(Received 30 October 2020; accepted 11 December 2020; published 24 December 2020)

We investigate the phononic in-plane longitudinal low-temperature thermal conductivity $\kappa_{ab}$ of the Kitaev quantum magnet $\alpha$-RuCl$_3$ for large in-plane magnetic fields up to 33 T. Our data reveal, for fields larger than the critical field $B_c \approx 8$ T, at which the magnetic order is suppressed, a dramatic increase of $\kappa_{ab}$ at all temperatures investigated. The analysis of our data shows that the phonons are not only strongly scattered by a magnetic mode at relatively large energy which scales roughly linearly with the magnetic field, but also by a small-energy mode which emerges near $B_c$ with a square-root-like field dependence. While the former is in striking agreement with recent spin-wave theory (SWT) results of the magnetic excitation spectrum at the $\Gamma$ point, the energy of the latter is too small to be compatible with the SWT-expected magnon gap at the $M$ point, despite the matching field dependence. Therefore, an alternative scenario based on phonon scattering off the thermal excitation of random-singlet states is proposed.

I. INTRODUCTION

For more than a decade, the celebrated Kitaev model describing spin-1/2 degrees of freedom on a honeycomb lattice with bond-dependent interactions [1] has been attracting much attention. This strongly frustrated spin model is exactly solvable and has been shown to exhibit a gapless quantum spin liquid (QSL) ground state with spin excitations which fractionalize into localized $Z_2$ gauge fluxes and itinerant Majorana fermions [1–3]. An external magnetic field renders the ground state a topological quantum spin liquid (TQSL), with peculiar properties. Chiral Majorana edge modes arise within the field-induced gap, and the $Z_2$ vortices acquire non-Abelian anyonic statistics, rendering Kitaev materials relevant for quantum computing [1].

Substantial effort has been devoted towards experimentally realizing Kitaev’s spin liquid. Candidate materials are Ir and Ru compounds where considerable spin-orbit interaction leads to the emergence of Kitaev interaction between spin-orbit entangled $J_{eff} = 1/2$ moments [4–6]. However, most of these compounds exhibit a magnetically ordered ground state due to the presence of additional interactions in the Hamiltonian [7–9]. Consequently, ways of suppressing this order in favor of a spin liquid have been sought for, and one of the most promising materials here is $\alpha$-RuCl$_3$. It displays zigzag antiferromagnetic order in zero magnetic field below $T_N \approx 7$ K [10–12]. This long-range order can be suppressed by an in-plane field of $B_c \approx 8$ T, where signatures of quantum criticality have been reported [13–16]. At fields larger than $B_c$, magnetic order remains absent, and it has been speculated that a field-induced TQSL exists for $B > B_c$ in a window of magnetic fields [13,17,18]. This notion seems to be spectacularly corroborated by the recent report of half-integer quantization of the thermal Hall conductance near $B_c$ [19]. Independently, there is evidence that the magnetic excitation spectrum at $B > B_c$ is adiabatically connected to the polarized state realized in the high-field limit: Field-dependent magnon-type excitations at the $\Gamma$ point, as observed by electron spin resonance (ESR) [20,21] and Raman spectroscopy [22], as well as a field-dependent low-energy gap extracted from specific-heat data [13], appear consistent with semiclassical spin-wave theory (SWT) and exact-diagonalization (ED) results [13,23,24] for extended Heisenberg-Kitaev-Gamma models. Here, the high-field magnon spectrum is characterized by a dispersion minimum at the $M$ point and a van Hove singularity at the $\Gamma$ point.

Magnetic excitations affect the heat transport in solids in two distinct ways: They carry heat themselves, leading to a magnetic contribution to thermal conductivity which may expose important information about the excitations’ heat capacity and scattering properties [25–27]. In addition, magnetic...
excitations act as scattering channels for other heat-carrying modes, most importantly phonons. If thermal conductivity is dominated by the latter, then thermal conductivity carries information about spin-phonon scattering \cite{28,29}.

