Precise radial velocities of giant stars

IV. A correlation between surface gravity and radial velocity variation and a statistical investigation of companion properties

ABSTRACT

Context. Since 1999, we have been conducting a radial velocity survey of 179 K giants using the Coudé Auxiliary Telescope at UCO/Lick observatory. At present ~20–100 measurements have been collected per star with a precision of 5 to 8 m s⁻¹. Of the stars monitored, 145 (80%) show radial velocity (RV) variations at a level >20 m s⁻¹, of which 43 exhibit significant periodicities.

Aims. Our aim is to investigate possible mechanism(s) that cause these observed RV variations. We intend to test whether these variations are intrinsic in nature, or possibly induced by companions, or both. In addition, we aim to characterise the parameters of these companions.

Methods. A relation between log g and the amplitude of the RV variations is investigated for all stars in the sample. Furthermore, the hypothesis that all periodic RV variations are caused by companions is investigated by comparing their inferred orbital statistics with the statistics of companions around main sequence F, G, and K dwarfs.

Results. A strong relation is found between the amplitude of the RV variations and log g in K giant stars, as suggested earlier by Hatzes & Cochran (1998). However, most of the stars exhibiting periodic variations are located above this relation. These RV variations can be split in a periodic component which is not correlated with log g and a random residual part which does correlate with log g. Compared to main-sequence dwarf stars, K giants frequently exhibit periodic RV variations. Interpreting these RV variations as being caused by companions, the orbital parameters are different from the companions orbiting dwarfs.

Conclusions. Intrinsic mechanisms play an important role in producing RV variations in K giants stars, as suggested by their dependence on log g. However, it appears that periodic RV variations are additional to these intrinsic variations, consistent with them being caused by companions. Indeed the majority of the periodic RV variations in K giants is interpreted as due to substellar companions, then massive planets are significantly more common around K giants than around F, G, K main-sequence stars.

1. Introduction

For more than a decade, radial velocity observations with accuracies of order m s⁻¹ have been within reach (see for instance Marcy & Butler 2000; and Queloz et al. 2001). Even accuracies of less than 1 m s⁻¹ (Pepe et al. 2003) are possible now. With these observations, more than 200 sub-stellar companions have been discovered by measuring the reflex motions of their parent stars. Most of these sub-stellar companions have been detected around F, G and K main sequence stars, but detections around an A star (Galland et al. 2006) and several subgiants (Johnson et al. 2006, 2007) have also been reported recently. Moreover, 10 giant stars were reported to have sub-stellar companions (α Draconis (K2III) Frink et al. 2002; HD 104985 (G9III) Sato et al. 2003; HD 47526 (K1III) Setiawan et al. 2003; HD 13189 (K2II-III) Hatzes et al. 2005; HD 11977 (G5III) Setiawan et al. 2005; Pollux (K0III) Hatzes et al. 2006; Reffert et al. 2006; 4UMa (K1III) Döllinger et al. 2007, NGC 2423 No. 3 and NGC 4349 No. 127 Lovis & Mayor 2007; and recently HD 17092 (K0III) Niedzielski et al. 2007). In addition to searches for extra-solar companions, radial velocity observations prove to be very useful for detecting solar-like oscillations in stars with turbulent atmospheres, such as the dwarf α Cen A (e.g. Bedding et al. 2006), the subgiant Procyon (e.g. Eggenberger et al. 2004; Martí et al. 2004) and the giant ε Ophiuchi (e.g. De Ridder et al. 2006).

With techniques for accurate radial velocity observations at hand, a survey was started in 1999 to verify whether K giants are stable enough to be used as astrometric reference stars for SIM/PlanetQuest (Space Interferometry Mission) (Frink et al. 2001). This survey contains 179 stars and uses the Coudé Auxiliary Telescope (CAT) at University of California Observatories / Lick Observatory, in conjunction with the Hamilton Echelle Spectrograph. The survey has recently been expanded to about 380 giants and is still ongoing. For the

