ABSTRACT
We observed the Galactic black hole X-ray binary V4641 Sgr with the high resolution transmission gratings on Chandra during the source’s 2020 outburst. Over two epochs of Chandra gratings observations, we see numerous highly ionized metal lines, superimposed on a hot, disc-dominated X-ray continuum. The measured inner disc temperatures and luminosities imply an unfeasibly small inner disc radius, such that we suggest that the central engine of V4641 Sgr is obscured, and we are viewing scattered X-rays. We find that the emission lines in the Chandra spectra cannot be constrained by a single photoionized model, instead finding that two separate photoionized model components are required, one to reproduce the iron lines and a second for the other metals. We compare the observed X-ray spectra of V4641 Sgr to optical studies during previous outbursts of the source, suggesting that the lines originate in an accretion disc wind, potentially with a spherical geometry.

1 INTRODUCTION
Galactic black hole transients are typically low-mass X-ray binaries (LMXBs) in which a black hole (BH) accretes material from a donor star via an accretion disc. They spend long periods of time in a quiescent state, characterized by low X-ray luminosities $L_x \lesssim 10^{-3} L_{\text{Edd}}$ (where $L_{\text{Edd}}$ is the Eddington luminosity) and an X-ray spectrum consistent with a power law with photon index $\Gamma \sim 2$ (e.g. Reynolds & Miller 2013; Plotkin, Gallo & Jonker 2013). Quiescence is followed by bright outbursts during which the source luminosity increases by several orders of magnitude across most of the electromagnetic spectrum (see e.g. Remillard & McClintock 2006; Tetarenko et al. 2016). During an outburst a BH–LMXB will transition through several ‘accretion states,’ (typically) identified by, and named after, the properties of the X-ray spectrum (see e.g. Done, Gierliński & Kubota 2007; Motta et al. 2021, for reviews). Due to correlated timing properties, variability can also be used to identify the accretion state. Typical X-ray binary outbursts evolve from the quiescent state to a hard accretion state (and vice versa), with a large fraction of outbursts showing (potentially multiple) transitions between the hard and soft accretion state. The soft state is characterized by a multitemperature disc-dominated X-ray spectrum and little to no short-term variability. Conversely, the X-ray spectrum in the hard state is usually well described by a power law with $\Gamma \sim 2$. The transition from the hard to the soft state is often marked with the disappearance (emergence) of a compact radio jet and the appearance (disappearance) of strong fast variability in the X-ray and optical light curves (e.g. Belloni et al. 2005; Remillard & McClintock 2006; Gandhi et al. 2016).

The soft state is often strongly associated with the emergence of strong outflows in the form of accretion disc winds, seen at X-ray – near-infrared wavelengths. So far, X-ray winds have only been detected in high inclination systems, which suggests they have an equatorial geometry (Díaz Trigo et al. 2006; Miller et al. 2006; Ponti et al. 2012). In addition, until recently, it was assumed that the presence of an X-ray wind was linked to the spectral state, appearing only when the jet was quenched in the soft state (Miller et al. 2006; Neilsen & Lee 2009; Ponti et al. 2012, 2016). However, the hard-state outburst of V404 Cyg in 2015 showed that winds can, in fact, be seen simultaneously with the jet (King et al. 2015; Muñoz-Darias et al. 2016), further complicating already complex theories of accretion-outflow coupling. Homan et al. (2016) showed that hard state winds can also be seen in neutron star LMXBs (see also Castro Segura et al. 2022).

Accretion disc winds typically manifest in the X-ray spectrum as blue-shifted H- and He-like absorption lines (e.g. Lee et al. 2002; Ueda et al. 2004; Miller et al. 2006, 2008). However, some sources exhibit strong emission lines with associated P-Cygni profiles (Brandt & Schulz 2000; King et al. 2015), which are also seen in optical spectra (Muñoz-Darias et al. 2016; Muñoz-Darias, Torres & García 2018) and are a sign of photons being scattered out of our line of sight, potentially even hinting at a spherical geometry. Studies of accretion disc winds through optical and (high-

* E-mail: aarrans@unr.edu
resolution) X-ray spectroscopy allow us to investigate the potential launching mechanisms (see Miller et al. 2008, and references therein).

2 V4641 SGR

V4641 Sgr (SAX J1819.3–2525) is an X-ray binary (often classified as an Intermediate-mass X-ray binary) containing a 6.4 ± 0.6 M⊙ BH accreting matter from a 2.9 ± 0.4 M⊙ B9III companion (MacDonald et al. 2014) with an orbital period $P_{\text{orb}} = 2.82$ d (Orosz et al. 2001). MacDonald et al. (2014) determined the distance to V4641 Sgr to be $d = 6.2 \pm 0.7$ kpc, consistent with the distance distribution calculated using the Gaia data release 2 (DR2; Gaia Collaboration et al. 2018) parallax assuming a volume density prior for LMXBs in the Milky Way (Gandhi et al. 2019; Atri et al. 2019).

The outburst characteristics of V4641 Sgr are somewhat unusual compared to other LMXBs. It exhibited a 12.2 Crab outburst in 1999 September that lasted only 2 h before fading to 0.1 Crab (Smith, Levine & Morgan 1999; Hjellming et al. 2000); this extremely bright outburst was also much more rapid than those of typical LMXBs. V4641 Sgr has since shown regular outbursts with a median recurrence time of $\sim 220$ d (Tetarenko et al. 2016), but none have reached the extreme luminosity of the 1999 event. Another unusual aspect of the system is that it has been seen to remain in a soft disc-dominated state at very low Eddington fractions, exhibiting soft X-ray spectra at an X-ray luminosity $L_X \sim 0.01 L_{\text{Edd}}$ during the 2014 outburst (Pahari et al. 2015) and as low as $L_X \sim 6 \times 10^{-4} L_{\text{Edd}}$ during the 2015 outburst (Bahrainian et al. 2015). V4641 Sgr finds itself in a growing population of BH–LMXBs (see also XTE J1720–318 4U 1630–47 and Swift J1753.5–0127; Kalemi et al. 2013; Tomskick et al. 2014; Shaw et al. 2016) that appear to remain in soft states at lower Eddington fractions than the average soft-to-hard transition luminosity of $L_X \sim 0.03 L_{\text{Edd}}$ (Dunn et al. 2010).

In this work, we present the first ever high-resolution X-ray spectroscopic study of V4641 Sgr obtained with the Chandra High Energy Transmission Grating Spectrometer at two epochs during its 2020 outburst. In Section 3, we present our observations and the data reduction procedures. We then present our spectral analysis in Section 4, including a detailed look at the lines found in the Chandra data. We discuss our results in 5, performing plasma diagnostics with the observed emission lines and fitting photoionization models to the X-ray spectra. Finally, we look at the future of high-resolution X-ray spectroscopy for studies like this one in Section 6 and present our conclusions in Section 7.

3 OBSERVATIONS AND DATA REDUCTION

Increased X-ray activity from V4641 Sgr was first detected by the Gas Slit Camera instrument on the Monitor for All-Sky X-ray Image Gas Slit Camera (MAXI/GSC; Matsuoka et al. 2009) on 2020 Jan 7, when the source emerged from the Sun constraint (Shaw et al. 2020). It is likely that the outburst commenced prior to the January detection but the source was obscured by the Sun. Follow-up observations were initially limited due to the Sun constraint. However, as the outburst progressed, V4641 Sgr became accessible to more observatories. Here we detail the X-ray observations and data reduction performed.

