(Dated: February 1, 2008)

Dielectric micro-cavities are widely used as laser resonators and characterizations of their spectra are of interest for various applications. We experimentally investigate micro-lasers of simple shapes (Fabry-Perot, square, pentagon, and disk). Their lasing spectra consist mainly of almost equidistant peaks and the distance between peaks reveals the length of a quantized periodic orbit. To measure this length with a good precision, it is necessary to take into account different sources of refractive index dispersion. Our experimental and numerical results agree with the superscar model describing the formation of long-lived states in polygonal cavities. The limitations of the two-dimensional approximation are briefly discussed in connection with micro-disks.

\section*{I. INTRODUCTION}

Two-dimensional micro-resonators and micro-lasers are being developed as building blocks for optical telecommunications \cite{1,2}. Furthermore they are of interest as sensors for chemical or biological applications \cite{2,3,4} as well as billiard toy models for quantum chaos \cite{5,6}. Towards fundamental and applied considerations, their spectrum is one of the main features. It was used, for instance, to experimentally recover some information about the refractive index \cite{7} or geometrical parameters \cite{8}.

In this paper we focus on cavities much larger than the wavelength and propose to account for spectra in terms of periodic orbit families. Cavities of the simplest and most currently used shapes were investigated: the Fabry-Perot resonator, polygonal cavities such as square and pentagon, and circular cavities.

Our experiments are based on quasi two-dimensional organic micro-lasers \cite{9}. The relatively straightforward fabrication process ensures good quality and reproducibility as well as versatility in shapes and sizes (see Fig. 1). The experimental and theoretical approaches developed in this paper can be easily extended to more complicated boundary shapes. Moreover this method is useful towards other kinds of micro-resonators, as it depends only on cavity shape and refractive index.

The paper is organized as follows. In Section II a description of the two-dimensional model is provided together with its advantages and limitations. In Section III micro-lasers in the form of a long stripe are investigated as Fabry-Perot resonators to test the method and evaluate its experimental precision. This protocol is then further applied to polygonal cavities. In Section IV the case of square cavities is discussed whereas in Section V dielectric pentagonal cavities are investigated. The theoretical predictions based on a superscar model are compared to experiments as well as numerical simulations and a good agreement is found. Finally, in Section VI the case of several coexisting orbits is briefly dealt with on the example of circular cavities.

\section*{II. PRELIMINARIES}

Dielectric micro-cavities are quasi two-dimensional objects whose thickness is of the order of the wavelength but with much bigger plane dimensions (see Fig. 1). Al-
though such cavities have been investigated for a long time both with and without lasing, their theoretical description is not quite satisfactory. In particular, the authors are not aware of true three-dimensional studies of high-excited electromagnetic fields even for passive cavities. Usually one uses a two-dimensional approximation but its validity is not under control.

Within such approximation fields inside the cavity and close to its two-dimensional boundary are treated differently. In the bulk, one considers electromagnetic fields as propagating inside an infinite dielectric slab (gain layer) with refractive index \( n_{gl} \) surrounded by media with refractive indices \( n_1 \) and \( n_2 \) smaller than \( n_{gl} \). In our experiments, the gain layer is made of a polymer (PMMA) doped with a laser dye (DCM) and sandwiched between the air and a polymer (SOG) layer (see Fig. 2 (a) and [9]). It is well known (see e.g. [10] or [11]) that in such geometry there exist a finite number of propagating modes confined inside the slab by total internal reflection. The allowed values of transverse momentum inside the slab, \( q \), are determined from the standard relation

\[
e^{2i\pi q h} r_1 r_2 = 1
\]

(1)

where \( h \) is the slab thickness and \( r_{1,2} \) are the Fresnel reflection coefficients on the two horizontal interfaces. For total internal reflection

\[
r_i = \exp(-2i\delta_i)
\]

(2)

where

\[
\delta_i = \arctan \left( \frac{\nu_i \sqrt{n_{gl}^2 \sin^2 \theta - n_i^2}}{n_{gl} \cos \theta} \right)
\]

(3)

Here \( \theta \) is the angle between the direction of wave propagation inside the slab and the normal to the interface. The \( \nu_i \) parameter is 1 (resp. \( (n_{gl}/n_i)^2 \)) when the magnetic field (resp. the electric field) is perpendicular to the slab plane. The first and second cases correspond respectively to TE and TM polarizations.

