(for the BABAR Collaboration)

The BABAR detector, which operates at the SLAC PEP-II asymmetric $e^+e^-$ collider at energies near the $\Upsilon(4S)$ resonance, started operation on the 26th of May 1999. We present the first study of $\sin^2\beta$, with samples of $B^0 \to J/\psi K_S^0$ and $B^0 \to \psi(2S)K_S^0$ decays, using 9.0 fb$^{-1}$ of data recorded between January and July 2000 at the $\Upsilon(4S)$ resonance and 0.8 fb$^{-1}$ recorded 40 MeV below the $\Upsilon(4S)$ resonance. A preliminary result of $\sin^2\beta = 0.12 \pm 0.37$ (stat) $\pm 0.09$ (syst) was obtained. Details of the analysis are given. Moreover, we present measurements of charged and neutral $B$ meson lifetimes and $B^0\bar{B}^0$ oscillation frequency.

1 Introduction

The primary goal of the BABAR experiment at PEP-II is to overconstrain the Unitarity Triangle. The sides of this triangle can be measured through non-CP violating physics, such as $V_{ub}$, $V_{cb}$, $V_{td}$ measurements [1], while its angles are accessible through CP violating processes [1].

2 PEP-II

The PEP-II $B$ Factory [2] is an $e^+e^-$ colliding beam storage ring complex on the SLAC site designed to produce a luminosity of at least $3 \times 10^{33} \text{ cm}^{-2}\text{s}^{-1}$ at a center–of–mass energy of 10.58 GeV, the mass of the $\Upsilon(4S)$ resonance. In the 2000 run, the achieved average luminosity was $2.5 \times 10^{33} \text{ cm}^{-2}\text{s}^{-1}$, with a daily average integrated luminosity of 135 pb$^{-1}$. The total collected luminosity was about 22 fb$^{-1}$. The machine is asymmetric with a High Energy Ring (HER) for the 9.0 GeV electron beam and a Low Energy Ring (LER) for the 3.1 GeV positron beam. This corresponds to $\beta\gamma=0.56$ and makes it possible to measure time dependent CP violating asymmetries. It corresponds to an average separation of $\beta\gamma c \tau=250 \mu$m between the two B mesons vertices.

3 BABAR

3.1 Detector description [2]

The volume within the BABAR superconducting solenoid, which produces a 1.5 T axial magnetic field, consists of: a five layer silicon strip vertex detector (SVT), a central drift chamber (DCH), a quartz-bar Cherenkov radiation detector (DIRC) and a CsI crystal electromagnetic calorimeter (EMC). Two layers of cylindrical resistive plate counters (RPCs) are located between the barrel calorimeter and the magnet cryostat. All the detectors located inside the magnet have full acceptance in azimuth. The integrated flux return (IFR) outside the cryostat is composed of 18 layers of steel, which successively increase in thickness away from the interaction point, and are instrumented with 19 layers of planar RPCs in the barrel and 18 in the endcaps.

3.2 Event reconstruction [2]

Charged particles are detected and their momentum is measured by a combination of the DCH and SVT. The charged particle momentum resolution is approximately given by $(\frac{\delta p_T}{p_T})^2 = (0.0015 p_T)^2 + (0.005)^2$, where $p_T$ is in GeV/$c$. The SVT, with a typical resolution of 10 $\mu$m per hit, provides excellent vertex resolution both in the transverse plane and in $z$. The vertex resolution in $z$ is typically 50 $\mu$m for a fully reconstructed $B$ meson and of order 100 $\mu$m for the distance among the two $B$ mesons when only one is fully reconstructed. Leptons and hadrons are identified using a combination of measurements from all the BABAR components, including the energy loss $dE/dx$ in the helium-based gas of the DCH (40 samples maximum) and in the silicon of the SVT (5 samples maximum). Electrons and photons are identified in the barrel and the forward regions by the EMC, and muons are
identified in the IFR. In the barrel region the DIRC provides excellent kaon identification over the full momentum range above 250 MeV/c.