3.1 X-ray monitoring

In addition to the MAXI/GSC monitoring, regular pointed X-ray observations of V4641 Sgr were performed with the X-ray Telescope on-board the Neil Gehrels Swift Observatory (Swift/XRT; Burrows et al. 2005) and the X-ray Timing Instrument on the Neutron star Interior Composition Explorer (NICER/XTI; Gandert et al. 2016).

Swift/XRT monitored V4641 Sgr from 2020 Feb 11 to 2020 Apr 19 (MJD 58890–58958; ObsID 00013205001–00013205016). Most observations were performed in windowed timing (WT) mode. However, the observation on 2020 Apr 7 (MJD 58946) was performed in photon counting (PC) mode owing to the low count rate (0.18 counts s$^{-1}$). Two more observations on 2020 Apr 18 and 19 (MJD 58957–58958) were performed in both PC and WT mode, and the PC mode observations were heavily piled up, so we only utilized the WT mode observations on those dates. Data were reprocessed using the xrtpipeline tool, part of HEASOFT v6.28 software suite of analysis tools for high energy astronomical data. Spectra and associated response files were generated using the xrtproducts tool, with source photons extracted from a circular region with a 20 pixel ($\sim 47$ arcsec) radius. Background counts were extracted from an annulus centred on the source, with inner and outer radii 80 and 120 pixels, respectively. Response matrices were generated using version 20200724 of the calibration database (CALDB). Spectra were grouped such that each bin contained a minimum of 15 counts.

NICER/XTI monitored V4641 Sgr regularly throughout the first half of 2020. We choose observations that cover a similar time frame to the Swift coverage, in the range 2020 Jan 31–2020 May 4 (MJD 58879–58973; ObsIDs 3200300101–3200300129). Data were processed using nicerl2 and spectra extracted using XSELECT. Canned response matrices were obtained from the CALDB and background spectra were created using the nisbgestimator tool. Similar to Swift NICER spectra were grouped such that each spectral bin contained a minimum of 15 counts.

3.2 NuSTAR

At the beginning of the outburst, V4641 Sgr was Sun-constrained to most imaging X-ray telescopes. However, the Nuclear Spectroscopic Telescope Array (NuSTAR Harrison et al. 2013) can point close to, and even at, the Sun at the expense of accurate pointing reconstruction. Therefore, we obtained Director’s Discretionary Time (DDT) observations of V4641 Sgr with NuSTAR on 2020 Jan 22 for a total exposure time of 27.8 ks. Data were reduced using the NuSTAR data analysis software (NUSTARDAS) v2.0.0 originally packaged with HEASOFT v6.28. The nuspipe line tool was used to perform standard reduction tasks, including filtering for high levels of background during the telescope’s passage through the South Atlantic Anomaly.

Due to the near-solar pointing of NuSTAR during the observation, the majority of the observation occurred in observation mode 06. Mode 06 is utilized when an aspect solution is not available from the on-board star tracker located on the X-ray optics bench (Camera Head Unit #4; CHU4). In such a scenario, the aspect reconstruction is derived using CHUs 1, 2, and 3 with degraded positional accuracy. This mode leads to images with multiple centroids from the same target, often manifesting as a seemingly elongated source. To allow accurate scientific analysis, we used the nusplitsc tool to decompose the mode 06 image into four images for each of Focal Plane Modules A and B (FPMA and FPMB), representative of the four CHU combinations NuSTAR used.

1https://heasarc.gsfc.nasa.gov/docs/software/heasoft/
Approximately 3.4 ks of the observation was performed in SCIENCE mode, also known as ‘mode 01,’ the standard operating mode of NuSTAR. We extracted source and background spectra and requisite response files using nuproducts. Source spectra were extracted using a circular source extraction region with radius 70 arcsec and background spectra were extracted from a 90 arcsec radius circular region centred on a source-free region of the same chip as the target.

The remaining exposure was performed in mode 06 and, though the method of spectral extraction was the same, we only extracted data from mode 06 images in which the source exhibited a circular PSF, namely CHU2\textsuperscript{2} and CHU3. Source spectra were extracted from a circular region with radius 60 arcsec for all images, while background spectra were extracted from a 70 arcsec radius circular region from the CHU2 images and a 90 arcsec radius circular region for CHU3.\textsuperscript{3}

The total useful exposure time for each focal plane module, using mode 01 and 06 data, was 7.5 ks. For each focal plane module, we had three spectra (mode 01, CHU2, and CHU3), which were grouped using the ftgrouppha tool, such that each spectral bin had a minimum S/N=5.

3.3 Chandra

Chandra observed V4641 Sgr on 2020 Feb 14 and 15 (MJD 58893 and 58894) for 44.0 and 29.4 ks, respectively (ObsIDs 22389 and 23158; PI: Shaw). We used the High Energy Transmission Grating Spectrometer (HETGS; Canizares et al. 2005), which uses two gratings, the High Energy Grating (HEG) and Medium Energy Grating (MEG), to disperse photons across the Advanced CCD Imaging Spectrometer (ACIS; Garmire et al. 2003) S chips.

Data were reduced and spectra were extracted using the Chandra Interactive Analysis of Observations software (CIAO; Fruscione et al. 2006) v4.12. Data were mostly reduced following standard procedures, using the chandra_repro tool, following CIAO threads and using CIAO CALDB v4.9.1. However, we used slightly narrower spectral extraction regions than the default to reduce overlap between the two gratings and to improve spectral S/N at shorter wavelengths (higher energies). The average Chandra count rate in Epoch 1 was measured to be 3.5 and 6.0 count s\textsuperscript{-1} in the HEG and MEG, respectively, while in Epoch 2 we measured 1.9 and 3.1 count s\textsuperscript{-1} in HEG and MEG, respectively. The Chandra detectors are very prone to photon pileup when observing bright sources, and with observing with the gratings, photons are dispersed across the entire ACIS detector, often mitigating pileup effects. We estimated the pileup fraction in the first Chandra epoch (higher flux than the second epoch; Fig. 1) to be low, at most only 3 per cent in the MEG spectrum, at $\lambda \sim 3$ Å.$^4$

4 ANALYSIS AND RESULTS

4.1 Long-term X-ray light curve

We compiled an X-ray light curve of the 2020 outburst of V4641 Sgr using the available monitoring data from MAXI/GSC, Swift/XRT, and NuSTAR.

\textsuperscript{2}For CHU2, we had to invoke the splitmode = STRICT and timeout = yes flags in nusplitsc to produce an image with a circular PSF.

\textsuperscript{3}The reason for the discrepancy between background region sizes is due to the source in the CHU2 image having a larger PSF than in the CHU3 image. We therefore reduced the size of the background region in CHU2 to avoid source photons from the wings of the CHU2 PSF.

\textsuperscript{4}Following the methodology shown here: https://cxc.harvard.edu/proposer/threads/binary/index.html.

NICER/XTI. For Swift and NICER, we extracted 2–10 keV fluxes by modelling the X-ray spectra. Spectral fitting was performed in XSPEC v12.11.1 (Arnaud 1996) using the $\chi^2$ statistic.