For $\alpha$-RuCl$_3$, previous studies have revealed that the longitudinal heat conductivity is primarily phononic, with substantial spin-phonon coupling leading to strongly field- and temperature-dependent spin scattering of the phonons \cite{30,31}. Considerable controversy exists, however, with respect to a sizable transversal heat conductivity that has been observed in the material for out-of-plane magnetic fields \cite{32,33}. On one hand, this has been interpreted as evidence for thermal transport by Majorana fermions \cite{32}, which directly connects to the aforementioned half-integer quantization of the thermal Hall conductance \cite{19}. On the other hand, it has been pointed out that a purely phononic origin cannot be excluded \cite{33,34}. For example, several theories have investigated the particular role of spin-phonon interaction on the phonon thermal Hall effect \cite{35–37}.

Motivated by these results, we investigate in this work the in-plane longitudinal thermal conductivity $\kappa_{ab}$ for in-plane magnetic fields in an extended magnetic field and temperature range, namely, fields up to 33 T, from sub-Kelvin temperatures up to 80 K. Our data reveal that for $B > B_c$, the heat conductivity dramatically increases with the magnetic field at all temperatures investigated. These results provide strong evidence that the phonons are scattered not only by a magnetic mode at the $\Gamma$ point, but additionally by further, quite different magnetic excitations. While the energy of the former, as already inferred previously \cite{30}, strongly increases with increasing field above $B_c$, reaching about 100 K at 30 T, the energy of the latter is more than an order of magnitude smaller. As we show, this appears inconsistent with spin-wave modes of the high-field phase. We conjecture that this scattering arises from a small concentration of residual defects which create random-singlet-type excitations below the bulk energy gap of the high-field phase, possibly consistent with nuclear magnetic resonance (NMR) results showing persistent relaxation at temperatures below the bulk gap \cite{17,38}.

II. EXPERIMENTAL DETAILS

Single crystals of $\alpha$-RuCl$_3$ have been grown by chemical vapor transport \cite{30}. For $8 \leq T \leq 80$ K, $\kappa_{ab}$ measurements were performed in a home-built probe, employing a four-points measurement geometry. One face of the rectangularly shaped single crystal (sample 1) was thermally excited by a resistive chip heater, and the resulting temperature gradient across the sample was picked up by a differential Au/Fe-Chromel thermocouple. The field calibration of the thermocouple was obtained \textit{in situ} by monitoring the temperature gradient of a glass sample (Herasil) in an identical four-points configuration with a second thermocouple of identical build, assuming a field-independent thermal conductivity for this nonmagnetic material. Data were taken up to 30 T at constant temperatures with the magnetic field ramped in 2 T steps, with the required holding time to allow for thermal equilibrium to be reached at each $B$ and $T$ value.

Measurements at $T < 4$ K were performed on a second single crystal (sample 2). A closed-cycle $^3$He-cooled setup was used, employing a standard steady-state one-heater, two-sensors (Cernox chip thermometers) geometry. The two thermometers were calibrated \textit{in situ}, where data were taken up to 33 T in an analogous manner to the high-$T$ ($T \geq 8$ K) measurements. For both samples, magnetic fields were applied in-plane, directed perpendicular to the heat current. All high-field measurements have been conducted at HFML. For sample 1, additional measurements with $B \leq 16$ T have been performed at IFW Dresden using the same setup, yielding field-dependent data in excellent agreement with the HFML results for the overlapping field range. The three data sets obtained show good consistency and are presented in this work modulo a fixed scaling factor for direct comparability.

III. RESULTS

We first address the in-plane thermal conductivity $\kappa_{ab}$ for temperatures $T \geq 5$ K in high external magnetic in-plane fields $0 \leq B \leq 30$ T, as shown in Fig. 1. For $B \leq 18$ T, these data are very similar to our previous results for the same temperature range \cite{30}: At zero magnetic field (gray circles), $\kappa_{ab}$ first exhibits a sharp kink at the magnetic ordering temperature at about 7.7 K, followed by a broad peak at about 40 K. The well-defined $T_N \approx 7$ K is a clear indication that our samples are free from stacking faults \cite{12}. Applying an in-plane external magnetic field $B \geq B_c$ causes a strong enhancement of $\kappa_{ab}$, with the increase below $T \approx 40$ K being most prominent. Remarkably, the further enhancement of the magnetic field up to 30 T causes a mere continuation of the field enhancement of $\kappa_{ab}$ lacking any signs of saturation, resulting in a fivefold amplification of $\kappa_{ab}$ at $T = 15$ K as compared to its zero-field value (see Fig. 1).

