Abstract: Background: We conducted a meta-analysis to quantitatively assess the association between asbestos exposure and esophageal cancer. Methods: We systematically collected articles from three electronic databases and calculated the pooled standardized mortality rate (SMR) from the meta-analysis. Subgroup analysis according to the type of asbestos exposure, follow-up years, sample size, industry classification, sex, and high-dose exposure was conducted. Results: From 242 studies, 34 cohort studies were included in our meta-analysis. Pooled SMR was positively associated with asbestos exposure and esophageal cancer (pooled SMR = 1.28; 95% confidence interval (CI) 1.19–1.38, p < 0.00001). In the subgroup analysis, (1) chrysotile, (2) four groups with follow-up over ten years, (3) the textile industry and shipyard, (4) both male and female, and (5) eight studies on highest asbestos exposure, all the subgroups showed significantly increased pooled SMRs. Conclusion: Asbestos exposure was significantly and positively associated with esophageal cancer, especially chrysotile. Considering the long latency period, we suggest that patients should be followed up for cancer, including esophageal cancer, for over ten years.

Keywords: asbestos exposure; esophageal cancer; carcinogen; occupational medicine; environmental medicine; meta-analysis

1. Introduction

Asbestos has been classified as a group 1 carcinogen (carcinogenic to humans) since the 1970s [1]. Exposure to asbestos may result in asbestosis, recurrent pleural or pericardial effusion, pleural plaque and malignancy, including pleural and peritoneal mesothelioma, pharyngeal cancer, laryngeal cancer, and lung cancer [1,2].

After being inhaled or ingested into the body, longer asbestos fibers cannot be efficiently engulfed and cleared by macrophages [3]. The accumulation of asbestos fibers catalyzes the generation of free radicals and increases the uptake and metabolism of many specific proteins as well as carcinogenic molecules (for example, polycyclic aromatic hydrocarbons) by respiratory tract epithelial cells [4,5]. In addition, asbestos bodies formed by
“frustrated phagocytosis” and surrounding inflammatory cells induce chronic inflammation of affected tissue [3]. The above mechanism results in the formation of mesothelioma and respiratory tract malignancies.

Esophageal cancer is a common cancer worldwide and is the sixth leading cause of cancer death, accounting for over 500,000 cancer deaths annually (approximately 5.3% of all global cancer deaths) [6]. Esophageal cancer can be classified into squamous cell carcinoma and adenocarcinoma based on histology. In addition, men are at three to four times higher risk of developing esophageal squamous cell carcinoma and seven to ten times higher risk of developing esophageal adenocarcinoma [6]. Risk factors for esophageal cancer include genetic factors, sex, race, gastroesophageal reflux disease, obesity, nitrosamine, tobacco, alcohol consumption, drug use, low socioeconomic status, and nutritional deficiency [6,7]. However, studies on occupational or environmental factors of esophageal cancer are still rare.

The causal link between asbestos and gastrointestinal cancer has been discussed since asbestos is regarded as a group 1 carcinogen and is associated with asbestos exposure. However, the association between asbestos exposure and esophageal cancer has been debated in the last 20–30 years. Morgan et al. demonstrated that asbestos exposure may elevate the risk of esophageal cancer (standardized mortality ratio (SMR): 2.38; 95% confidence interval (CI) 1.45–3.68) and total gastrointestinal cancer (SMR: 1.05; 95% CI 0.98–1.13) [8]. In a large cohort of 58,279 employees, Offermans et al. shown an increase hazard ratio (2.22, 95% CI 1.00–4.94) of esophageal cancer in the asbestos exposure workers [9]. In a study of 4427 shipbreaking workers, Wu et al. found an increased hazard ratio (2.31, 95% CI 1.00–5.41) of esophageal cancer in asbestos exposure [10]. Clin et al. analyzed 2024 subjects with history of occupational asbestos exposure and they found increased incidence of esophageal cancer (standardized incidence ratio (SIR) 1.60, 95% CI 1.00–2.42) [11]. On the other hand, Reid et al. estimated 129 cases with a history of occupational crocidolite (one classification of asbestos) exposure, and the results revealed no significantly association between asbestos exposure and esophageal cancer (SIR 1.11 with 95% CI 0.60–2.07, (SMR): 0.89 with 95% CI 0.44–1.78) [12]. Similar result was also found on cohort study of workers with history of asbestos exposure from de La Provote et al. (SIR 1.29, 95% CI 0.73–2.09) [13]. Moreover, Gustavsson et al. [14], Parent et al. [15], and Santibañez et al. [16] also shown no significantly increased risk of esophageal cancer in asbestos exposure case control studies, which revealed relative risk (RR) 1.21 (95% CI 0.67–2.17), odds ratio (OR) 1.4 (95% CI 0.7–2.7), and OR 1.27 (95% CI 0.77–2.10), respectively. The association between asbestos exposure and esophageal cancer was still inconsistent till now.