For Swift, all spectra were well fitted ($\chi^2$/dof~1; where dof is degrees of freedom) with a multicolour disc blackbody model (diskbb in XSPEC) with an inner disc temperature range of $kT_{\text{in}} \sim 1.5 - 2.0$ keV across the observations. We used the tbbabs absorption model (Wilms, Allen & McCray 2000), with Wilms et al. (2000) abundances and Verner et al. (1996) cross-sections, and fixed the hydrogen column density to $N_H = 2.5 \times 10^{21}$ cm\textsuperscript{-2}, consistent with previous observations of the system (e.g. Pahari et al. 2015). The 2–10 keV unabsorbed flux was extracted using the $\text{cflux}$ model and we plot the resultant light curve in Fig. 1.

For NICER, we followed a similar fitting methodology, employing $\chi^2$ as the fitting statistic. Spectra were fit with an absorbed disc blackbody model, with a fixed $N_H = 2.5 \times 10^{21}$ cm\textsuperscript{-2} and a Gaussian in the 6–7 keV region to account for the Fe emission seen in this energy range. As with the Swift spectral fits, all fits to the NICER data were good ($\chi^2$/dof~1) and $kT_{\text{in}}$ was in the range of $\sim 1.5 - 2.0$ keV. Unabsorbed 2–10 keV fluxes were again extracted with the $\text{cflux}$ model. We plot the NICER/XTI light curve alongside the Swift/XRT one in Fig. 1.

4.2 NuSTAR spectral analysis

We present the NuSTAR spectra in Fig. 2, showing only the mode 01 FPMA and FPMB spectra, for clarity. Analysis of the NuSTAR spectra was performed with XSPEC, employing $\chi^2$ as the fit statistic. Spectra were not combined, but fit simultaneously, with a cross-normalization factor applied between FPMA and FPMB spectra (constant in XSPEC). We attempted to characterize the continuum of the spectrum by fitting an absorbed disc blackbody (tbbabs*diskbb in XSPEC and ISIS notation). As with the Swift and NICER spectra from Section 3.1, we fix $N_H = 2.5 \times 10^{21}$ cm\textsuperscript{-2} and find a best-fitting $kT_{\text{in}} = 1.39$ keV. However, the fit is poor ($\chi^2$/dof=2432.5/1061), such that we are unable to determine meaningful uncertainties on $kT_{\text{in}}$. We show the data/model ratio in the lower panel of Fig. 2.
From the residuals, we note a number of prominent features. The most striking is the strong emission feature in the ~6–7 keV range. At NuSTAR energy resolution, this feature appears to be asymmetric, but we later show that the line can be resolved with Chandra into 6.7 and 6.97 keV Fe XXV and Fe XXVI emission lines, respectively, potentially with a small contribution from neutral Fe Kα. Secondly, we also find evidence of a weak feature at ~8 keV, similar to the one described by Pahari et al. (2015) in a 2014 NuSTAR observation of V4641 Sgr in the soft state.

To determine the best-fitting model for the NuSTAR spectrum of V4641 Sgr, we incrementally add model components to the original absorbed disc blackbody fit shown in Fig. 2. We first focus on attempting to model the emission features. Including two broad Gaussians in the model, similar to the approach taken by Pahari et al. (2015), improves the fit significantly ($\chi^2$/dof=1337.6/1055). We find best-fitting central energies of 6.83 ± 0.02 and 8.10 ± 0.06 keV for each Gaussian, with widths of $\sigma = 150^{+25}_{-35} eV$ and $< 223 eV$, respectively. Pahari et al. (2015) suggest that their 8.3 keV feature could be due to highly ionized nickel. However, knowing from the Chandra/HETG (Section 4.3.1) that the 6.83 keV feature is largely a blend of highly ionized Fe XXV Lyα and Fe XXVI Heα, we suggest here that the 8.1 keV line that we detect is a blend of Fe XXV Heβ and Fe XXVI Lyβ at 7.88 and 8.25 keV, respectively. It is possible that there is some contribution from nickel, but NuSTAR’s spectral resolution precludes us from resolving individual lines.

We attempt to improve the fit by modeling the Fe 6–7 keV region as three narrow (i.e. with a fixed width $\sigma = 100\ eV$) Gaussians and the (likely Fe) 8.1 keV feature as two equally narrow Gaussians. However, we find that the fit prefers only two Gaussians in the 6–7 keV range, one at 6.22^{+0.12}_{-0.11} keV and the other at 6.86^{+0.02}_{-0.01} keV. In addition, we are unable to separate the two components that make up the 8.1 keV feature, and instead the fit prefers a single narrow Gaussian at 8.09 ± 0.06 keV ($\chi^2$/dof=1280.9/1055). We also find that the addition of an absorption edge ($e$edge in XSPEC) at $E_{edge} = 9.55 ± 0.19$ produces a statistically significant improvement to the fit ($\Delta \chi^2 = -42.1$ for 2 fewer dof).

Finally, we test the addition of a power law to the model, but find that the improvement to the fit is only marginal (while $\Delta \chi^2 = -15.5$ for 2 fewer dof, the power-law normalization is poorly constrained). We find a best-fitting power-law index $\Gamma = 1.56^{+1.33}_{-1.39}$ and a normalization $N_{low}$ in the range $3.3 \times 10^{-6}$–$0.014$ (90 per cent confidence). It is likely that we would be able to measure the power law with greater confidence with a longer exposure, but the extremely soft spectrum shown by V4641 Sgr in 2020 January combined with only 7.5 ks of effective exposure time means we are unable to strongly constrain the power-law tail. We note that the focus of this work remains on the high-resolution Chandra/HETG spectra, so we only present the NuSTAR data as a broadband overview of the X-ray spectrum of V4641 Sgr. The best-fitting parameters for models fit to the NuSTAR data are presented in Table 1.

| Table 1. Best-fitting parameters for models fit to NuSTAR FPMA and FPMB spectra of V4641 Sgr. |

4.3 High-resolution X-ray spectroscopy

Chandra/HETG spectra were analyzed using using the interactive spectral interpretation system (ISIS; Houck & Denicola 2000). We treated each epoch separately, as we know from the NICER monitoring that the shape of the X-ray spectrum of V4641 Sgr can vary on time-scales of less than a day. To extract the most S/N from the high-resolution spectra, we combined the positive and negative first-order HEG and MEG spectra using combine_data_sets, after rebinning the HEG spectra on to the MEG wavelength grid using match_data_set_grids. This practice is well documented in other analyses of Chandra/HETG data (see e.g. Miškovičová et al. 2016; Grinberg et al. 2017). Nowak et al. (2019) note that these functions have been well tested against HEASoft and CIAO functions that combine spectra and their associated responses and backgrounds. We utilize Cash (1979) statistics as the fit statistic when modeling the Chandra/HETG spectra.

The 0.9–10 keV Chandra spectra for each epoch are shown in Fig. 3, where a number of strong emission lines are visible. Prior to studying the emission lines, we first characterized the X-ray
with Si XIV Ly α (2.00 keV = 6.18 Å) and a possible Ne X Ly α line (1.02 keV = 12.13 Å).

