/Reb1/Rap1 (Figure 3 A&B). However, the RAD27-FRB exo1Δ strain showed significantly reduced termination on the replication-fork proximal edge of the transcription-factor binding sites relative to the wild-type strain. The RAD27-FRB DNA2-FRB; exo1Δ strain generated slightly fewer fragments terminating at transcription-factor binding sites than the RAD27-FRB exo1Δ double mutant, suggesting that the decreased strand-displacement and nick translation on non-nucleosomal DNA in the absence of both Rad27 and Exo1 can be further reduced by removal of Dna2. These data are consistent with a globally similar distribution of nuclease activity on non-nucleosomal DNA to that observed within nucleosomes—i.e. major redundant roles for Rad27 and Exo1 and a limited role for Dna2. However, the distribution of Okazaki fragment termini around TF binding sites in both RAD27-FRB and exo1Δ strains...
Figure 2. Contributions of individual nucleases to Okazaki fragment processing in the context of nucleosomal DNA. (A) Distribution of Okazaki fragment 5′ termini around consensus dyad locations of the top 50% most highly occupied nucleosomes in the S. cerevisiae genome (38). WT, single mutants, double mutants and the triple mutant are displayed in separate graphs for clarity. Data are presented such that Okazaki fragment synthesis proceeds from left to right. Data are normalized to the maximum signal in the range, and smoothed to 5 bp. (B) Distribution of Okazaki fragment 3′ termini around nucleosome dyads, as in (A).

closely resembles that of a wild-type strain (Figure 3A and B). Therefore, our data suggest more extensive redundancy of Rad27 and Exo1 outside nucleosomes than on nucleosomal templates.

Uncoupling of Okazaki fragment processing from DNA synthesis

To investigate the extent to which the processing and ligation of the lagging strand can be uncoupled from its synthesis in vivo, we constructed strains in which expression of RAD27, DNA2, EXO1 or CDC9 was driven by the CLB2 promoter, and the protein fused to the N-terminal degron of the Clb2 protein. Expression of such CLB2-tagged constructs is limited to very late S- and G2 phase (29). Myc-tagged versions of Clb2-Cdc9, Clb2-Rad27, Clb2-Exo1 and Clb2-Dna2 were detectable by western blot: all proteins displayed the anticipated cell cycle expression profile, with expression limited to late S/G2 (Supplementary Figure S2A–F). The lower band in the Cdc9 blot represents the mitochondrial isoform of Cdc9 (30), which does not cycle in a cell cycle-dependent manner.

Sporulation of a heterozygous diploid CLB2-CDC9/CDC9 strain produced four viable spores per tetrad, indicating that expression of DNA ligase I exclusively at the end of S-phase and in G2 is sufficient to support viability (Figure 4A). Consistent with delayed ligation of Okazaki fragments when CDC9 expression is restricted, the CLB2-CDC9 strain transiently accumulated Okazaki fragments following release from G1 arrest which disappeared when ligation was enabled by CLB2-CDC9 expression in late S/G2 (Figure 4B). Sporulation of a CLB2-RAD27/RAD27 CLB2-EXO1/EXO1 strain also generated four viable spores per tetrad, although CLB2-RAD27 CLB2-EXO1 double mutant haploids grew slowly (Figure 4C). CLB2-RAD27 cells phenocopied the temperature-sensitivity and slow growth of rad27 cells, suggesting that these phenotypes arise due to a lack of Rad27 during S-phase (Supplementary Figure S2G). The observation that Rad27 and Exo1 together process the majority of Okazaki fragments in S. cerevisiae (Figures 2 and 3), but can maintain viability when expressed only after the bulk of replication has been completed, suggests that Okazaki fragment processing need not occur concurrently with replication.

Sporulation of a CLB2-RAD27/RAD27 CLB2-DNA2/DNA2 strain produced a mixture of viable and inviable spores (Figure 4D). Colonies formed from CLB2-DNA2 spores have an essentially wild-type growth phenotype (Figure 4D). Thus, the essential contribution of Dna2 to viability can apparently be executed after the majority of the genome has been synthesized. In contrast to CLB2-RAD27 CLB2-EXO1 double mutants, CLB2-RAD27 CLB2-DNA2 haploids are inviable (Figure 4D).
Figure 3. Contributions of individual nucleases to Okazaki fragment processing in the context of non-nucleosomal DNA. (A) Distribution of Okazaki fragment 5’ termini around binding sites for Abf1, Reb1 and Rap1 (25,39). As in Figure 2, WT, single mutants, double mutants and the triple mutant are displayed in separate graphs for clarity. Data are presented such that Okazaki fragment synthesis proceeds from left to right. Data are normalized to the median signal in the range, and smoothed to 5 bp. (B) Distribution of Okazaki fragment 3’ termini around binding sites for Abf1, Reb1 and Rap1, as in (A).

Therefore, although Exo1 apparently contributes to the overall processing of Okazaki fragments to a greater extent than Dna2 (Figure 2), at least some contribution from an endonucleolytic flap cleavage pathway (i.e. Dna2 or Rad27) is required for cells to progress through S-phase. We reasoned that the requirement for endonucleolytic Okazaki fragment processing during S-phase could arise from the accumulation of a small number of long, unprocessed flaps that might persist in \textit{CLB2-RAD27 CLB2-DNA2} cells (20). These long flaps could deplete cellular RPA pools, leading to checkpoint-mediated cell cycle arrest (31) and/or catastrophic failure of replication (32). To test whether excessive exposure of single-stranded DNA was the underlying cause of death in \textit{CLB2-RAD27 CLB2-DNA2} cells, we expressed the \textit{Escherichia coli} single-stranded binding protein SSB from a galactose-inducible promoter. \textit{CLB2-RAD27 CLB2-DNA2 GAL1-SSB} cells were inviable when grown on YPD to repress SSB expression, but viable when SSB was induced by growth on 2% galactose (Figure 4E). Thus, expression of a generic single-strand binding protein restores viability when neither Rad27 nor Dna2 is expressed during early or mid S-phase, indicating that endonucleolytic processing of the lagging strand can be deferred until after the majority of replication has been completed. To test whether this suppression of lethality was solely due to suppression of checkpoint activity, we generated \textit{CLB2-RAD27 CLB2-DNA2 rad9Δ} strains. Unlike SSB overexpression, deletion of \textit{RAD9} did not restore viability to \textit{CLB2-RAD27 CLB2-DNA2} cells (Figure 4F).