4 sin2β measurement

In $e^+e^-$ storage rings operating at the $\Upsilon(4S)$ resonance a $B^0\bar{B}^0$ pair produced in a $\Upsilon(4S)$ decay evolves in a coherent $P$-wave until one of the $B$ mesons decays. If one of the $B$ mesons ($B_{tag}$) can be ascertained to decay to a state of known flavor at a certain time $t_{tag}$, the other $B$ ($B_{CP}$) is at that time known to be of the opposite flavor. For the measurement of $\sin^2\beta$, $B_{CP}$ is fully reconstructed in a $CP$ eigenstate ($J/\psi K_S^0$ or $\psi(2S)K_S^0$). By measuring the proper time interval $\Delta t = t_{CP} - t_{tag}$ from the $B_{tag}$ decay time to the decay of the $B_{CP}$ ($t_{CP}$), it is possible to determine the time evolution of the initially pure $B^0$ or $\bar{B}^0$ state:

$$f\pm(\Delta t; \Gamma, \Delta m_d, D\sin 2\beta) = \frac{1}{4} \Gamma e^{-\Gamma|\Delta t|} [1 \pm D\sin 2\beta \times \sin \Delta m_d \Delta t] ,$$

(1)

where the $+ \text{ or } -$ sign indicates whether the $B_{tag}$ is tagged as a $B^0$ or a $\bar{B}^0$, respectively. The dilution factor $D$ is given by $D = 1 - 2w$, where $w$ is the mistag fraction, i.e., the probability that the flavor of the tagging $B$ is identified incorrectly. A direct $CP$ violation term proportional to $\cos \Delta m_d \Delta t$ could arise from the interference between two decay mechanisms with different weak phases. In the Standard Model, we consider that the dominant diagrams for the decay modes have no relative weak phase, so no such term is expected.

To account for the finite resolution of the detector, the time-dependent distributions $f_{\pm}$ for $B^0$ and $\bar{B}^0$ tagged events (Eq. 1) must be convoluted with a time resolution function $R(\Delta t; \hat{a})$:

$$F_{\pm}(\Delta t; \Gamma, \Delta m_d, D\sin 2\beta, \hat{a}) = f_{\pm}(\Delta t; \Gamma, \Delta m_d, D\sin 2\beta) \otimes R(\Delta t; \hat{a}) ,$$

(2)

where $\hat{a}$ represents the set of parameters that describe the resolution function.

It is possible to construct a $CP$-violating observable

$$A_{CP}(\Delta t) = \frac{F_+(\Delta t) - F_-(\Delta t)}{F_+(\Delta t) + F_-(\Delta t)} ,$$

(3)

which is approximately proportional to $\sin^2\beta$:

$$A_{CP}(\Delta t) \sim D\sin 2\beta \times \sin \Delta m_d \Delta t .$$

(4)

Since no time-integrated $CP$ asymmetry effect is expected, an analysis of the time-dependent asymmetry is necessary. At an asymmetric-energy $B$ Factory, the proper decay-time difference $\Delta t$ is, to an excellent approximation, proportional to the distance $\Delta z$ between the two $B^0$-decay vertices along the axis of the boost, $\Delta t \approx \Delta z/c \langle \beta \gamma \rangle$.

Since the amplitude of the time-dependent $CP$-violating asymmetry in Eq. 3 involves the product of $D$ and $\sin^2\beta$, one needs to determine the dilution factors $D_i$ (or equivalently the mistag fractions $w_i$) in order to extract the value of $\sin^2\beta$. The mistag fractions are determined from the data by studying the time-dependent rate of $B^0\bar{B}^0$ oscillations.
The value of the single free parameter $\sin 2\beta$ is extracted from the tagged $B_{CP}$ sample by maximizing the likelihood function

$$
\ln L_{CP} = \sum_i \left[ \sum_{B^0 \text{ tag}} \ln F_+ (\Delta t; \Gamma, \Delta m_d, \hat{a}, D_i \sin 2\beta) + \sum_{B^0 \text{ tag}} \ln F_- (\Delta t; \Gamma, \Delta m_d, \hat{a}, D_i \sin 2\beta) \right],
$$

where the outer summation is over tagging categories $i$.

### 4.1 Analysis

For this analysis we use a sample of 9.8 fb$^{-1}$ of data recorded between January and the beginning of July 2000, of which 0.8 fb$^{-1}$ was recorded 40 MeV below the $\Upsilon(4S)$ resonance (off-resonance data).

The measurement of the $CP$-violating asymmetry has five main components:

- Selection of the signal $B^0/\bar{B}^0 \rightarrow J/\psi K^0_s$ and $B^0/\bar{B}^0 \rightarrow \psi(2S)K^0_s$ events, as described in detail in [3].