To search for and characterize more lines, we adopt a statistical approach in the form of a blind line search based on a Bayesian Blocks (BB) algorithm (Scargle et al. 2013). Though often associated with characterizing variability in time series data, Young et al. (2007) used a Bayesian Blocks (BB) algorithm on spectral data using the SITAR package available in ISIS. The algorithm tests for the presence of lines against a continuum model, in our case the continuum model discussed above and shown in Fig. 3. The algorithm groups the data into ‘blocks’ by determining how far each (unbinned) data point lies above or below the continuum defined by a parameter α, which acts as a significance threshold. The spectrum is considered to have no significant lines if the algorithm returns a single block, and a line is considered to be present between two block change points.

The parameter α, set by the user, is defined such that the significance of a line is approximately \( p \sim \exp(-2\alpha) \) and therefore the probability of a positive detection is roughly \( P \sim 1 - \exp(-2\alpha) \). In this work, we define a positive detection to be at least 95 per cent significant, therefore we require \( \alpha > 1.5 \). The BB line-search method has been published and benchmarked against other methods by Young et al. (2007), and has been utilized successfully in high-resolution spectroscopic studies of e.g. Vela X-1 (Grinberg et al. 2017) and 4U 1700−37 (Martínez-Chicharro et al. 2021).

To initiate the blind line search, we divide the 1.25−14 Å (0.9–10 keV) spectrum into five distinct regions, so named for the strongest line(s) usually found in each of the respective wavelength ranges. The regions are as follows: Fe (1.25−2.5 Å), S/Ar (2.5−6 Å), Si (6−8 Å), Mg (8−10 Å), and Ne (10−14 Å). We then apply the BB algorithm against the best-fitting partially covered disc blackbody continuum model, which is frozen in place, and iterates from \( \alpha = 10 \) to \( \alpha = 1.5 \) (in steps of \( \Delta \alpha = -0.1 \)) until a line is found. Once a line is found by the BB algorithm, we fit a Gaussian⁵ and apply the algorithm again, iteratively adding Gaussian components until no more lines are detected above ~95 per cent significance. For both Chandra epochs, we describe our results for each spectral region below. Line identifications and their reference wavelengths, \( \lambda_{\text{ref}} \), are made using \( \lambda_{\text{cmp}} \mathrm{DB} \) 3.0.9 (Foster et al. 2012) and identified lines for all wavelength regions are presented in Table 3.

### 4.3.1 Fe region

The spectra of the Fe region are presented in Fig. 4. In both epochs, the strongest lines identified are Fe XXVI Ly α and Fe XXV He α. Additionally, the BB line search detects a line consistent with Fe XXVI Ly β in the second epoch at the lower limit of \( \alpha = 1.5 \). Interestingly, though Fig. 3 (see also Fig. 4) suggests the presence of neutral Fe K α, at least in the second epoch, this line is not detected at \( \alpha \geq 1.5 \) by the BB algorithm. Including a Gaussian component at the location of Fe K α results in \( \Delta C = -11 \) and \( \Delta C = -19 \) for two fewer degrees of freedom for Epoch 1 and 2, respectively. Regardless of whether Fe K α is present or not, it is clear that the Fe region is dominated by highly ionized iron and any fluorescent neutral iron is weak.

In both epochs, the H-like ions are consistent with velocity \( v = 0 \) km s\(^{-1}\). The He-like Fe XXV lines, conversely, are shifted by \( v = -485 \pm 373 \) and \( v = 646\pm325 \) km s\(^{-1}\) for Epoch 1 and

---

2, respectively. However, this does not necessarily mean that the lines are indeed Doppler shifted, as He-like Fe XXV consists of a triplet of lines that are not resolved by Chandra. The published rest wavelength \( \lambda_0 = 1.855 \) Å is effectively the central wavelength of the triplet and an apparent Doppler shift can simply be explained by a change in relative strength of the forbidden (\( \lambda_0 = 1.858 \) Å), intercombination (\( \lambda_0 = 1.858 \) Å), or resonance (\( \lambda_0 = 1.850 \) Å) components (Drake 1988). To investigate this possibility, we examined just the HEG spectra from each epoch, as the HEG has a slightly higher resolution than MEG (0.012 Å).\(^7\) The HEG spectra of the Fe XXV region are shown in the insets of both panels of Fig. 4, indicating that a change in relative line strengths may have occurred between the two epochs. However, the spectral resolution of the HEG precludes us from confidently disentangling individual triplet components or performing plasma diagnostics, so we are only able to speculate.

4.3.2 Si/Ar region

The BB algorithm does not find statistical evidence for any lines in Epoch 1 (\( \alpha < 1.5 \)). However, a visual inspection of the spectra and their residuals (Fig. 5) suggest that there are lines consistent with the known wavelengths of Ca XX Ly \( \alpha \) (3.018 Å) and Ar XVIII Ly \( \alpha \) (3.733 Å) in Epoch 1. If we include two Gaussians in the model for Epoch 1 we find \( \Delta C = −27 \) for four fewer degrees of freedom (\( \Delta C = −14 \) and \( \Delta C = −13 \) for Ca and Ar, respectively), and best-fitting velocities of \( v = 596 ± 398 \) and \( v = 321 ± 241 \) km s\(^{-1}\) for Ca XX and Ar XVIII, respectively. By Epoch 2, we no longer see evidence for these lines, and instead Ca and Ar have been replaced by a statistically significant S XVI Ly \( \alpha \) line with \( v = 190±190 \) km s\(^{-1}\).

4.3.3 Si region

The Si region exhibits two easily identifiable lines in both epochs (Fig. 6), those of Si XIV Ly \( \alpha \) and the forbidden transition of the He-like Si XIII triplet. In addition, the BB algorithm identifies two features in Epoch 1 that are difficult to reconcile with known features. The first feature is centred at \( \lambda = 7.805±0.016 \) Å and is consistent with the He-like Al XII intercombination line. However, there is no evidence for Al XIII Ly \( \alpha \) elsewhere in the spectrum and the 7.805 Å feature is broad in comparison to most of the other lines. Thus, the line is likely not due to Al XII. The second unidentified line is centred at \( \lambda = 7.959±0.003 \) Å. The closest known feature in the AtComDB is Li-like Fe XXIV. However, if this was the true identity of the detected line, it would have \( v = −1127±159 \) km s\(^{-1}\), very inconsistent with other lines. As such, we consider the two features measured in Epoch 1 to remain unidentified.

The rest wavelength of Si XIII \( f \) is almost identical to that of Mg XII Ly \( \gamma \). However, if the measured line is indeed Mg XII Ly \( \gamma \), then we would also expect the stronger Mg XII Ly \( \beta \) at 7.1 Å, which

\(^7\)https://cxc.harvard.edu/proposer/POG/html/chap8.html
4.3.4 Mg region

In the Mg region, the BB algorithm identifies two lines (Fig. 7). The first, in Epoch 1, is an absorption line at $9.470 \pm 0.003$ Å, which we are unable to identify with any line transitions commonly seen in LMXBs. AtomDB does not note some $n = 5 \rightarrow 1$ transitions of Ne X at similar energies, but we do not detect any stronger $n = 4, 3 \rightarrow 1$ transitions in the spectra. In addition, Ne X Ly $\alpha$ only appears (in emission) in Epoch 2, so the absorption feature remains puzzling.