The nonsaturating field dependence $\kappa_{ab}(B)$ at fixed temperature can be observed more accurately in Fig. 2(a). While a small decrease of $\kappa_{ab}(B)$ is discernible at $B \lesssim B_c$, larger fields $B \gtrsim B_c$ cause a strong increase of $\kappa_{ab}(B)$ for all $T \geq 8$ K. The slope $\partial \kappa_{ab}/\partial B$ is highest at 8 to 15 K, then gradually decreases

FIG. 1. Temperature dependence of the longitudinal heat conductivity $\kappa_{ab}$ of $\alpha$-RuCl$_3$ parallel to the honeycomb layers in zero and high in-plane magnetic fields. Data for $10 \leq B \leq 16$ T were taken at IFW Dresden (squares), data for the same sample, $B = 0$ and $B \geq 18$ T at HFML (circles). The temperature scale is logarithmic; dashed lines are guides to the eye.
FIG. 2. (a),(b) Magnetic field-dependent data of the longitudinal heat conductivity $\kappa_{ab}$ of $\alpha$-RuCl$_3$ parallel to the honeycomb layers at constant $T$. The data of sample 1 were taken at IFW Dresden (open squares) as well as at HFML (open circles); sample 2 was measured at HFML (open triangles). (a) At $B \gtrsim B_c$, $\kappa_{ab}$ increases strongly at all temperatures measured. (b) Semilogarithmic plot of the low-$T$ data—a substantial field dependence up to the highest field is visible down to the lowest temperatures, as discussed in the main text. (c) Illustration of the expected relative field dependencies $\kappa_{rel} = [\kappa_{ab}(B) - \kappa_{ab}(10\,\text{T})]/\kappa_{ab}(10\,\text{T})$ at three distinct temperature regimes (see text) for a model comprising one characteristic magnetic scattering mode of energy $\Delta$. Details on the calculations are specified in the Appendix.

with increasing $T$, where even at 80 K a finite slope is still detectable.

Qualitatively, the observed $\kappa_{ab}(T, B)$ is consistent with an all-phononic heat conductivity, which is affected by a strong, $B$- and $T$-dependent spin-phonon scattering. More specifically, as has been shown in Ref. [30], at fields above about 8 T, a single magnetic mode, the energy $\hbar\omega_0$, of which increases about linearly with the field, is capable of causing a concomitant strong enhancement of $\kappa_{ab}(T, B)$ if the heat-transporting phonons of the mode’s energy are strongly scattered off it. As mentioned in Sec. I, the existence of such a magnetic mode has been confirmed by several probes, including NMR [17], ESR [20,21], Raman [22], as well as neutron scattering [39], and is also predicted theoretically in SWT and ED model calculations, where it is connected to a van Hove singularity near the $\Gamma$ point [13,23,24]. The nonsaturated $\kappa_{ab}(B)$ even at 30 T therefore suggests that the energy of this mode continues to increase linearly beyond 18 T, up to the highest field measured.

In such a scenario, the reduction of the slope $\partial\kappa_{ab}/\partial B$ with increasing temperature naturally results from the scattered phonons’ reduced contribution to the total phonon heat conductivity: This is because the phonons predominantly carrying the heat have an energy $\hbar\omega \sim k_B T$ [30,40,41]. Thus, for $T \to \infty$, the field dependence of $\hbar\omega_0$ becomes increasingly unimportant for $\kappa_{ab}(T, B)$ and leads to a vanishing slope as soon as $T > \hbar\omega_0/(k_B)$. To illustrate this temperature effect, Fig. 2 shows the heat conductivity’s expected relative magnetic field dependence $\kappa_{rel}$ for three temperature regimes, with a single magnetic scattering mode of energy $\Delta$ present in the system. Consequently, for the case $T \gg \Delta/k_B$ shown in the top panel, the strong field increase present at intermediate temperatures ($T \sim \Delta/k_B$, center panel) is reduced to less than 2% over the investigated field range. The corresponding limit is reached in the experimental data at approximately 80 K; see Fig. 2(a). In a similar fashion to the high-temperature case, one can argue that towards $T \to 0$, one would expect a rapidly diminishing slope $\partial\kappa_{ab}/\partial B$ [see bottom panel of Fig. 2(c)].