Distributions of $\Delta E$, the difference between the reconstructed and expected $B$ meson energy measured in the center–of–mass frame, and $m_{ES}$, the beam–energy substituted mass, are shown in Fig. 1 for the $J/\psi K^0_s (K^0_s \rightarrow \pi^+\pi^-)$ and $J/\psi K^0_s (K^0_s \rightarrow \pi^0\pi^0)$ samples. Signal event yields and purities, determined from a fit to the $m_{ES}$ distributions after selection on $\Delta E$, are summarized in Table 1.

- Measurement of the distance $\Delta z$ between the two $B^0$ decay vertices along the $\Upsilon(4S)$ boost axis, as described in detail in [4] and [5].
Table 1: Event yields for the different samples used in this analysis, from the fit to $m_{ES}$ distributions after selection on $\Delta E$. The purity is quoted for $m_{ES} > 5.270 \text{MeV}/c^2$.

| Final state | Yield | Purity (%) |
|-------------|-------|------------|
| $J/\psi K^0_S (K^0_S \rightarrow \pi^+ \pi^-)$ | 124±12 | 96 |
| $J/\psi K^0_S (K^0_S \rightarrow \pi^0 \pi^0)$ | 18±4 | 91 |
| $\psi(2S)K^0_S$ | 27±6 | 93 |

From the measurement of $\Delta z$, $\Delta t$ can be computed. The time resolution function is described accurately by the sum of two Gaussian distributions, which has five independent parameters:

$$R(\Delta t; \hat{a}) = \sum_{i=1}^{2} \frac{f_i}{\sigma_i \sqrt{2\pi}} \exp\left(-\frac{(\Delta t - \delta_i)^2}{2\sigma_i^2}\right). \quad (6)$$

A fit to the time resolution function in Monte Carlo simulated events indicates that most of the events ($f_1 = 1 - f_2 = 70\%$) are in the core Gaussian, which has a width $\sigma_1 \approx 0.6 \text{ps}$. The wide Gaussian has a width $\sigma_2 \approx 1.8 \text{ps}$. Tracks from forward-going charm decays included in the reconstruction of the $B_{tag}$ vertex introduce a small bias, $\delta_1 \approx -0.2 \text{ps}$, for the core Gaussian.

- Determination of the flavor of the $B_{tag}$, as described in detail in [4].

Each event with a $CP$ candidate is assigned a $B^0$ or $\bar{B}^0$ tag if the rest of the event (i.e., with the daughter tracks of the $B_{CP}$ removed) satisfies the criteria from one of several tagging categories. In other words, a $B^0$ tag indicates that the $B_{CP}$ candidate was in a $B^0$ state at $\Delta t = 0$; a $\bar{B}^0$ tag indicates that the $B_{CP}$ candidate was in a $B^0$ state.

Three tagging categories rely on the presence of a fast lepton ($\text{Lepton}$ categories) and/or one or more charged kaons in the event ($\text{Kaon}$ category). Two categories, called neural network categories ($\text{NT1}$ and $\text{NT2}$), are based upon the output value of a neural network algorithm applied to events that have not already been assigned to lepton or kaon tagging categories.

- Measurement of the dilution factors $D_i$ from the data for the different tagging categories, as described in detail in [4].

The figure of merit for each tagging category is the effective tagging efficiency $Q_i = \varepsilon_i (1 - 2w_i)^2$, where $\varepsilon_i$ is the fraction of events assigned to category $i$ and $w_i$ is the mistag fraction.

The mistag fractions are measured directly in events in which one $B^0$ candidate, called the $B_{rec}$, is fully reconstructed in a flavor eigenstate mode. The flavor-tagging algorithms are applied to the rest of the event, which constitutes the potential $B_{tag}$, assuming the $B_{rec}$ is properly tagged.