The second line, detected by the BB algorithm only in Epoch 2, corresponds to Mg XII Ly $\alpha$ with $v = 249 \pm 71$ km s$^{-1}$. Though this feature is not detected by the BB algorithm in Epoch 1 (with a threshold for detection $\alpha \geq 1.5$), the residuals in the top panel of Fig. 7 suggest that a weak line may be present. Including a Gaussian line in the model results in $\Delta C = -14$ for two fewer degrees of freedom, and a best-fitting $v = 499 \pm 143$ km s$^{-1}$. This line, if real, is much weaker in Epoch 1 (Flux $= 4.81^{+2.35}_{-1.06} \times 10^{-2}$ photons cm$^{-2}$ s$^{-1}$) than in Epoch 2 (Flux $= 1.02^{+0.25}_{-0.20} \times 10^{-4}$ photons cm$^{-2}$), something that is also seen in the Si region across epochs.

4.3.5 Ne region

In the Ne region spectra (Fig. 8), we can only confidently identify one of the lines detected by the BB algorithm, that of Ne X Ly $\alpha$ at $v = 247 \pm 74$ km s$^{-1}$ in Epoch 2. In Epoch 1, broad lines at $\lambda = 11.170^{+0.018}_{-0.007}$ and $12.477^{+0.021}_{-0.016}$ Å may be associated with the large number of Fe L-shell transitions known to occur around $\sim 1$ keV, but their true nature is unclear. Similarly, the feature at $\lambda = 10.633^{+0.004}_{-0.003}$ Å in Epoch 2 is also difficult to identify. At $\lambda \gtrsim 12.5$ Å, the source counts are very low, preventing the detection of

Figure 4. Chandra/HETG spectra of the Fe region. Epoch 1 (ObsID: 22389) is shown in the upper panel and Epoch 2 (ObsID: 23158) in the lower panel. In both panels, we show the best-fitting model spectrum in red, including lines determined to be significant by the BB algorithm. Features labelled in parentheses are lines that were not detected by the BB algorithm, but could be present in the spectrum given knowledge of expected line energies of particular elements. Data/model ratios are also plotted for each epoch. In each panel, we also plot the HEG-only spectrum of the Fe XXV region inset. Dotted lines show the rest wavelengths of the resonance ($r$), intercombination ($i$), and forbidden ($f$) components of the He-like triplet.

Figure 5. Chandra/HETG spectra of the Si/Ar region. Epoch 1 (ObsID: 22389) is shown in the upper panel and Epoch 2 (ObsID: 23158) in the lower panel. In both panels, we show the best-fitting model spectrum in red, including, where relevant, lines determined to be significant by the BB algorithm. Features labelled in parentheses are lines that were not detected by the BB algorithm, but could be present in the spectrum given knowledge of expected line energies of particular elements. Data/model ratios are also plotted for each epoch.
Figure 6. Chandra/HETG spectra of the Si region. Epoch 1 (ObsID: 22389) is shown in the upper panel and Epoch 2 (ObsID: 23158) in the lower panel. In both panels, we show the best-fitting model spectrum in red, including lines determined to be significant by the BB algorithm. Lines with an uncertain identification are labelled ‘?’ Data/model ratios are also plotted for each epoch. In each panel we show a zoom of the SiXIII region inset, with dotted lines showing the rest wavelengths of the resonance (r), intercombination (i), and forbidden (f) components of the He-like triplet.

In both panels, we show the best-fitting model spectrum in red, including lines determined to be significant by the BB algorithm. Features labelled in parentheses are lines that were not detected by the BB algorithm, but could be present in the spectrum given knowledge of expected line energies of particular elements. Lines with an uncertain identification are labelled ‘?’ Data/model ratios are also plotted for each epoch.

5 DISCUSSION

In this section, we will discuss the Chandra spectra and use several diagnostics to determine the nature of the plasma, i.e. whether it is photoionized or if there are other ionization processes at work.

5.1 A note on the X-ray continuum

In Table 2, we show the best-fitting spectral parameters for the Chandra X-ray continuum indicating that the inner disc temperature in both epochs is $kT_{\text{in}} \approx 1.4-1.5$. Considering the MacDonald et al. 2014 distance to V4641 Sgr ($d = 6.2 \pm 0.7$ kpc) and the corresponding $L_X \sim 4 \times 10^{35}$ erg s$^{-1}$, the measured $kT_{\text{in}}$ corresponds to a very small inner disc radius $R_{\text{in}} \sim 2.9 \times 10^5$ cm in Epoch 1 (which is smaller still in Epoch 2). This is smaller than the Schwarzschild radius for a 6.4 M$_\odot$ BH ($R_S \sim 1.9 \times 10^8$ cm), and even smaller than the expected innermost stable circular orbit (ISCO) for a maximally rotating Kerr BH ($1.235 R_S \sim 1.2 \times 10^6$ cm where $R_S = R_S/2$). Thus, this $R_{\text{in}}$ can be considered unfeasibly small for a source such as V4641 Sgr. We suggest, instead, that the observed flux is coming from X-rays that are scattered above the disc and that the intrinsic X-ray luminosity is actually much higher than measured. This is consistent with other studies of V4641 Sgr during the 2020 outburst, namely the in-depth analysis of the NICER data presented by Buisson et al. (in preparation). In addition, both Revnivtsev et al. (2002) and Koljonen & Tomsick (2020) also suggest that the central engine in V4641 Sgr may be obscured, potentially by an optically thick equatorial outflow, resulting in the low X-ray luminosities often seen in the system during outburst. We estimate that if the inner disc is at $kT_{\text{in}} = 1.235 R_S$ with $kT_{\text{in}} = 1.4$ keV, then the intrinsic $L_X$ needs to be at least 20 times larger than the value we measure in Epoch 1. In Epoch 2, we estimate that the intrinsic $L_X$ should be >40 times the measured $L_X$. These estimates are important when considering the locations of the line-emitting mediums in Section 5.3.
5.2 Plasma diagnostics with He-like triplets

As discussed in Section 4.3.3, resolving He-like lines in X-ray spectra of astrophysical plasmas allows us to determine key properties of the medium, including its density, temperature, and the dominant ionization processes (Porquet & Dubau 2000). In the case of V4641 Sgr, we detect a strong line at $\lambda = 6.74$ Å, consistent with the forbidden, $f$, transition of Si XIII. This line is strong in both Chandra epochs.

Most notable about the Si region is the apparent lack of emission from the other members of the Si XIII triplet, namely the intercombination ($i$; $\lambda_0 = 6.687$ Å) and resonance ($r$; $\lambda_0 = 6.648$ Å) transitions. A weak $r$ line relative to $f$ and $i$ is a strong indicator of a purely photoionized plasma. To test this, we utilized the triplet_fit function available as an add-on to xis,8 which allows us to measure line ratios directly.