One can test the latter expectation quite conveniently by probing the thermal conductivity at about 1 K. Here, $T \ll \hbar\omega_0(B)/k_B$ should always be fulfilled since $\hbar\omega_0(B)/k_B \gtrsim 30\,\text{K}$ at $B > 12\,\text{T}$ [20,30]. Figures 2(a) and 2(b) show our pertinent low-temperature measurements (sample 2) for $T < 4\,\text{K}$ as a function of the magnetic field up to 33 T. While the data in the magnetically ordered phase at $B \lesssim 7.5\,\text{T}$ show a similar nonmonotonic field dependence as reported previously [16,31], for a magnetic field beyond $\sim 8\,\text{T}$, $\kappa_{ab}(B)$ still substantially increases with the magnetic field. This entails a sizable positive slope of $\kappa_{ab}(B)$ even at 0.7 K and high
B > 20 T, in clear contradiction to the expectation described above and depicted in the lower panel of Fig. 2(c).

Clearly, this main finding of our work, i.e., the unexpected field-induced enhancement of the low-temperature thermal conductivity, provides information about the low-energy excitations of α-RuCl₃. A new transport channel carried by magnetic excitations rising in field appears unlikely since the increasing Zeeman energy naturally depletes magnetic low-energy excitations in the quantum disordered phase at B ≳ Bc. Thus, the only way to rationalize the observed enhancement is to understand it similarly to the higher-temperature findings as a result of a field-induced reduction of the phonon scattering. However, since the known lower bound hω₀(B) of magnetic excitation energies of α-RuCl₃ is far too large to cause the observed field dependence, we conjecture that additional magnetic scattering at energies hω₁ persists with ω₁ ≪ ω₀, even at 33 T.

In our previous work, we had employed a modified Callaway model for describing the in-plane field dependence of κ_ab by introducing a magnetic scattering term to the conventional expressions for phonon-phonon, phonon-defect, and phonon-boundary scattering [30]. More specifically, we had used an empirical field-dependent magnetic phonon scattering rate

\[ \tau_{\text{mag},0}^{-1} = C_0 \Theta(K - h\omega) \frac{\exp\left(-\frac{h\omega_0}{k_B T}\right)}{1 + 3 \exp\left(-\frac{h\omega_0}{k_B T}\right)} , \]

which mimics phonons scattering off a magnetic excitation continuum effective in zero field in the energy range \( 0 ≤ h\omega ≤ |K| \). Here, K is the Kitaev interaction, \( \Theta \) is the step function, and \( C_0 \) is a field-dependent parameter measuring the scattering strength. The energy scale \( h\omega_0 \) plays the role of a field-induced low-energy cutoff. Indeed, using the high-temperature (\( T ≥ 8 \) K), high-field data, good fits can be obtained with parameters consistent with our previous results [see Fig. 3(a); fit parameters are presented in the Appendix]. Remarkably, as to be expected from our qualitative discussion of the high-field data, our fit yields \( \omega_0(B) \) to increase approximately linearly up to 30 T [inset of Fig. 3(a)].

To account for additional low-energy scattering in the model, as explained above, a straightforward approach is to introduce a second magnetic scattering rate \( \tau_{\text{mag},1}^{-1} \) of identical form as Eq. (1), with the coupling \( C_1 \) and the field-dependent energy scale \( h\omega_1 \), such that with

\[ \tau_{\text{mag}}^{-1} = \tau_{\text{mag},0}^{-1} + \tau_{\text{mag},1}^{-1} , \]
a two-mode model is defined.