Denoting the longitudinal momentum, \( p = n_{gl} k \sin \theta \), as \( p = n_{eff} k \), the effective refractive index, \( n_{eff} \), is determined from the following dispersion relation

\[
\frac{2\pi h}{\lambda} \sqrt{n_{gl}^2 - n_{eff}^2} = \arctan \left( \nu_{eff} \sqrt{n_{eff}^2 - n_1^2} \right)
\]

+ \arctan \left( \nu_{eff} \sqrt{n_{eff}^2 - n_2^2} \right) + l\pi, \; l \in \mathbb{N}.

(4)

This equation has only a finite number of propagating solutions which can easily be obtained numerically. Fig. 3 presents possible propagating modes for our experimental setting \( n_1 = 1 \) (air), \( n_2 = 1.42 \) (SOG) [28] and \( n_{gl} = 1.54 \) deduced from ellipsometric measurements (see Fig. 2 (b)) in the observation range.

The Maxwell equations for waves propagating inside the slab are thus reduced to the two-dimensional scalar Helmholtz equation:

\[
(\Delta + n_{eff}^2 k^2) \Psi_{in}(x, y) = 0.
\]

(5)

\( \Psi \) represents the field perpendicular to the slab, i.e. the electric field for TM and the magnetic field for TE polarization [29].

This equation adequately describes the wave propagation inside the cavity. But when one of these propagating modes hits the cavity boundary, it can partially escape from the cavity and partially be reflected inside it. To describe correctly different components of electromagnetic fields near the boundary, the full solution of the three dimensional vectorial Maxwell equations is re-
quired, which to the authors knowledge has not yet been addressed in this context. Even the much simpler case of scalar scattering by a half-plane plate with a small but finite thickness is reduced only to numerical solution of the Wiener-Hopf type equation [12].

To avoid these complications, one usually considers that the fields can be separated into TE and TM polarization and obey the scalar Helmholtz equations [2]:

\[
(\Delta + n_{\text{in, out}}^2 k^2) \Psi_{\text{in, out}}(x, y) = 0. \tag{6}
\]

with \(n_{\text{in}}\) is the \(n_{\text{eff}}\) effective index inferred from Eq. (4) and \(n_{\text{out}}\) the refractive index of the surrounding media, usually air so \(n_{\text{out}} = 1\). This system of two-dimensional equations is closed by imposing the following boundary conditions

\[
\Psi_{\text{in}}|_B = \Psi_{\text{out}}|_B, \quad \nu_{\text{in}} \partial \Psi_{\text{in}} / \partial \vec{\tau}|_B = \nu_{\text{out}} \partial \Psi_{\text{out}} / \partial \vec{\tau}|_B. \tag{7}
\]

Here \(\vec{\tau}\) indicates the direction normal to the boundary and \(\nu\) depends on the polarization. When the electric (resp. magnetic) field is perpendicular to the cavity plane, called TM polarization (resp. TE polarization), \(\nu_{\text{in, out}} = 1\) (resp. \(\nu_{\text{in, out}} = 1/n_{\text{in, out}}^2\)). Notice that these definitions of \(\nu\) are not the same for horizontal and vertical interfaces.

We consider this standard two-dimensional approach keeping in mind that waves propagating close to the boundary (whispering gallery modes) may deviate significantly from two-dimensional predictions. In particular leakage through the third dimension could modify the life-time estimation of quasi-stationary states.

Our polymer cavities are doped with a laser dye and uniformly pumped one by one from above [9], so that the pumping process induces no mode selection. The pumping area is larger than the width of the stripe, thus the gain is uniformly distributed over the section. Moreover the pumping area is very small compared to the length (see Fig. 4 (a)) and the material is slightly absorbing, so that reflections at far extremities can be neglected. Moreover the pumping area is larger than the width of the stripe, thus the gain is uniformly distributed over the section. For a Fabry-Perot cavity, the emission is expected along both \(\theta = 0\) and \(\theta = \pi\) directions (see Fig. 4 (a) for notations). Fig. 4(b) shows that this directional emission is observed experimentally which confirms the validity of our set-up.

### III. Fabry-Perot Resonator

The Fabry-Perot configuration is useful for the calibration control of further spectral experiments due to the non ambiguous single periodic orbit family which sustains the laser effect.

A long stripe can be considered to a good approximation as a Fabry-Perot resonator. In fact the pumping area is very small compared to the length (see Fig. 4 (a)) and the material is slightly absorbing, so that reflections at far extremities can be neglected. Moreover the pumping area is larger than the width of the stripe, thus the gain is uniformly distributed over the section. For a Fabry-Perot cavity, the emission is expected along both \(\theta = 0\) and \(\theta = \pi\) directions (see Fig. 4 (a) for notations). Fig. 4(b) shows that this directional emission is observed experimentally which confirms the validity of our set-up.