The mistag fractions and the tagging efficiencies obtained by combining the results from maximum likelihood fits to the time distributions in the $B^0$ hadronic and semileptonic samples are summarized in Table 2.
Table 2: Mistag fractions measured from a maximum-likelihood fit to the time distribution for the fully-reconstructed $B^0$ sample. The Electron and Muon categories are grouped into one Lepton category. The uncertainties on $\varepsilon$ and $Q$ are statistical only.

| Tagging Category | $\varepsilon$ (%) | $w$ (%) | $Q$ (%) |
|------------------|-------------------|---------|---------|
| Lepton           | 11.2 ± 0.5        | 9.6 ± 1.7 ± 1.3 | 7.3 ± 0.7 |
| Kaon             | 36.7 ± 0.9        | 19.7 ± 1.3 ± 1.1 | 13.5 ± 1.2 |
| NT1              | 11.7 ± 0.5        | 16.7 ± 2.2 ± 2.0 | 5.2 ± 0.7 |
| NT2              | 16.6 ± 0.6        | 33.1 ± 2.1 ± 2.1 | 1.9 ± 0.5 |
| all              | 76.7 ± 0.5        |          | 27.9 ± 1.6 |

Table 3: Summary of systematic uncertainties. The different contributions to the systematic error are added in quadrature.

| Source of uncertainty                                      | Uncertainty on $\sin^2\beta$ |
|------------------------------------------------------------|-------------------------------|
| uncertainty on $\tau_B^0$                                 | 0.002                         |
| uncertainty on $\Delta m_d$                               | 0.015                         |
| uncertainty on $\Delta z$ resolution for CP sample        | 0.019                         |
| uncertainty on time-resolution bias for CP sample         | 0.047                         |
| uncertainty on measurement of mistag fractions            | 0.053                         |
| different mistag fractions for CP and non-CP samples       | 0.050                         |
| different mistag fractions for $B^0$ and $\bar{B^0}$      | 0.005                         |
| background in CP sample                                   | 0.015                         |
| total systematic error                                    | **0.091**                    |

- Extraction of the amplitude of the CP asymmetry and the value of $\sin^2\beta$ with an unbinned maximum likelihood fit.

The maximum-likelihood fit for $\sin^2\beta$, using the full tagged sample of $B^0/\bar{B^0} \to J/\psi K_S^0$ and $B^0/\bar{B^0} \to \psi(2S)K_S^0$ events, gives:

$$\sin^2\beta = 0.12 \pm 0.37 \text{ (stat)} \pm 0.09 \text{ (syst)}. \quad (7)$$

For this result, the $B^0$ lifetime and $\Delta m_d$ are fixed to the current best values [3]. The log likelihood is shown as a function of $\sin^2\beta$ and the $\Delta t$ distributions for $B^0$ and $\bar{B^0}$ tags are shown in Fig. 2. The contributions to the systematic uncertainty are summarized in Table 3. They are added in quadrature to obtain the total systematic error.

Improvements in the $\sin^2\beta$ measurement are expected in the near future with the accumulation and analysis of more data and further systematic studies.
Figure 2: Variation of the log likelihood as a function of $\sin 2\beta$ (left). The two horizontal dashed lines indicate changes in the log likelihood corresponding to one and two statistical standard deviations. Distribution of $\Delta t$ for (a) the $B^0$ tagged events and (b) the $B^0$ tagged events in the CP sample (right).

5 Measurements of charged and neutral $B$ meson lifetimes and $B^0\overline{B}^0$ oscillations

These measurements can be used to test theoretical models of heavy–quark decays and to constrain the Unitarity Triangle (via the sensitivity to the value of the CKM matrix element $V_{td}$).

One $B$ ($B_{rec}$) is fully reconstructed in an all-hadronic ($B^0 \rightarrow D^{(*)} \pi^+$, $D^{(*)} \rho^+$, $D^{(*)} a_1^+$, $J/\psi K^{*0}$ and $B^+ \rightarrow D^{(*)0} \pi^+$, $J/\psi K^+$, $\psi(2S)K^+$) or semileptonic decay mode ($B^0 \rightarrow D^{*} \ell^+\nu$). A total of about 2600 $B^0$ and a similar number of charged $B$ are reconstructed in the hadronic modes, with a mean purity of $\sim$ 90%. The background is mainly combinatorial. About 7500 $B^0$ are reconstructed in the semileptonic modes, with a mean purity of $\sim$ 84%. Backgrounds to the semi-leptonic mode are due to combinatorics, wrong leptons, $c\bar{c}$ events, and charged $B$ decays from $B^+ \rightarrow D^{*+}\ell^+\nu$.