Due to the controversial and inconsistent relationship between asbestos exposure and esophageal cancer, our aim was to conduct a meta-analysis to investigate the association between asbestos exposure and esophageal cancer.

2. Materials and Methods

2.1. Protocol and Registration

We conducted a meta-analysis of the association between asbestos exposure and esophageal cancer based on the guidelines of Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). The review protocol is registered at the International Prospective Register of Systematic Reviews (PROSPERO) (ID: 265920, under the process of registration), which is an open-access online database of prospectively registered systematic reviews on topics related to health and social care.

2.2. Data Sources and Search Terms

We initially searched related studies in electronic databases, including PubMed, Embase and Web of Science, on May 16, 2021. We did not set any limitations on publication date, and all studies containing target keywords were identified. Initial searches of research using various keywords were performed by two researchers (H.Y. Chuang, and C.C.)
Yang). Keyword combinations proposed by researchers were as follows: “Asbestos” OR “Asbestos, Amphibole” OR “Asbestos, Amosite” OR “Asbestos, Crocidolite” OR “Asbestos, Serpentine” OR “Asbestos, Amphibole-group Minerals” OR “Asbestos, Amphibole group Minerals” OR “Amphibole Asbestos” OR “Amphiboles” OR “Amphibole” OR “Crocidolite” OR “Crocidolite Asbestos” OR “Blue Asbestos” OR “Asbestos, Blue” OR “Asbestos, Crocidolite” OR “Asbestos, Serpentine” OR “Asbestosis” AND “Esophageal Neoplasm” OR “Neoplasm, Esophageal” OR “Esophagus Neoplasm” OR “Esophagus Neoplasms” OR “Cancer of Esophagus” OR “Cancer of the Esophagus” OR “Esophagus Cancer” OR “Cancer, Esophagus” OR “Cancers, Esophagus” OR “Esophageal Neoplasms” OR “Esophageal Neoplasms” OR “Esophageal Squamous Cell Carcinoma” OR “Esophageal Neoplasms”(Mesh) OR “Esophageal Neoplasms”. However, words such as actinolite, tremolite, and anthophyllite do not belong the entry terms about asbestos in PubMed database were not use in the search. We considered the search strategies for the Embase and Web of Science databases as appropriate.

2.3. Eligibility Criteria

Studies were included based on the following inclusion criteria: (1) no participant limitation, (2) history of asbestos exposure, and (3) outcome of esophageal cancer. (4) studies mentioning SMR, or mentioning observed and expected group. Studies were excluded according to the following exclusion criteria: (1) studies lacking key information about asbestos exposure and esophageal cancer, (2) studies without full-text or relevant data resources could not be obtained, (3) letters, reviews, case reports, expert opinions, or laboratory studies, (4) nonhuman research, (5) guidelines, (6) articles focusing on policy discussion, and (7) articles not included during analysis.

2.4. Study Selection Process

Initially, first-time screening was performed by two investigators (C.W. Wu and C.C. Yang) by assessing the titles and abstracts of preliminarily identified studies. A second round of screening was performed by screening the full text of articles meeting the eligibility criteria and those with unclear eligibility. Five researchers (H.Y. Chuang, D.L. Tsai, T.Y. Kuo, H.C. Chen, and C.H. Kuo) further comprehensively evaluated the eligibility of each study to consider whether it should be included if two researchers initially disagreed on the eligibility of the study.