* Based on data obtained at UCO/Lick Observatory, USA.
The period of the star in Fig. 1 is highly significant, while the
periodicity of the radial velocity variations is determined first of all from a
classical Lomb-Scargle (LS) periodogram (Scargle 1982). The
significance threshold is set to 6σ, where the noise level is
determined from the average power of the residual Scargle pe-
riodogram for frequencies between 0 and 0.03 cycles per day
(c/d) (0.35 μHz) and a frequency step of 0.00001 c/d (0.12 × 10⁻³ μHz).
We adopted the conventional method of iterative
sinewave fitting ( "prewhitening" ) to search for subsequent fre-
quencies (Kuschnig et al. 1997). In Figs. 1 and 2, the radial ve-
clocity variation as a function of phase is shown for two stars.
The period of the star in Fig. 1 is highly significant, while the
evolution of the investigated timescales, are most likely caused by some
intrinsic mechanism, while the periodic variability can also be
caused by companions. We also investigate the characteristics of
these companions.

In Sect. 2, the radial velocity observations are described in
detail. In Sect. 3, the relation between the observed radial ve-
clocity amplitude and surface gravity is investigated. In Sect. 4,
we explore the hypothesis that all periodic radial velocity varia-
tions are caused by sub-stellar companions, and we compare the
inferred orbital parameters with those obtained for sub-stellar
companions orbiting main sequence stars. Our conclusions are
presented in Sect. 5.

2. Radial velocity variations

The initial 179 stars selected for the radial velocity survey are
used in the present work. These stars have been selected from the
Hipparcos catalogue (Perryman & ESA 1997), based on the
criteria described by Frink et al. (2001). The selected stars are
all brighter than 6 mag, are presumably single and have photometric variations <0.06 mag in V. The survey started in 1999 at
Lick Observatory using the Coudé Auxiliary Telescope (CAT)
in conjunction with the Hamilton Echelle Spectrograph (R =
60 000). The system with an iodine cell in the light path has been
described by Marcy & Butler (1992) and Valenti et al. (1995).
With integration times of up to thirty minutes for the faintest
stars (m_v = 6 mag) we reach a signal to noise ratio of about
80–100 at λ = 5500 Å, yielding a radial velocity precision of
5–8 m s⁻¹. As we are looking for radial velocity variations of
order 10 to 100 m s⁻¹, this is adequate and hence no attempt has
been made to reach the 3 m s⁻¹ accuracy which is in principle
possible with this setup (Butler et al. 1996). For the determina-
tion of the radial velocities the pipeline described by Butler et al.
(1996) is used. In this pipeline, a template iodine spectrum and
a template spectrum of the target star obtained without an iodine
cell in the lightpath are used to model the stellar observations
with a superposition iodine spectrum. The Doppler shift is a free
parameter in this model. Note that with this method the absolute
radial velocity is not measured, but the radial velocity relative to
the stellar template is obtained.

All 179 stars are subjected to a period search. The periodic-
ity of the radial velocity variations is determined first of all from a
classical Lomb-Scargle (LS) periodogram (Scargle 1982). The
significance threshold is set to 6σ, where the noise level is
determined from the average power of the residual Scargle pe-
riodogram for frequencies between 0 and 0.03 cycles per day
(c/d) (0.35 μHz) and a frequency step of 0.00001 c/d (0.12 × 10⁻³ μHz).
We adopted the conventional method of iterative
sinewave fitting ( "prewhitening" ) to search for subsequent fre-
quencies (Kuschnig et al. 1997). In Figs. 1 and 2, the radial ve-
clocity variation as a function of phase is shown for two stars.
The period of the star in Fig. 1 is highly significant, while the
one in Fig. 2 is close to the significance threshold. Periodograms
are shown in the bottom panels of these figures. As properly
emphasized by Cumming et al. (1999), such a classical period
search may not be appropriate for unevenly spaced sparse data,
even though we set the significance level at a conservatively high
level. In order to check this, we have done an additional LS anal-
ysis after prewhitening the original data by a linear polynomial.
This led almost always to the same frequencies. We only ac-
cepted a frequency when it was found to meet the significance
criterion for both these analyses. The significant frequencies are
listed in Table 1.