The separation between the two $B$ vertices ($z_{rec}$ and $z_{T\Delta G}$ for the reconstructed and tagged vertex, respectively) along the boost direction, $\Delta z = z_{rec} - z_{tag}$, is measured and used to estimate the decay time difference, $\Delta t = \Delta z / \beta z c$. The $\Delta t$ resolution is dominated by the precision on the $B_{tag}$ vertex, and has little dependence on the decay mode of the $B_{rec}$.

\[1\] Throughout this paper, conjugate modes are implied.
5.1 Lifetime Measurements

The $B^0$ and $B^+$ lifetimes are extracted from a simultaneous unbinned maximum likelihood fit to the $\Delta t$ distributions of the signal candidates, assuming a common resolution function. Only hadronic modes have been used. An empirical description of the $\Delta t$ background shape is assumed, using $m_{ES}$ sidebands with independent parameters for neutral and charged mesons. Fig. 3 shows the $\Delta t$ distributions with the fit result superimposed.

5.2 Time-dependent $B^0\bar{B}^0$ mixing

A time-dependent $B^0\bar{B}^0$ mixing measurement requires the determination of the flavor of both $B$ mesons. Considering the $B^0\bar{B}^0$ system as a whole, one can classify the tagged events as mixed or unmixed depending on whether the $B_{tag}$ is tagged with the same flavor as the $B_{rec}$ or with the opposite flavor.

From the time-dependent rate of mixed ($N_{mix}$) and unmixed ($N_{unmix}$) events, the mixing asymmetry $a(\Delta t) = (N_{unmix} - N_{mix})/(N_{unmix} + N_{mix})$ is calculated as a function of $\Delta t$ and fit to the expected cosine distribution. A simultaneous unbinned likelihood fit to the mixing asymmetry frequency and its amplitude allows the determination of both $\Delta m_d$ and the mistag rates, $w_i$, for the different tagging categories. The fit is performed simultaneously in each tagging category, assuming a common resolution function. Fig. 4 shows the $a(\Delta t)$ distributions with the fit result superimposed.
5.3 Results

The preliminary results for the $B$ meson lifetimes are $\tau_{B^0} = 1.506 \pm 0.052$ (stat) $\pm 0.029$ (syst) ps and $\tau_{B^+} = 1.602 \pm 0.049$ (stat) $\pm 0.035$ (syst) ps and for their ratio is $\tau_{B^+}/\tau_{B^0} = 1.065 \pm 0.044$ (stat) $\pm 0.021$ (syst).

From the hadronic $B^0$ sample we measure the $B^0\bar{B}^0$ oscillation frequency: $\Delta m_d = 0.516 \pm 0.031$ (stat) $\pm 0.018$ (syst) $\text{h}^{-1}$ and from the $D^*-\ell^+\nu$ sample the result is $\Delta m_d = 0.508 \pm 0.020$ (stat) $\pm 0.022$ (syst) $\text{h}^{-1}$. Combining the two $\Delta m_d$ results, we obtain the preliminary result: $\Delta m_d = 0.512 \pm 0.017$ (stat) $\pm 0.022$ (syst) $\text{h}^{-1}$. The mistag rates and $\Delta t$ resolution function extracted from these fits to the data are used in the BABAR CP violation asymmetry analysis [7]. The above results are consistent with previous measurements [6] and are of similar precision. The mixing result is compatible with a BABAR measurement using dileptons [8].

6 Conclusions

We have presented BABAR’s first measurement of the CP-violating asymmetry parameter $\sin2\beta$ in the $B$ meson system:

$$\sin2\beta = 0.12 \pm 0.37 \text{ (stat) } \pm 0.09 \text{ (syst).}$$

Our measurement is consistent with the world average $\sin2\beta = 0.9 \pm 0.4$ [3], and is currently limited by the size of the $CP$ sample.

We have presented also the time–dependent mixing and lifetime measurements, performed for the first time at the $\Upsilon(4S)$. 

Figure 4: Time-dependent asymmetry $a(\Delta t)$ between unmixed and mixed events for (left) hadronic $B$ candidates with $m_{ES} > 5.27\text{ GeV}/c^2$ and (right) for $B \to D^*\ell\nu$ candidates.
Other important competitive measurements have been achieved by BABAR. All measurement are foreseen to be improved in the near future, with the accumulation and study of more data and further systematic studies.