2.5. Data Collection

From each article included in our study, information regarding study characteristics, asbestos exposure, and esophageal cancer was extracted. We also obtained the association between asbestos exposure and esophageal cancer. We contacted the corresponding authors for further verification if the above information was ambiguously described or was mentioned in doubt.

2.6. Study Characteristics

Data related to study characteristics were extracted as follows: first author, publication year, country where the study was completed, sample size, characteristics of participants, and number of outcome events (for example, the observed and expected number of participants with esophageal cancer, or the standardized mortality ratio (SMR)).

2.7. Asbestos Exposure

Asbestos exposure was defined based on individual studies, including past working history provided by factories, national agencies, or solitary institutions, questionnaires, and information from interviews. In addition, information on dust measurement and cumulative fiber dose was provided according to individual studies.
2.8. Esophageal Cancer

We defined esophageal cancer as one of the causes of death described in our included studies, which was validated by authors through death certificates, records provided by institutions or hospitals (including hospitalization records, reports from histological material or autopsy), and International Classification of Disease (International Statistical Classification of Disease, Injuries, and Cause of Death) codes.

2.9. Statistical Analysis

We calculated all SMRs from the number of observed deaths and patients with esophageal cancer, with the mortality rate for the population regarded as the basis for comparison, and their 95% CIs were recalculated according to the Boice-Monsom method [17]. We derived the pooled standardized mortality rate (SMR) from the respective SMR of each included study, and the standard error (SE) for the SMR was assessed according to the 95% confidence interval (95% CI). If SMR wasn’t mentioned in articles, we recalculated SMR and its 95% CI through observed death and expected death mentioned in articles [18]. We used the main SMRs and SEs to estimate the pooled SMR and its 95% CI through a fixed-effects model while conducting the main analysis. We applied the fixed-effects model to assess the possibility of heterogeneity in SMRs among the studies included based on the study characteristics. We quantified the effect of the heterogeneity among the included studies by using I² statistics. Publication bias was estimated by using a funnel plot. We performed further subgroup meta-analysis of the included studies including type of asbestos exposure, follow-up years of the included studies, sample size, industry classification, gender, and highest exposure group. All statistical analyses were conducted using Review Manager version 5.4 and R version 3.6.2.

3. Results

3.1. Selected Studies

Figure 1 shows the PRISMA flow chart of the selection procedure. In the first step, we found 239 articles from three databases (PubMed, Embase, and Web of Science), and an additional three studies were identified by reference screening [19,20]. Among the 242 articles, 64 duplicates were removed, and two authors (C.W. Wu, and C.C. Yang) recognized the remaining 178 studies through title and abstract screening. After excluding 126 studies by title and abstract, two authors assessed the full-text articles of the 52 studies for eligibility. After screening the full text of the 52 articles, two studies were omitted because they did not meet the following criteria: no comparison of esophageal cancer between the asbestos exposure and reference populations (N = 1) and a perspective article (N = 1). Finally, 50 studies were included in the qualitative synthesis, and 34 studies were included in the quantitative synthesis using meta-analysis.
Table 1 demonstrates the basic characteristics of the 34 included studies [19–52]. Among the included studies, all 34 were cohort studies, of which the earliest was published in 1963, while the latest was published in 2017. Most of the studies were conducted in both genders or mainly in males, while four studies focused on females or performed subgroup analyses of females [34,40,50,52]. Different asbestos types, including seven studies of chrysotile [30,34,39,44,46,49,50], four studies of amosite [20,22,32,51], two studies of crocidolite [28,42], and 20 studies of mixed asbestos, were investigated for further subgroup analysis of the type of asbestos. Two studies had a follow up of less than or equal to 10 years [23,34,52], seven studies were above 10 years but no more than 20 years [19,20,27,29,30,32,50], six studies were above 20 years but no more than 30 years [38,39,42,46,48,49], eight studies were above 30 years but no more than 40 years [21, 22,26,28,41,43,47,51], and eight studies were above 40 years [24,31,35–37,44,45,52]. The sample size of five studies was less than 1000 participants [20,32,38,45,47], 20 studies were between 1000 and 10,000 [19,22–24,26–28,31,33,34,37,39,40,42,44,46,48,49,51,52], and eight studies were over 10,000 [21,29,30,35,36,41,43,50]. Regarding industry classification, seven studies focused on the textile industry [23,33,34,39,40,44,47], three studies focused on the shipyard industry [36,45,48], and five studies focused on miners [28,30,42,46,49]. Eight studies included the highest asbestos exposure subgroup according to their individual definition [23,25,27,31,33,45,48,49].
Table 1. Studies included in the meta-analysis study (N = 34).