We used a power law to approximate the continuum in the Si region and placed three Gaussian emission lines with $\sigma = 0.003$ Å at the wavelengths of the $i$, $r$, and $f$, but shifted by the measured values of $\nu$ for Si XIII $f$ as detailed in Table 3. We allowed the line flux to vary but fixed $\lambda_{\text{obs}}$. In both epochs, we find that the best-fitting line flux for the $r$ is consistent with zero. A weak resonance line means that collisional processes are negligible and the plasma is likely photoionized (Porquet & Dubau 2000). We can quantify this by measuring the ratio $G = \frac{f}{r}$. A value of $G > 4$ is the signature of a purely photoionized plasma. In Epochs 1 and 2, we measure $G > 4.37$ and $G > 2.67$, respectively which, though not definitive in the case of Epoch 2, is evidence for photoionization being the dominant ionization process in the medium. For a purely photoionized plasma, Fig. 10 of Porquet & Dubau (2000) tells us the expected range of electron temperature, $T_e$ and in the case of Si XIII this range is $T_e \sim 5 \times 10^4 - 2 \times 10^6$ K.

Next we measure the ratio $R = \frac{r}{i}$, which is an indicator of the particle density of the plasma ($n_e$). The strong forbidden lines (relative to other members of the triplet) present in the spectra at both epochs are indicative of a low density plasma. In Epoch 1, we find $R = 1.97^{+5.32}_{-0.64}$ effectively $R > 1.35$. According to Porquet & Dubau (2000), this suggests an upper limit of $n_e \leq 5 \times 10^{13}$ cm$^{-3}$. In Epoch 2, the $i$ measured line flux is consistent with zero, meaning we measure a best-fitting $R > 5.33$. This is outside the range at which $R$ is sensitive to density and thus implies a plasma density $n_e < 10^{12}$ cm$^{-3}$.

8https://space.mit.edu/~dph/triplet/triplet.html
5.3 Photoionization modelling

Analysis of the He-like $\text{Si}
\text{XIII}$ lines implies that photoionization dominates, at least in the Si-emitting region of the plasma. The $R$ ratio provides an upper limit to the density of the plasma, and the derived $G$ ratio implies $T_e \sim 5 \times 10^5 - 2 \times 10^6 \text{ K}$. We can use this information to simulate a photoionized medium and apply it to the spectra of $\text{V4641 Sgr}$.

We used the best-fitting continuum model as an input to XSTAR v2.54a\(^9\) to calculate grids of photoionized spectra. We used the resultant grids to determine the best-fitting $n_e$ and ionization parameter $\xi$, which is defined according to Tarter, Tucker & Salpeter (1969):

$$\xi = \frac{L_X}{n_e r^2},$$

where $r$ is the distance of the line-emitting medium from the central ionizing source.

In Epoch 1, we find that a single photoionized plasma provides an acceptable fit ($C/dof = 2706/2544$) to the spectrum with $\log_{10} \xi = 5.12^{+0.04}_{-0.01}$ and $n_e \geq 9.5 \times 10^{13} \text{ cm}^{-3}$. However, this single model is unable to account for the $\text{Si}
\text{XIII}$ He-like lines (Fig. 9, upper panel, blue), which are indicative of a lower density than that implied by the best-fitting XSTAR model. Similarly, in Epoch 2, we find $C/dof = 3015/2544$ for a single photoionized plasma with $\log_{10} \xi = 4.80^{+0.16}_{-0.11}$ and $n_e = 8.9^{+0.5}_{-0.3} \times 10^{12} \text{ cm}^{-3}$, again find that the $\text{Si}
\text{XIII}$ He-like lines remain poorly constrained in such a model (Fig. 9, lower panel, blue). A single photoionized model applied to the full energy range instead preferentially models two Fe lines, in both epochs.

In an attempt to solve this, we consider the possibility that there are multiple emission zones responsible for the lines observed in the spectrum of $\text{V4641 Sgr}$. We therefore apply the photoionized plasma grid generated by XSTAR to just the Si lines, limiting the fit to the 6–7Å range. In Epoch 1, we derive a best-fitting $n_e = 6.2^{+0.6}_{-0.5} \times 10^{12} \text{ cm}^{-3}$, which is consistent with the density derived from $R$. However, we also find $\log_{10} \xi < 3.18$, much lower than the value derived from fitting to the full spectrum (Fig. 9, upper panel, red). This model does not reproduce the Fe lines when applied to the full spectrum. In the case of Epoch 2, we find similar values for the best-fitting XSTAR grid, with $n_e = 6.2^{+1.4}_{-0.8} \times 10^{12} \text{ cm}^{-3}$ and $\log_{10} \xi < 3.10$. This is at odds with the $n_e < 10^{12} \text{ cm}^{-3}$ implied by the measured $R$. However, we note here that (a) the best-fitting XSTAR

\(^9\)https://heasarc.gsfc.nasa.gov/ftools/xstar/xstar.html

Figure 10. Full Chandra/HETG spectra of $\text{V4641 Sgr}$. Epochs 1 (ObsID: 22389) and 2 (ObsID: 23158) are shown in the upper and lower panel, respectively. In both panels, we show, in red, the best-fitting model (presented in Table 4) of a partially covered disc blackbody, with two XSTAR photoionized plasmas. In the insets, we show zoom-ins of some of the emission features that have been modelled. Data/model ratios are also plotted for each epoch.
Table 4. Best-fitting spectral parameters for the fully modelled 0.9–10 keV Chandra/HETG spectra of V4641 Sgr. The model consists of the partially covered disc-blackbody continuum, plus two photoionized plasmas, the first of which models the non-Fe plasma and includes both an absorption and emission component. The second photoionized plasma models the Fe emission only.

| Parameter                  | Epoch 1          | ObsID Epoch 2       |
|----------------------------|------------------|---------------------|
| $N_{\text{H}} (10^{21} \text{ cm}^{-2})$ | $2.8^{+0.0}_{-0.1}$ | $3.0^{+0.1}_{-0.1}$ |
| $N_{\text{H}, \text{pc/abs}} (10^{21} \text{ cm}^{-2})$ | $51.3^{+0.0}_{-0.1}$ | $70.7^{+0.2}_{-0.2}$ |
| $f$                        | $0.324^{+0.007}_{-0.003}$ | $0.370^{+0.003}_{-0.007}$ |
| $kT_{\text{abs}}$ (keV)    | $1.441^{+0.001}_{-0.000}$ | $1.533^{+0.002}_{-0.003}$ |
| $N_{\text{disc}}$          | $10.70^{+0.03}_{-0.10}$ | $54.91^{+0.02}_{-0.09}$ |
| $z_{\text{abs}, 1} \times 10^{4}$ | $-7.5^{+1.2}_{-2.0}$ | $-16.8^{+0.8}_{-1.0}$ |
| $n_{e 1}$ (10 cm$^{-3}$)   | $6.7^{+0.1}_{-0.3}$ | $5.1^{+1.2}_{-1.1}$ |
| $N_{e 1} (10^{21} \text{ cm}^{-2})$ | $2.6^{+0.1}_{-0.2}$ | $2.8^{+0.1}_{-0.2}$ |
| $\log \text{io}\Sigma_{1}$ | $<3.06^{+0.03}_{-0.03}$ | $<3.14^{+0.03}_{-0.03}$ |
| $N_{\text{XSTAR}, 1} \times 10^{-5}$ | $17.7^{+7.6}_{-2.1}$ | $8.3^{+1.0}_{-0.2}$ |
| $n_{e 2}$ (10 cm$^{-3}$)   | $5.8^{+1.1}_{-2.2}$ | $12.4^{+1.2}_{-1.6}$ |
| $N_{e 2} (10^{21} \text{ cm}^{-2})$ | $92.2^{+0.9}_{-0.9}$ | $7.0^{+0.9}_{-0.8}$ |
| $\log \text{io}\Sigma_{2}$ | $1.31^{+0.2}_{-0.9}$ | $<0.3^{+0.0}_{-0.0}$ |
| $\text{io}$               | $5.35^{+0.01}_{-0.00}$ | $5.15^{+0.03}_{-0.05}$ |
| $N_{\text{XSTAR}, 2}$      | $12.9^{+1.0}_{-5.4}$ | $4.9^{+0.6}_{-0.7}$ |
| $C/\text{dof}$             | $2582.2/2534$ | $2828.6/2534$ |