3. Radial velocity amplitude – surface gravity
relation

Hatzes & Cochran (1998) already investigated the origin of the
observed radial velocities in K giant stars. Although their sample
contained only 9 stars, they suggested that the amplitude of the
radial velocity increases with decreasing surface gravity (log g).
In lower surface gravity it takes longer to decrease the velocity
of a moving parcel which results in larger amplitudes and the
relation suggested by Hatzes & Cochran (1998) would therefore
be evidence for pulsations or rotational modulation as the mech-
anism for these long period radial velocity variations.

For the present sample, log g values were determined spec-
roscopically by Hekker & Meléndez (2007), by imposing exci-
tation and ionisation equilibrium of iron lines through stel-
lar models. The equivalent width of about two dozen carefully
selected iron lines were used for a spectroscopic LTE analysis
based on the 2002 version of MOOG (Sneden 1973) and Kurucz
model atmospheres which include overshooting (Castelli et al.
1997). These authors estimated the error on log g to be 0.22 dex
from the scatter found in a comparison with literature values. A
detailed description of the stellar parameters for individual stars
and a comparison with literature values are available in Hekker
& Meléndez (2007) and is therefore omitted here.
In Fig. 3, we show half of the peak-to-peak value of the observed radial velocity variations as a function of log $g$ for K giants in our sample. A clear trend is visible between increasing radial velocity variations in single stars, and decreasing log $g$, which provides a strong indication that, at least for a large fraction of stars in our sample, the observed radial velocity variations are induced by a mechanism intrinsic to the star. This trend is present for stars with random as well as stars with periodic radial velocity variations. Also, nearly all stars with periodic radial velocity variations and log $g \geq 1.6$ are located above the fit in Fig. 3. Seven single stars have a higher radial velocity variation than expected based on their log $g$ value, i.e. they are situated more than 3.5$\sigma$ above the best fit for the relation obtained for single stars. These stars are indicated with arrows in Fig. 3. The radial velocity variation observed for HIP 53229 may be due to a stellar companion in a wide orbit, with a period much longer than the observation time span. Due to this long period the companion mass, and, therefore, the (sub)-stellar nature, is still very uncertain. HIP 33152 is classified as a supergiant. The observed radial velocity variations for HIP 80693, HIP 36616, and HIP 88048 can be fitted with two Keplerian orbits, while HIP 75458 can be explained by an eccentric sub-stellar companion (Frink et al. 2002) and an additional linear trend, indicating a companion in a wide orbit. HIP 34693 can be fitted very accurately with a Keplerian orbit of a single nearly sinusoidal sub-stellar companion.

In order to investigate the simultaneous occurrence of sub-stellar companions and oscillations in giants, the best Keplerian fits are subtracted from the observed radial velocity variations of both the binaries and the single stars with significant periodic radial velocity variations. The half peak-to-peak values of these residuals are plotted as a function of surface gravity in Fig. 4, also showing the linear fit through the non-periodic stars, and the amplitudes of the subtracted periodic signals. There are several interesting points to make about this graph. Firstly, almost all periodic stars show larger radial velocity variations than predicted by the relation found for non-periodic stars, but when the periodicities are removed, their residual radial velocity variations follow the same relation as found for the non-periodic stars. This could be interpreted as evidence for both intrinsic (non-periodic radial velocity variation) and extrinsic (periodic variations) mechanisms playing a role in these stars. Secondly, there is no correlation between the amplitude of the subtracted periodic signal and log $g$, which provides additional evidence for the presence of companions. Thirdly, almost all (8 out of 9) stars with log $g \leq 1.6$ exhibit periodic variations. If these indeed have an extrinsic mechanism, it would mean that ~90% of these stars have sub-stellar companions. However, from an astrophysical point of view, stars with such low surface gravities are already very high on the giant branch or even on the asymptotic giant branch. At these low gravities, stars cannot be constant anymore, as the outer layers are so diluted that instabilities occur easily, either periodic or random. Stated differently, these stars are very close to the semi-regulars, which are on their way to become Mira variables. Hence, these periodic variations could well be intrinsic.

4. Companion interpretation

From the analysis of the correlation between radial velocity amplitude and surface gravity we have evidence for the presence of both intrinsic variability and companions in at least a fraction of the K giant stars with periodic radial velocity variations. In order to study the characteristics of these companions, we take the hypothesis that the periodic radial velocity variations detected in 43 of our K giant stars, excluding binaries, are caused by sub-stellar companions. Under this hypothesis, we investigate the statistical properties of the orbital parameters of the sample and compare these with the statistical properties of companions orbiting F, G and K dwarfs.