Because the two magnetic scattering modes contribute to the field dependency of κ_ab at well-separated temperature regimes, the very low-temperature data (\( T < 1.5 \) K) can be fit by the two-mode model with \( \tau_{\text{mag},0}^{-1} \) set to zero, as the corresponding scattering becomes significant only at higher energies/temperatures. This leaves only a single magnetic scattering term for fitting multiple κ_ab(B) curves, while maintaining the previously obtained phononic parameters. As shown in Fig. 3(b), it is indeed possible to reproduce the low-temperature field dependence. With this fitting approach, we find that \( h\omega_1(B) / k_B \) varies in a sublinear fashion with \( B - B_c \) and reaches approximately 6 K at 33 T (see the Appendix for the fit parameters and a comparison of various power-law fits). Moreover, the scattering intensity of the low-energy excitation, as quantified by the prefactor \( C_1 \), appears to be by a factor of 50 smaller than that of the higher-energy scattering mechanism. This is also the reason why including the second magnetic scattering term in the modeling does not change the conclusions concerning the dominant high-energy scattering mechanism.
IV. DISCUSSION AND SUMMARY

As already mentioned above, the large-energy scale $\hbar\omega_0$ with its linear field dependence is in almost perfect agreement with magnon-type excitations at the $\Gamma$ point, as probed by ESR and Raman scattering [20–22]. Thus, in the temperature regime of about 8 to 80 K, the very strong field dependence of $\kappa_{ab}$ is straightforwardly interpreted to originate from phonon scattering off such magnons with small momenta [30]. Quite clearly, such magnons are consistent with microwave absorption data [20,21]. In fact, using a parameter set which results from fits to inelastic neutron-scattering spectra, theoretical results for the magnetic excitation spectrum both in ED and SWT [13,23,24] yield a magnon mode at the $\Gamma$ point which, beyond the critical field $B_c$, reproduces remarkably well the ESR data and our results for $\hbar\omega_0$ concerning both the mode’s energy as well as its linear field dependence. Since these excitations are the lowest-lying ones near the $\Gamma$ point, the conjectured mode at $\hbar\omega_0$ must be of a different nature. While its sublinear field dependence may be consistent with that of quantum critical excitations at the $M$ point [13,24], the mode energy $\hbar\omega_0$ which we extract from our data is smaller, by at least a factor of 10, than the magnon gap energy as calculated in SWT and experimentally extracted from specific-heat measurements [13,24]. This inconsistency appears to rule out the possibility that the low-energy magnetic scattering originates from conventional high-field magnons (or bound states thereof).

Alternatively, it seems quite possible that the scattering arises from defect-induced low-energy excitations. Signatures of such excitations appear in NMR data on nominally clean $\alpha$-RuCl$_3$ [17], and they have been studied recently in some detail in Ir-doped $\alpha$-RuCl$_3$ [38]. The excitations have been discussed in terms of random spin singlets with a broad distribution of (relatively small) binding energies. The thermal excitations of such singlets inevitably scatter phonons and thus one can expect an impact on the phonon heat conductivity. Since the external magnetic field increasingly polarizes such singlets, their density of states is field dependent, and the phonon scattering should become weaker with increasing field. In this case, the extracted energy scale $\hbar\omega_0$ does not directly correspond to a specific mode energy, but rather is an effective quantity which accounts for the field-induced depletion of random singlets. We note that the relatively small scattering intensity of the low-energy excitations, $C_1 \ll C_0$, is fully compatible with them being defect induced. A detailed modeling of phonon scattering by random singlets requires more insights into the microscopics of disordered Kitaev magnets at elevated fields and is left for future work.

In summary, our high-field/low-temperature study of the phonon heat conductivity of the Kitaev material $\alpha$-RuCl$_3$ reveals that low-energy spin excitations exist which are incompatible with conventional magnonlike excitations. A possible origin for these low-energy modes is random singlets, which could emerge from natural impurities in the system. Thus, our study underpins the intriguingly rich quantum nature of the ground state $\alpha$-RuCl$_3$ and calls for further experimental and theoretical studies.

### APPENDIX

#### A. Fitting of $\kappa_{ab}$ data

The temperature-dependent data were fit via an analogous routine as described in great detail in the supplement of [30].

More specifically, we use the Callaway model [40,41] for analyzing the phononic heat conductivity. The model yields the low-$T$ approximation,

$$\kappa_{ab}(T) = \frac{\kappa_B}{2\pi^2 v_s} \left( \frac{\kappa_B T}{\hbar} \right)^3 \int_0^{\Theta_D/T} \frac{x^4 e^x}{(e^x - 1)^2} \tau_x(\omega, T) \, dx,$$

(A1)

with Boltzmann’s constant $\kappa_B$, Planck’s constant $\hbar$, the Debye temperature $\Theta_D$, $x = \hbar\omega/k_B T$, and the effective phonon scattering rate $\tau_x^{-1}$ which depends on both $\omega$ and $T$.