Notes. $z_{\text{abs}, 1}$: redshift of the absorption component of the first photoionized plasma
$n_{e 1}$: electron density of the first/second photoionized plasma
$N_{e 1}$: column density of the first/second photoionized plasma
$\log \text{io}\Sigma_{1}$: logarithm of the ionization parameter for the first/second photoionized plasma
$z_{\text{emis}, 1}$: redshift of the emission component of the first/second photoionized plasma
$N_{\text{XSTAR}, 1}$: normalization of the first/second photoionized plasma

Model slightly underestimates the strength of the Si XIII f line (Fig. 9, lower panel, red) and (b) our measured $R > 5.33$ is higher than any value of $R$ considered by Porquet & Dubau (2000) for the Si XIII triplet. Thus, our estimate of $n_{e 1}$ from line ratios may be inaccurate. Again, the model in Epoch 2 does not reproduce the Fe lines when applied to the full spectrum.

Interestingly, when the model derived just from the Si complex is applied to the full spectrum, we find that, even though the Fe complex is not reproduced, many other lines are. Most notably, the model reproduces the Mg XII Ly $\alpha$ lines detected in both epochs, but we also find that it predicts the S X VI and Ne X lines that are detected by the BB algorithm in Epoch 2. It is therefore possible that multiple emission zones exist within the V4641 Sgr system, where the Fe emission is separate to emission from many other metal ions.

We add a second XSTAR component to the model derived from the Si region alone, in an effort to constrain the Fe lines at the same time as those from other ions are constrained. The results of the fit are shown in Table 4. We find acceptable fits for both epochs, with $C/\text{dof} = 2582.2/2534$ in Epoch 1 and $C/\text{dof} = 2828.6/2534$ in Epoch 2. In both epochs, the best-fitting model implies that there can be two separate photoionized plasma components, each with their own density and ionization parameter. In Epoch 1, we find $n_{e 2} > 9.2 \times 10^{23} \text{ cm}^{-3}$ and $\log \text{io}\Sigma_{2} > 3.06$ for the first photoionized component, which we interpret as the Si-emitting plasma. For the second photoionized model component, we find $n_{e 2} > 7.0 \times 10^{23} \text{ cm}^{-3}$ and $\log \text{io}\Sigma_{2} > 5.35$ for the second (Fe-emitting) plasma component. We show the full fit to the Chandra/HETG spectra from both epochs in Fig. 10.

Utilizing equation (1), we can estimate the distance, $r$, of the presumed two line emitting mediums from the central ionizing source. Recalling, from Section 5.1, that the intrinsic $L_X$ is likely more than an order of magnitude brighter than what we measure. For the purposes of these estimates we assume a fiducial factor of 50 such that $L_X = 2.0 \times 10^{38} \text{ erg s}^{-1}$ in Epoch 1 and $L_X = 1.1 \times 10^{38} \text{ erg s}^{-1}$ in Epoch 2. Bearing in mind that we only find an upper limit for $\log \text{io}\Sigma_{2}$ in Epoch 1, we find a lower limit $r_{\text{Si}} > 1.6 \times 10^{14} \text{ cm}$ for the Si-emitting medium, whilst in Epoch 2 we find $r_{\text{Si}} > 1.3 \times 10^{15} \text{ cm}$. For the Fe-emitting plasma, we estimate $r_{\text{Fe}} \lesssim 3.1 \times 10^{10} \text{ cm}$ and $r_{\text{Fe}} \sim 1.1 \times 10^{10} \text{ cm}$ in Epochs 1 and 2, respectively - much closer to the BH than the Si-emitting medium.

In addition, we can use the best-fitting $n_{e 2}$ to estimate the size of the emitting regions, since $N_{e} = n_{e} \Delta r$, where $N_{e}$ is the column density of the photoionized plasma (which is also fit by the XSTAR grid) and $\Delta r$ is the size of the medium. In Epoch 1, we find $N_{e 2} > 2.6 \times 10^{21} \text{ cm}^{-2}$ and $N_{e 2} < 1.3 \times 10^{21} \text{ cm}^{-2}$ for the Si- and Fe-emitting plasma, respectively, implying $\Delta r_{\text{Si}} > 3.9 \times 10^{6} \text{ cm}$ and $\Delta r_{\text{Fe}} < 1.4 \times 10^{7} \text{ cm}$. In Epoch 2, we find $N_{e 2} > 2.8 \times 10^{21} \text{ cm}^{-2}$ and $N_{e 2} < 3.0 \times 10^{20} \text{ cm}^{-2}$ for the Si- and Fe-emitting plasma, respectively, implying $\Delta r_{\text{Si}} > 5.5 \times 10^{8} \text{ cm}$ and $\Delta r_{\text{Fe}} < 4.3 \times 10^{7} \text{ cm}$. This implies that the Fe-emitting region is more compact than the Si-emitting plasma, in both Chandra epochs.

5.4 Line Origins: a spherical outflow?

We find that the narrow lines in the two Chandra/HETG spectra of V4641 Sgr are best described by two photoionized plasma components in conjunction with a partially covered disc blackbody model. Although the BB algorithm we used to perform the initial line search did not pick out any blue-shifted absorption features at 95 per cent confidence, we find that the best-fitting twin photoionized plasma model implies the existence of weak P Cygni profiles in the spectra (at least for the non-Fe plasma; see Fig. 9, red, and Fig. 10), hinting at the existence of a spherical outflow, or at the very least, one with a non-zero solid angle (see e.g. Mauche & Raymond 1987; Matthews et al. 2015). The best-fitting velocities in Epoch 1 (from the $z$ values in Table 4) are $v = -150^{+60}_{-90} \text{ km s}^{-1}$ and $v = 480 \pm 180 \text{ km s}^{-1}$ for the blue absorption and red emission components of the non-Fe plasma, respectively. In Epoch 2, we find $v = -480^{+280}_{-90} \text{ km s}^{-1}$ and $v = 240^{+120}_{-60} \text{ km s}^{-1}$. Although these are lower velocity shifts than, say, those seen in V404 Cyg (King et al. 2015), similar centroid velocities were seen in H$\alpha$ during previous outbursts of V4641 Sgr (see fig. 4 of Muñoz-Darias et al. 2018), who ascribe the observed profiles to a spherical wind. In addition, Lindstrøm et al. (2005) noted a weak P Cygni-like profile in Fe II $\lambda 5179$ during the 2004 outburst, with the absorption component blueshifted by $v \sim 500 \text{ km s}^{-1}$, again consistent with our measurements in the second Chandra
epoch. We must emphasize here that, as the blue-shifted absorption features were not detected at 95 per cent confidence by the BB line search, the spherical wind hypothesis is speculative. However, such a hypothesis does line up with previous, optical, studies of V4641 Sgr.