| Study (Year) | Country | N         | Follow-up Period | Study Population | Asbestos Type | Comparison | Observed/Expected of EC | SMR (95%CI) | Reference Population |

CI: confidence interval; EC: esophageal cancer; NR: not reported; SMR: standardized mortality ratio.
3.3. Meta-Analysis

The association between asbestos exposure and esophageal cancer was determined by a fixed-effect model meta-analysis, in which the pooled SMR resulted from 36 SMRs of 34 studies (Table 1, Figure 2) [19–52]. Compared with the reference group, the pooled SMR of esophageal cancer was significantly increased in participants with asbestos exposure (pooled SMR = 1.28; 95% CI 1.19–1.38; z = 6.47, \( p < 0.00001 \)). The heterogeneity was not significant (\( I^2 = 20\%, \chi^2 = 43.68, p = 0.15 \)). Figure 3 shows a funnel plot of the log transformed SMRs of the 34 studies, and the SEs revealed significant SMRs with relatively and reasonably smaller SEs.

| Study or Subgroup | log(Rate Ratio) | SE   | Weight | Rate Ratio IV, Fixed, 95% CI | Rate Ratio IV, Fixed, 95% CI |
|-------------------|----------------|------|--------|----------------------------|----------------------------|
| 2017 Oddone       | -0.21072103    | 0.38611126 | 1.0%   | 0.81 [0.38, 1.73]           |                             |
| 2016 Levin        | -0.22314355    | 0.68437051 | 0.3%   | 0.80 [0.21, 3.06]           |                             |
| 2016 Kovalevskiy  | 0.37843644     | 0.12575714 | 9.2%   | 1.46 [1.14, 1.87]           |                             |
| 2014 Lin          | 0.37156356     | 0.32807086 | 1.4%   | 1.45 [0.76, 2.76]           |                             |

Figure 2. Asbestos exposure and standardized mortality ratio (SMRs) of esophageal cancer in the 33 studies: a fixed-effect model.
3.4. Subgroup Analysis