According to our analysis, 55 stars in the sample would have a single companion, and 11 stars multiple companions. Twenty-three (22 single and 1 in a multiple system) of these companions have $m \sin i$ larger than 100 $M_{\text{Jup}}$ and should be interpreted as stellar binaries. By advancing the multiple sub-stellar systems forward in time via a Runge-Kutta integration, we investigated the stability of the systems, taking into account the mutual interactions of the companions. With the orbital parameters that minimise $\chi^2$ taken at face value, we found that most of the inferred sub-stellar multiple systems would be "likely unstable", with a change in semi-major axis $>1\%$ and $<10\%$, or "unstable" with a change in semi-major axis $>10\%$ on a time scale of 100 years due to companion-companion interaction.

However, the inferred stability depends on the starting epoch of the computations, as well as on the orbital parameters, which might change with an increasing number of observations. Furthermore, there is no guarantee that the obtained $\chi^2$ minimum is a global minimum. Therefore, stars with multiple inferred substellar companions that seem to be unstable, might also have stable solutions. One could also use the equations for dynamical stability described by Gladman (1993) and Marcy et al. (2001). Gladman (1993) also notes that the Hill stability criteria for companions in initially eccentric orbits may not be met, but that the systems may still be found to be empirically quite stable for a long period of time. In order to draw a firm conclusion on the stability of a particular system, a more thorough investigation is needed, as well as data with a longer time base, which is beyond the scope of this paper.

For all stars with periodic radial velocity variations, we checked the Hipparcos (Perryman & ESA 1997) photometry. We checked periodograms for significant frequencies close to the obtained radial velocity period, and plotted the photometric values phased with the radial velocity period. None of the stars show photometric variations related to the observed radial velocity variations.

The mass distribution of our K giant sample is not known very well. The stellar masses are typically between 1 and 4 $M_\odot$. Hence most of their main sequence progenitors should have been of A or F spectral class. The distribution of orbital parameters of substellar companions orbiting A and F main sequence stars is still unknown. The core accretion model predicts more giant planets around more massive stars, so that the distribution of orbital parameters of substellar companions...
Fig. 4. Top: half of the peak-to-peak variation of the radial velocity as a function of surface gravity (log $g$), as in Fig. 3, but showing only those stars with periodic radial velocity variations (blue ◦) and stellar binaries (black ◦). The blue + and black × symbols indicate the amplitude of the radial velocity variations for these stars after subtraction of the Keplerian fits. (Colours are only visible in the online version of the paper.) The solid line indicates the linear fit through the stars with non-periodic radial velocity variations (from Fig. 3). Bottom: amplitudes of the subtracted Keplerian fits as a function of log $g$.

orbiting F, G and K main-sequence stars probably cannot serve as a proxy. However, it should be instructive to compare the two distributions.

Since the data presented here span $\sim 2500$ days, radial velocity variations with longer periods are uncertain, and, therefore, not taken into consideration. Companions with periods exceeding the observation time span are also excluded from the F, G, and K main sequence star statistics.

4.1. Mass distribution

Figure 5 shows the distribution of inferred companion masses of our K giant sample. First, notice that 30% of the inferred companions would have masses in the brown dwarf regime $15 M_{\text{Jup}} < m \sin i < 80 M_{\text{Jup}}$. This is in sharp contrast to the brown dwarf statistics around F, G and K main sequence stars for which only very few companions are found with $m \sin i > 15 M_{\text{Jup}}$ around more than thousand stars. This is known as the brown dwarf desert and is possibly caused by migration and merging of brown dwarfs in a viscous disk with a mass at least comparable to the brown dwarf mass (Armitage & Bonnell 2002).