6 HIGH-RESOLUTION X-RAY SPECTROSCOPY WITH FUTURE INSTRUMENTATION

Since launch, Chandra/HETGS has proved a powerful tool to study astrophysical plasmas at high resolution. The next generation of X-ray instrumentation will probe X-ray spectra with resolutions as low as a few eV (∼10⁻⁴ Å). Here we present simulated spectra of V4641 Sgr to visualize how our knowledge of the spectrum might improve with the successful launch of future X-ray missions. In particular, we focus on the Fe and Si regions.

The X-ray Imaging and Spectroscopy Mission (XRISM; Tashiro et al. 2018) will carry a microcalorimeter called Resolve (Ishikawa et al. 2018) as part of its instrumentation suite. Resolve’s energy resolution is expected to be 5–7 eV in the 0.3–12 keV bandpass, with a nominal requirement of at least 7 eV (0.0024 Å). The Fe XXVI Ly α line is actually a fine-structure doublet, whereas Fe XXV is an He-like triplet similar to the Si XIII lines studied in this work. These lines are unresolved in Chandra/HETG,¹¹ but should be resolved by XRISM/Resolve.

To test this, we performed simulations in the 1.7–1.9 Å range using the publicly available response matrices for the minimum energy resolution requirement of 7 eV. Our input spectrum included six Gaussians, two consist of the Ly α 1/2 (λ = 1.778 Å) and Ly α 3/2 (λ = 1.783 Å) doublet with a flux ratio of 2:1 as implied by the theoretical model. The remaining 4 Gaussian lines make up the r (λ = 1.850 Å), i (λ₁ = 1.855 Å, λ₂ = 1.860 Å), and f (λ = 1.868 Å) components of the He-like Fe XXV, which is actually a quadruplet due to the intercombination doublet. We use a fiducial flux ratio of r:i:1:2:3:f = 3:2:2:8, as implied by the measured R ∼ 2 and G ∼ 4 values of Si XIII from the first Chandra/HETG epoch, but note that this may not hold for He-like Fe XXV (see e.g. Fig. 4; inset). The width of the line was fixed to 0.0007 Å. We find that with just a 5 s exposure with XRISM/Resolve, the Ly α doublet can be easily resolved. In addition, we are able to resolve the r and f components of Fe XXV, though the two intercombination lines remain undetected.

Beyond XRISM, the Advanced Telescope for High Energy Astrophysics (Athena; Nandra et al. 2013; Barret et al. 2020) has a target launch date of 2035 and will carry the X-ray Integral Field Unit (X-IFU Barret et al. 2016). X-IFU will provide better than 2.5 eV (∼0.0006 Å) resolution up to 7 keV, with a large effective area (∼970 cm² at 7 keV). We simulated Athena/X-IFU spectra of the Fe region using the same input model as for XRISM/Resolve, though with the line widths instead fixed to 0.0002 Å. We find that we are able to easily resolve the Fe XXVI Ly α doublet, as well as Fe XXV r and f in just 1 ks. Increasing the exposure time to 5 ks, as we did with the XRISM/Resolve simulation, allows us to measure the individual components of the intercombination doublet. The two simulated spectra from XRISM/Resolve and Athena/X-IFU are presented in Fig. 11.

Resolving the He-like lines of Fe will allow us to perform plasma diagnostics on the iron-emitting plasma much like we did in Section 5.2 with Si XIII. Studying the Fe XXV complex will allow us to probe and accurately quantify higher densities than those allowed by lower Z ions such as Si XIII, up to a few 10¹⁷ cm⁻³, as well as probe higher temperatures via the G ratio (Porquet, Dubau & Grosso 2010). Furthermore, the large collecting area of the future X-ray missions, combined with the increase in spectral resolution, will enable us to trace line properties on ∼50 ks time-scales, measuring changes in, for example, equivalent widths over the binary orbital period, opening up the ability to study the spatial distribution of the line-emitting material at different orbital phases (Doppler tomography).

The large effective area of Athena/X-IFU will also allow us to probe plasma diagnostics at longer wavelengths, for example the Si XIII complex. We again simulated spectra of V4641 Sgr, this time in the Si region, using an input ratio r:i:1:2:3:f = 3:2:2:8 for Si XIII as implied by the measured R ∼ 2 and G ∼ 4 from Epoch 1 of Chandra/HETG. We acknowledge the large scatter in the measured R and G ratios (Si XIII r is actually consistent with zero in the Chandra data), but choose these ratios as an example to test the capabilities of Athena/X-IFU. In a 5 ks exposure, we find that, though the Si XIV Ly α and Si XIII intercombination doublets remain unresolved, the triplet is easily detected. Utilizing the triplet_fit function, as we did in Section 5.2, we measure R = 2.2^{+0.3}_{−0.4} and G = 3.5^{+0.7}_{−0.4}.

7 CONCLUSIONS

We have presented a study of the 2020 outburst of the BH–LMXB V4641 Sgr. We obtained spectra of the system with NuSTAR in 2020 January when it was in Sun constraint for the majority of other telescopes. NuSTAR revealed a hot disc-dominated spectrum with a strong emission feature in the 6–7 keV range. Two epochs of spectroscopy with the Chandra/HETGS also found a similar X-ray continuum. The measured inner disc temperatures and luminosities in both epochs imply that the central engine of V4641 Sgr is obscured, and that X-rays are scattered above the disc.

Chandra/HETG resolved the 6–7 keV emission feature seen by NuSTAR into two strong, highly ionized Fe lines at 6.7 and 6.97 keV (1.855 and 1.780 Å, respectively). Chandra also revealed a number of other highly-ionized metal emission lines, including Si XIV Ly α

¹¹Though see the insets in Fig. 4
and even He-like Si XIII. We used the He-like Si lines to perform some plasma diagnostics, measuring the ratio between the individual triplet components to find that the emission was consistent with a photoionized plasma. We then generated grids of photoionized plasmas using XSTAR, finding that the Chandra spectra in both epochs could be well described by two photoionized components, one to reproduce the Fe lines and a second for the non-Fe metals. This implies that there were two distinct emission regions responsible for the narrow line emission seen in V4641 Sgr, with separate ionization parameters and densities for each.

Though Chandra/HETGS revealed a myriad of strong lines in the X-ray spectrum of V4641 Sgr, we show that the next generation of X-ray instrumentation will deliver higher S/N spectra in a fraction of the time. In particular, Athena/X-IFU will provide high spectral resolution and effective area such that we will be able to track X-ray line properties over meaningful timescales, such as the binary orbital period, in BH-LMXBs such as V4641 Sgr.

ACKNOWLEDGEMENTS
We thank the anonymous referee for their insightful comments that helped improve this manuscript. This research has made use of ISIS functions (isisscripts) provided by ECAP/Remeis observatory and MIT (http://www.sternwarte.uni-erlangen.de/isis/). AWS would like to thank the NuSTAR Galactic Binaries working group for useful discussions regarding this work. Support for this work was provided by the National Aeronautics and Space Administration through Chandra Award Number GO0-21128X issued by the Chandra X-ray Center, which is operated by the Smithsonian Astrophysical Observatory for and on behalf of the National Aeronautics Space Administration under contract NAS8-03060.