For conventional phononic systems (i.e., nonmagnetic, electrically insulating crystals), the effective phonon scatter-

| 30                | 112.3                   | 3.39                   | 5.66                    | 4.5                     |
| 33                |                         |                        |                         |                         |
The phenomenological magnetic scattering rate $\tau_{\text{mag}}^{-1}$ is composed of conventional scattering mechanisms, for which empirical expressions are well established, viz. phonon-phonon umklapp scattering $\tau_p^{-1} = A T^c \omega_0 e^{-\omega_0 / hT}$, phonon-defect scattering $\tau_D^{-1} = D \omega_0^b$, and phonon-boundary scattering $\tau_B^{-1} = v_s L^{-1}$:

$$\tau_{c,0}^{-1} = \tau_p^{-1} + \tau_D^{-1} + \tau_B^{-1}. \quad (A2)$$

The phenomenological magnetic scattering rate $\tau_{\text{mag}}^{-1}$ adds to the the rate as

$$\tau_c^{-1} = \tau_{c,0}^{-1} + \tau_{\text{mag}}^{-1}. \quad (A3)$$

Table I lists the field-independent phononic parameters of $\tau_c^{-1}$ as well as the cutoff energy (Kitaev interaction) $K$ used for the fits shown in Fig. 3. Note that the data of sample 1 and sample 2, collected at HFML and IFW Dresden, were scaled prior to fitting them to the Callaway model, allowing for treatment as a single data set with common phononic parameters, spanning the entire $T$ and $B$ ranges. Table II lists the fitting parameters of the magnetic scattering term $\tau_{\text{mag}}^{-1} = \tau_{\text{mag},0}^{-1} + \tau_{\text{mag},1}^{-1}$ used for the fits shown in Fig. 3. It is remarkable that a field-dependent spin-phonon-coupling $C_0$ must be allowed for in order to satisfactorily explain the data with our simple model. The so found spin-phonon coupling increases roughly linearly by about 30% over the investigated field range.

### B. Illustration of $\kappa_{\text{ab}}(B, T)$ for a single magnetic scattering term

For the illustrations shown in Fig. 2(c), a single-mode model was used with realistic fitting parameters (Table I). The employed temperatures in the three panels of Fig. 2(c) are $T = 0.7 \, K$ (bottom panel), $T = 16 \, K$ (center panel), and $T = 128 \, K$ (top panel). Values for $\hbar \omega_0(B)/k_B$ were obtained by linearly extrapolating previous results [30], according to $\hbar \omega_0(B)/k_B = 4.02 \, K/T \times B - 22.2 \, K$.

### C. Fitting of the field dependence of $\hbar \omega_1$

Figure 4 shows the obtained field-dependent values of $\hbar \omega_1$ in detail. As discussed in the main text, the field dependency of $\hbar \omega_1$ may be described by a power law according to

$$\hbar \omega_1(B)/k_B = a[(B - B_c)/B_c]^c, \quad (A4)$$

where $c = 1/2$ leads to good agreement with our data. The corresponding fit, depicted in the inset of Fig. 3(a), is reproduced in Fig. 4 as a green dashed line. As can be inferred from several additional power-law fits plotted in Fig. 4 as dashed lines, mediocre fits can also be obtained for the approximate range $0.4 \leq c \leq 0.55$. The pink dashed line illustrates the best fit with $c = 0.7$ according to the previous analysis of specific-heat data [13], where a rather unrealistic $B_c \approx 5.8 \, T$ is used.

All parameters of the depicted fits are listed in Table III.

### Table III. Parameters of power-law fits for $\hbar \omega_1(B)/k_B$, as depicted in Fig. 4.

| Fit No. | $a$ (K) | $B_c$ (T) | $c$  |
|---------|---------|-----------|------|
| 1       | 3.68    | 8.91      | 0.5  |
| 2       | 3.49    | 9.81      | 0.35 |
| 3       | 3.41    | 8.29      | 0.55 |
| 4       | 1.77    | 5.82      | 0.7  |