![FIG. 4: (a) Diagram summarizing the main features of the Fabry-Perot experiment. (b) Detected intensity versus \(\theta\) angle for a Fabry-Perot experiment.](image)

The experimental spectrum averaged over 30 pump pulses is made up of almost regularly spaced peaks (see Fig. 4(a)) which is typically expected for a Fabry-Perot resonator. In fact, due to coherent effects, the \(k\) wavenumbers of quasi-bound states of a passive Fabry-Perot cavity are determined from the quantization condition along the only periodic orbit of \(L = 2W\) length as for [11]:

\[
r^2 e^j L k n_{\text{eff}}(k) = 1 \tag{9}
\]

where \(r\) is the Fresnel reflection coefficient and \(n_{\text{eff}}\) is the effective refractive index [4]. The solutions of this equation are complex numbers: the imaginary part corresponds to the width of the resonance and the real part (called \(k_m\) afterwards) gives the position of a peak in the
spectrum and verify

\[ L \kappa_m n_{\text{eff}}(k_m) = 2\pi m, \quad m \in \mathbb{N}. \quad (10) \]

With \( \delta k_m = k_{m+1} - k_m \) assumed to be small, the distance between adjacent peaks is constrained by

\[ \delta k_m [n_{\text{eff}}(k_m) + k_m \frac{\partial n_{\text{eff}}}{\partial k}(k_m)] L = 2\pi. \quad (11) \]

We call

\[ n_{\text{full}} = n_{\text{eff}}(k_m) + k_m \frac{\partial n_{\text{eff}}}{\partial k}(k_m) \quad (12) \]

the full effective refractive index. It is a sum over two terms: one corresponding to the phase velocity, \( n_{\text{eff}}(k_m) \), and the other one to the group velocity, \( k_m \frac{\partial n_{\text{eff}}}{\partial k}(k_m) \). If \( n_{\text{full}} \) is considered as a constant over the observation range, which is true with a good accuracy, \( \delta k \) can be retrieved from the experimental spectrum. For instance, the Fourier transform of the spectrum (intensity versus \( k \)) is made up of regularly spaced peaks (Fig. 5 (b) inset), with the first one (indicated with an arrow) centered at the optical length \( (L n_{\text{full}}) \) and the others at its harmonics. So the geometrical length of the periodic orbit can be experimentally inferred from the knowledge of \( n_{\text{full}} \) which is independently determined as described below. For the Fabry-Perot resonator, the geometrical length is known to be \( 2W \), thus allowing to check the experimental precision. The relative statistical errors on the \( W \) width is estimated to be less than 3 %. The error bars in Fig. 5 (b) are related to the first peak width of the Fourier transform and are less than 5 % of the optical length.

The full effective refractive index, \( n_{\text{full}} \), is independently inferred from ellipsometric measurement (Fig. 2 (b)) and standard effective index derivation described in the previous Section. Depending on the parameter \( h/\lambda \) (thickness over wavelength), one or several modes are allowed to propagate. Our samples are designed such as only one TE and TM modes exist with \( n_{\text{eff}} \) effective refractive index according to Eq. (4).

In Fig. 3 the refractive index of the gain layer, \( n_{\text{gl}} \), is assumed to be constant: \( n_{\text{gl}} = 1.54 \) in the middle of the experimental window, \( \lambda \) varying from 0.58 to 0.65 \( \mu \text{m} \). From Eq. (3) a \( n_{\text{eff}} = 1.50 \) is obtained in the observation range with a \( h = 0.6 \mu \text{m} \) thickness, and corresponds to the phase velocity term. The group velocity term \( k_m \frac{\partial n_{\text{eff}}}{\partial k}(k_m) \) is made up of two dispersion contributions: one from the effective index (about 4 %) and the other from the gain medium (about 7 %). The dependence of \( n_{\text{gl}} \) with the wavelength is determined with the GES S SOPRA ellipsoid from a regression with the Winelli II software (correlation coefficient: 0.9988) and plotted on Fig. 2 (b). Taking into account all contributions (that means calculating the effective refractive index with a dispersed \( n_{\text{gl}} \)), the \( n_{\text{full}} \) full effective refractive index is evaluated to be 1.645 ± 0.008 in the observation range. So the group velocity term made up of the two types of refractive index dispersion contribute for 10 % to the full effective index, which is significant compared to our experimental precision. The \( n_{\text{full}} \) index depends only smoothly on polarization (TE or TM), and on the \( h \) thickness, which is measured with a surface profiometer Veeco (Dektak\textsuperscript{3}ST). Thus, the samples are designed with thickness 0.6 \( \mu \text{m} \) and the precision is reported on the full effective index which is assumed to be 1.64 with a relative precision of about 1 % throughout this work.