Regarding asbestos type, the chrysotile subgroup showed a significantly increased pooled SMR of 1.27 (95% CI 1.07–1.51, \( p \)-value = 0.006) [34,39,44,46,49,50], while amosite and crocidolite did not show significantly increased pooled SMRs of 1.14 (95% CI 0.53–2.47, \( p \)-value = 0.73) [20,22,32,51] and 1.20 (95% CI 0.70–2.05, \( p \)-value = 0.51) [28,42], respectively (Figure 4). Studies with a follow-up of no more than 10 years did not show a significantly increased pooled SMR of 1.38 (95% CI 0.86–2.21, \( p \)-value = 0.19) [23,34], while the other four subgroups showed significantly increased pooled SMRs, with 1.31 (95% CI 1.10–1.55, \( p \)-value = 0.002) [19,20,27,29,30,32,50], 1.46 (95% CI 1.20–1.77, \( p \)-value = 0.0001) [38,39,42,46,48,49], 1.22 (95% CI 1.08–1.37, \( p \)-value = 0.001) [21,22,26,28,41,43,47,51], and 1.25 (95% CI 1.06–1.47, \( p \)-value = 0.007) [24,31,35–37,44,45,52], respectively (Figure 5). The pooled SMRs of studies with participants <1000, 1000–10,000, and >10,000 were significantly increased by 1.33 (95% CI 1.03–1.73, \( p \)-value = 0.03) [20,32,38,45,47], 1.32 (95% CI 1.12–1.56, \( p \)-value = 0.0009) [19,22,24,26–28,31,33,37,39,40,42,44,46,48,49,51,52], and 1.28 (95% CI 1.17–1.40, \( p \)-value < 0.00001) [21,29,30,35,36,41,43,50], respectively (Figure 6). The pooled SMRs of the textile industry and shipyard significantly increased by 1.45 (95% CI 1.13–1.86, \( p \)-value = 0.004) [23,33,35,39,40,44,47] and 1.39 (95% CI 1.15–1.68, \( p \)-value = 0.0006) [36,45,48], respectively, while the pooled SMR of miners did not significantly increase at 1.07 (95% CI 0.81–1.41, \( p \)-value = 0.62) [28,30,42,46,49] (Figure 7). Both pooled SMRs of females and males were significantly increased, with 1.61 (95% CI 1.07–2.42, \( p \)-value = 0.02) [34,40,50,52] and 1.37 (95% CI 1.21–1.55, \( p \)-value < 0.00001) [19–23,25–27,29–32,35,37,39,40,42,45,47–50,52], respectively (Figure 8). The pooled SMR of eight studies in the highest asbestos exposure groups was significantly increased, 1.84 (95% CI 1.27–2.68, \( p \)-value = 0.001) [23,25,27,31,33,45,48,49] (Figure 9).
Figure 4. Subgroup analysis of SMRs of esophageal cancer based on the type of asbestos exposure.
Figure 5. Subgroup analysis of SMRs of esophageal cancer based on follow-up years.

3.5. Risk of Bias Assessment

We evaluated the risk of bias of individual observational studies through the Risk of Bias Assessment tool for Non-Randomized Studies (RoBANS) [53]. The results are shown in Figures 10 and 11, which revealed a low probability of bias except for three categories: (1) confounding variables, (2) incomplete outcome data and (3) selective outcome reporting. The probability of bias related to confounding factors was high risk in all studies due to unadjusted the potential confounding variables. The probability of bias related to incomplete outcome data was of unclear risk in 2006 Giannandrea et al. [38] and high risk in 2004 Silver et al. [36] The probability of bias related to selective outcome reporting was of unclear risk in an article from 2006 Giannandrea et al. [38].

4. Discussion

To our knowledge, this study is the most comprehensive and first investigation of 34 cohort studies on the SMR of esophageal cancer in asbestos-exposed participants. Previous investigators have conducted studies on the relationship between asbestos and esophageal cancer since the 1980s, but the evidence remains insufficient [19,24,25,29,30,33,36,39,44,45,50]. Based on description from Institute of Medicine (US) Committee on Asbestos in 2006, the evidence related to association between asbestos and esophageal cancer was insufficient [54]. In contrast, Li et al. had conducted a meta-analysis through 20 cohort studies and they found positive association between esophageal cancer and asbestos exposure [55]. However, we made a more comprehensive search from 1963 to 2017, and finally included 34 studies which generated 36 SMR for meta-analysis. In the meta-analysis study, we quantitatively assessed the relationship between asbestos exposure and esophageal cancer based on 34 cohort studies, and the results demonstrated an increased SMR (1.28) in esophageal cancer patients with occupational or environmental asbestos exposure; that is, participants with a history of asbestos exposure were 1.28 times more likely to die from esophageal cancer than the general population. Asbestos-related esophageal cancer may result from the generation of free radicals such as reactive oxygen species and chronic inflammation due to asbestos disposition [56]. According to an animal study from Møller et al., gastrointestinal tract exposure to asbestos increased the level of 8-oxo-7,8-dihydroguanine, causing oxidative-damaged DNA in the internal organs [57]. Nevertheless, more evidence is needed to clarify the mechanism of asbestos-induced esophageal malignancy.