The dashed line in Fig. 5 indicates the rise of sub-stellar companion masses $M^{-1.05}$ from $10 M_{\text{Jup}}$ down to Saturn masses for main sequence stars (Marcy et al. 2005), normalised to the number of stars in our sample. We use a two-sided Kolmogorov-Smirnov test (Press et al. 1992) (hereafter KS-test) to compare the $M^{-1.05}$ fit and the mass distribution ($m \sin i < 80 M_{\text{Jup}}$) of our sample and find a probability of 0.05% (0.002%
4.2. Semi-major axis distribution

The distribution of the companions’ semi-major axis is shown in Fig. 7. No inferred companions with semi-major axis smaller than 0.3 AU are present in the K giant sample, possibly due to increased stellar radii of giants. The fraction of companions with an inferred companion with a semi-major axis between 1 and 3 AU is much higher among the K giants compared to the F, G and K dwarfs. This implies that inferred sub-stellar companions orbiting K giant stars in our survey have higher masses compared to companions around F, G and K main sequence stars.

Figure 6 shows the low-mass companion distribution of our survey. Most K giant companions would have inferred masses between 2 and 8 $M_{\text{Jup}}$, while the fraction of companions orbiting F, G and K dwarfs strongly decreases with increasing $m \sin i$.

4.3. Period distribution

In Fig. 8 the period distribution of the observed radial velocity variations is shown and compared with the companion period distribution of dwarfs. The large fraction of F, G and K dwarf companions with orbital periods shorter than 100 days corresponds to the ones with semi-major axis smaller than approximately 0.3 AU. The close-in short-period companions are not present around K giants, while about 80% of these stars with observed radial velocities have periods ranging between 400 and 800 days. A KS-test reveals a probability of less than 0.0001% for the two distributions to be identical. The probability remains below this level, when the companions orbiting main sequence stars with a semi-major axis <0.3 AU are omitted.

4.4. Eccentricity distribution

Figure 9 shows the distribution of companion eccentricities for K giants in our sample and for dwarfs. Companions of dwarfs with periods less than 20 days are excluded, as these might be tidally circularised. The fraction of companion eccentricities $<0.3$ for the giants is 75% compared to 50% for companions orbiting F, G and K dwarfs. The KS-test shows that these distributions are nearly identical (97%).

4.5. Iron abundance

Companion occurrence correlates strongly with the abundance of heavy elements (see for instance Gonzalez 1997; Fischer & Valenti 2005; and Santos et al. 2005), such that F, G, and K dwarf stars with supersolar abundance are more likely to harbour sub-stellar companions (about 50% of the stars with $0.3 < [\text{Fe/H}] < 0.5$). The increase of the fraction of F, G and K dwarfs harbouring companions with increasing metallicity is well fitted.
with a power law, yielding a probability for such a star to harbour a companion to be: $P = 0.03 \cdot (N_{\text{Fe}}/N_{\text{H}})/(N_{\text{Fe}}/N_{\text{H}})_\odot^{2.7}$ (Fischer & Valenti 2005).

In Fig. 10 the iron abundance distribution of stars with periodic radial velocity variations is shown as a percentage of the total number of observed stars with iron abundance in the same interval. The iron abundance is determined spectroscopically by imposing excitation and ionisation equilibrium in iron lines and is described by Hekker & Meléndez (2007). The maximum iron abundance of a K giant star in our sample is 0.29 and, therefore, we do not probe the high metallicity region in which F, G and K dwarfs are most likely to harbour a companion.

The mean metallicity of the K giants in the entire sample is $-0.12$ dex, while the mean metallicity of the stars with periodic radial velocity variations, presented in Fig. 10, is $-0.13$ dex. No correlation between companion occurrence and abundance, similar to the one which is present for dwarf stars, is found in this sample of giant stars.

### 5. Discussion and conclusion

The tight correlation we found between $\log g$ and half of the peak-to-peak radial velocity variations seems to indicate that a large fraction of the observed radial velocity variations in our sample of K giants is induced by mechanism(s) intrinsic to the stars. We also present evidence that both intrinsic and extrinsic mechanisms play a role. The stars with a significant periodic signal are almost all located above the radial velocity amplitude vs. $\log g$ relation, but when the periodic signal is removed, the residuals show the same trend as for the non-periodic stars. Furthermore, no correlation is present between the amplitude of the periodic signal and $\log g$.

Almost all of the lowest $\log g$ stars show periodic variations. It may be possible that stars with such low surface gravity cannot be constant and that in these dilute atmospheres instabilities can occur very easily, and therefore may be periodic, but not extrinsic.