DISCUSSION

In this study, we investigated Okazaki fragment processing in the absence of all combinations of the Okazaki fragment nucleases Rad27, Dna2 and Exo1 by carrying out a systematic \textit{in vivo} analysis of Okazaki fragment size, ligatability and terminus location. Similarly to observations \textit{in vitro} (5,19), we observe that strand displacement synthesis by Pol δ is limited by the absence of nucleolytic Okazaki fragment cleavage (Figures 2 and 3). Interestingly, despite a significant reduction in strand-displacement synthesis by Pol δ, Okazaki fragments synthesized in the absence of Rad27 do not have readily ligatable termini (Figure 1B and C). We believe that the most likely scenario is that short flaps persist when both Rad27 and DNA ligase I are absent. However, \textit{RAD27} is not an essential gene in \textit{S. cerevisiae}; therefore,
long-lived flaps must eventually be removed in rad27 cells, presumably by Exo1 or Dna2 in order for rad27 cells to remain viable.

A strain in which the expression of both flap endonucleases, Rad27 and Dna2, is restricted until after bulk DNA synthesis can only survive when a single-stranded binding protein is overexpressed. Consistent with previous results from *S. pombe* (20), our data suggest that the large majority of Okazaki fragment termini apparently remain closely juxtaposed—either as ligatable nicks or very short flaps—even without significant nuclease processing. However, the inviability of *CLB2-RAD27 CLB2-DNA2* cells and its suppression by SSB overexpression suggests that some long flaps form in the absence of endonucleolytic Okazaki fragment processing, and that the formation of these structures is toxic: we propose that this toxicity stems from RPA depletion as opposed to persistent checkpoint activation, as deletion of *RAD9* does not restore viability to a *CLB2-RAD27 CLB2-DNA2* strain.

Our data suggest that Rad27 and Exo1 have partially redundant activity in Okazaki fragment 5’ flap processing (Figures 2 and 3). If each nuclease acted exclusively on a preferred set of substrates, the most likely outcome would be a bimodal distribution of Okazaki fragment termini in single mutant strains. Substrates normally cleaved by the depleted/deleted nuclease would not be processed, and would show a dramatic change in Okazaki fragment terminus location. Substrates normally cleaved by the other nuclease would be unaffected. We do not observe distributions of Okazaki fragment termini consistent with completely distinct substrates for Rad27 and Exo1. Instead, removal of Exo1 alone has a small but widespread impact on the location of Okazaki fragment termini, while the absence of Rad27 alone shifts a substantial fraction of Okazaki fragment termini towards the replication-fork proximal edge of the nucleosome (Figure 2). Importantly, the most common location of termini in the absence of both nucleases is distinct from that observed in the sole absence of either nu-
clease (Figure 2). Thus, fragments whose processing is impaired by the absence of Rad27 can apparently still be at least partially processed by Exo1. We propose that distinct Okazaki nucleases do not have rigid substrate preferences, but instead compete to cleave lagging-strand substrates in vivo. We note that this model is consistent with the observed suppression of replication-associated rad27Δ phenotypes by overexpression of Exo1 (33).

Although Rad27 and Exo1 can redundantly process lagging-strand 5’ flaps, removal of either nuclease leads to a widespread reduction in strand-displacement synthesis by Pol δ, especially in the context of nucleosomes (Figures 2 and 3). The absence of Rad27 reduces strand displacement more than the absence of Exo1. Because each Okazaki fragment is initiated by the error-prone Pol α, such a widespread reduction in nick translation by Pol δ would most likely increase the extent to which DNA synthesized by Pol α is transmitted to daughter cells. Both rad27Δ (26) and exo1Δ (33) strains are mutants, and the phenotype of rad27Δ is notably more severe than that of exo1Δ. Given the correlation between the strength of the mutator phenotype and the extent to which strand-displacement by Pol δ is reduced, we speculate that retention of genomic DNA synthesized by Pol α underlies the elevated mutation rates observed when these genes are absent. Consistent with this model, temperature-sensitive dna2 strains are not mutators (17) and depletion of Dna2 does not significantly alter global strand displacement in vivo (Figures 2 and 3).

We observe that the contribution of Dna2 to Okazaki fragment processing is extremely limited in the uniquely mappable regions of the genome that can be assayed using our sequencing methodology (Figures 2 and 3). In addition, CLB2-DNA2 cells do not have a detectable growth defect (Figure 4D). Therefore, although the nuclease activity of Dna2 is essential for viability in checkpoint-proficient cells (34), the absence of Dna2 during S-phase is not obviously detrimental to exponentially dividing S. cerevisiae cells. It is possible that Dna2 is required for the cleavage of only a small number of Okazaki fragment 5’ flaps – either long flaps generated by low levels of ongoing strand displacement without nuclease cleavage, or those in specific, late-replicating repeat regions such as telomeres (35,36) or the rDNA repeat (37).

DATA AVAILABILITY

Sequencing data are available from GEO under accession number GSE118078.

SUPPLEMENTARY DATA

Supplementary Data are available at NAR Online.