Although all types of asbestos may be related to malignancy formation, different types of asbestos may have different potencies in inducing cancer. For example, amphibole fibers (including crocidolite and amosite) may cause a more harmful effect in inducing lung cancer than chrysotile fibers [1]. In our subgroup analysis of asbestos species, we found that exposure to chrysotile and mixed asbestos (containing chrysotile) was significantly associated with an increased SMR in esophageal cancer. A similar result was found in Wronkiewicz et al.’s study, which showed tissue surrounding pharyngeal cancer and laryngeal cancer in 6 cases with a history of occupational asbestos exposure through scanning electron microscopy, and chrysotile fibers were noted in the tissues of 3 cases [58]. Our results did not show a significantly increased SMR in participants who were exposed to amosite and crocidolite. Nevertheless, we found an elevated SMR or higher observed to expected death ratio of esophageal cancer after exposure to amosite and crocidolite in the included studies [20,28,32,42]. We believe that amosite and crocidolite also have the potential to induce esophageal cancer, but there are relatively few studies focusing on amosite and crocidolite. Chrysotile is currently the asbestos type that is most commonly used, so more studies discussing chrysotile and esophageal cancer were included in our study. More evidence is needed to clarify the relationship between asbestos type and esophageal cancer.

In the subgroup analysis of follow-up years, the results showed a significantly increased SMR of esophageal cancer in the four subgroups with more than ten years of follow-up. This is probably because of the long latency period of asbestos-related malignancy. Uguen et al. retrospectively reviewed and analyzed 146 patients with asbestos-related lung cancer, and the mean duration of the latency period was 10.5 ± 8.6 years [59]. According to a literature review published recently by Borrelli et al., the latency period of mesothelioma induced by occupational asbestos exposure was approximately 20–70 years [60]. Rarely could evidence discussing the duration of asbestos-related esophageal cancer be found. Based on our study, we recommend that workers with a history of occupational asbestos exposure should regularly be followed up for asbestos-related cancers, including esophageal cancer, for over 10 years.

In the subgroup analysis of industrial type, we found significant association between asbestos exposure and esophageal cancer in textile worker and shipyard, but not in asbestos miners. Our finding was lined with previous studies for asbestos-related cancer. Wang et al.
observed chrysotile mining cohort and chrysotile textile worker for 26 years, and they found higher death risk of lung cancer in textile worker than in mine worker [61]. Based on measurement report from Berman, asbestos fibers are longer in textile industry dust than in mine dust, which may be a possible reason indicating workers in textile factory are more easily to get asbestos-related cancer than workers in mine [62]. Moreover, milled asbestos fibers (longer fiber asbestos) are also used in shipyard, which may be the possible reason that shipyard workers are in a higher risk of esophageal cancer. Nevertheless, relatively rare studies discussing the possible mechanism between asbestos industrial type and incidence of asbestos-related cancer. More studies are needed for further survey.

There are several limitations to our study. First, the SMR of esophageal cancer may be affected by the most common methodological challenges associated with attrition bias. For instance, workers in several studies did not work for over one year, which might indicate a health worker effect. However, this limitation is unavoidable, and we assessed the risk of bias for the 33 included studies with the RoBANS. Second, we made quantitative synthesis of those articles mentioning standardized mortality rate or providing observed group and expected group using meta-analysis. The results of the meta-analysis using publication that were not included due to their study design, such as case-control study design. This may have some selection bias and could be a limitation. Finally, the formation of esophageal cancer was affected by multiple factors despite the duration of asbestos exposure. Adjusting for possible confounders, including smoking or alcohol consumption, will provide more comprehensive and rigorous evidence, and this is a direction of future research.

5. Conclusions

In conclusion, the findings of this study indicated that occupational or environmental asbestos exposure might significantly increase the risk of esophageal cancer. In the subgroup analysis based on asbestos type, chrysolite was found to be significantly associated with esophageal cancer. Finally, due to the long latency period of asbestos-related esophageal cancer, we suggest that patients with a history of asbestos exposure should continue follow-up cancer screening for more than ten years.