Based on the evidence that extrinsic mechanism(s) play a role for K giant stars with periodic radial velocity variations we investigated the hypothesis that this periodic signal is caused by the reflex motion of sub-stellar companions orbiting these stars. We presented the characteristics of the orbital parameters of these companions and compared them with the known orbital parameters of sub-stellar companions orbiting F, G and K dwarfs.

About 25% of the stars in our sample have radial velocity variations with significant periodicity, and could possibly harbour a sub-stellar companion, while approximately only 8% of the 1330 F, G and K main sequence stars investigated by Marcy et al. (2005) have a sub-stellar companion. Recently Johnson et al. (2007) and Lovis & Mayor (2007) showed that the number of companion harbouring stars increases with mass. The giants in the present sample have typical masses between 1 and 4 $M_\odot$ and are in general more massive than the main sequence stars investigated for companions. So, the high percentage is qualitatively in agreement with the results from the literature. Furthermore, Lovis & Mayor (2007) suggest that more massive stars form more massive planetary systems than lower mass stars. Figures 5 and 6 show that we find, in general, more massive companions around the more massive K giants than are present around F, G and K dwarfs.

The high percentage of more massive companions around the more massive K giant stars would also be compatible with the core accretion model. This model predicts very few giant planets, but a relatively large number of planets with the mass of Neptune or smaller around M dwarfs (Laughlin et al. 2004; Ida & Lin 2005). This is mainly the result of a much reduced surface density of the disk and the resulting shorter disk evolution timescales compared to those for more massive stars, implying that planet properties vary with the mass of their host stars. In particular, one would expect more sub-stellar companions with higher masses in our giant sample, as is indeed the case if we assume that the companion hypothesis is correct.

The mean metallicity of companion-hosting K giants would be similar to the mean metallicity of the total sample. This is in contrast with the correlation between companion occurrence and
metallicity present in F, G and K dwarfs (e.g. Fischer & Valenti 2005). So far, several groups have investigated the correlation between companion occurrence and metallicity for giants with different results. Sadakane et al. (2005) and Pasquini et al. (2007) agree that companion-hosting giants are on average not metal-rich, while Hekker & Meléndez (2007) find that giants with announced companions have higher metallicities than their total sample of giants. A detailed discussion about these different results is presented by Hekker & Meléndez (2007). They conclude that the samples on which the results are based are slightly different and the more metal-rich stars used in their study are lacking in the study by Pasquini et al. (2007). Furthermore, there is a difference in zero-point correction for the metallicities of announced companion-hosting stars from different surveys. All in all, these inferences are based on small-number statistics and all results have to be taken with caution.

The larger semi-major axis and long periods of the inferred companions orbiting K giant stars compared to companions orbiting dwarf stars are most likely due to the extended atmospheres of K giants. For the eccentricity no significant difference is found in the distribution between companions orbiting dwarfs or giants. Nevertheless, the high number of inferred companions around giants with eccentricities <0.3 is striking. One could suspect that companion orbits circularise over time and that the companions in circular orbits are older than the eccentric ones, but there is no evidence for this hypothesis.

In principle, nearly sinusoidal radial velocity variations could also be caused by pulsations or spots. Although the periods of the radial velocity variations could well be the rotational periods of the stars, the presence of prominent spots is not very likely. In that case one would also expect photometric variations with periods correlated with the radial velocity variations. From the Hipparcos photometry (Perryman & ESA 1997) such correlations were not found.

In order to distinguish with certainty between companions and pulsations as the cause of the observed radial velocity variations, one needs to perform a spectral line profile analysis. A technique for doing this with very high-resolution spectra (R ≥ 100 000) will be presented separately (Hekker et al., in preparation) because the amount of such data at hand today is insufficient to add significantly to the conclusions of this paper.

Acknowledgements. We thank Debra Fischer, Geoff Marcy and Paul Butler for useful discussions and the development of the instrumentation and software for the determination of the radial velocities at Lick Observatory. In addition, we thank the entire staff at Lick Observatory for their excellent support. Finally, we would like to thank the anonymous referee for valuable comments and suggestions.