Considering all of these parameters, we obtain a satisfactory agreement between measured and calculated optical lengths, which further improves when taking into account several Fabry-Perot cavities with different widths as shown on Fig. 5 (b). The excellent reproducibility (time to time and sample to sample) is an additional confirmation of accuracy and validity. With these Fabry-Perot resonators, we have demonstrated a spectral method to recover the geometrical length of a periodic...
angles at the boundary are larger than the critical angle \( \chi_c = \arcsin(1/n) \approx 42^\circ \).

In a square-shaped cavity light escapes mainly at the corners due to diffraction. Thus the quality design of corners is critical for the directionality of emission but not for the spectrum. Indeed for reasonably well designed squared micro-cavity (see Fig. 1), no displacement of the spectrum peaks is detectable by changing the \( \theta \) observation angle. The spectra used in this paper are thus recorded in the direction of maximal intensity.

Fig. 6 (a) presents a typical spectrum of a square-shaped micro-cavity. The peaks are narrower than in the Fabry-Perot resonator spectrum, indicating a better confinement, as well as regularly spaced, revealing a single periodic orbit. Data processing is performed exactly as presented in the previous Section: for each cavity the Fourier transform of the spectrum in (a) expressed as intensity versus wavenumber.

![FIG. 6: (a) Experimental spectrum of a square-shaped micro-laser of 135 \( \mu m \) side width. (b) Optical length versus a square side width. The experiments (red points) are linearly fitted by the solid red line. The dashed blue line corresponds to the theoretical prediction (diamond periodic orbit) without any adjusted parameter. Top inset: Two representations of the diamond periodic orbit. Bottom inset: Normalized Fourier transform of the spectrum in (a) expressed as intensity versus wavenumber.](image)

In general for integrable and pseudo-integrable systems (e.g. polygonal billiards) classical periodic orbits form continuous periodic orbit families and in two dimensions classical periodic orbits. For two-dimensional closed cavities

\[
d(k) = \sum_n \delta(k - k_n) \approx \sum_p c_p e^{i k L_p} + \text{c.c.} \quad (13)
\]

where \( k \) is the wavenumber and \( k_n \) are the eigenvalues of a closed cavity. The summation on the right part is performed over all periodic orbits labeled by \( p \). \( L_p \) is the length of the \( p \) periodic orbit, \( \mu_p \) is a certain phase accumulated from reflection on boundaries and caustics, and amplitude \( c_p \) can be computed from classical mechanics. In general for integrable and pseudo-integrable systems (e.g. polygonal billiards) classical periodic orbits form continuous periodic orbit families and in two dimensions

\[
c_p \approx \frac{A_p}{\sqrt{L_p}} \quad (14)
\]

where \( A_p \) is the geometrical area covered by a periodic orbit family (see the example of circular cavities in Section VI).
Non-classical contributions from diffractive orbits and different types of creeping waves (in particular, lateral waves [19]) are individually smaller by a certain power of $1/k$ and are negligible in semiclassical limit $k \to \infty$ compared to periodic orbits.

There exist no true bound states for open systems. One can only compute the spectrum of complex eigenfrequencies of quasi-stationary states. The real parts of such eigenvalues give the positions of resonances and their imaginary part measure the losses due to the leakage from the cavity.

For such systems it is quite natural to assume that the density of quasi-stationary states

$$d(k) \equiv \frac{1}{\pi} \sum_{n} \frac{\text{Im}(k_n)}{(k - \text{Re}(k_n))^2 + \text{Im}(k_n)^2}$$

(15)

can be written in a form similar to (13) but the contribution of each periodic orbit has to be multiplied by the product of all reflection coefficients along this orbit (as it was done in a slightly different problem in [19])

$$d(k) \approx \sum_{p} c_p \left[ \prod_{j=1}^{N_p} r_p^{(j)} \right] e^{ikL_p - i\mu_p} + c.c.$$  \hspace{1cm} (16)

Here $N_p$ is the number of reflections at the boundary and $r_p^{(j)}$ is the value of reflection coefficient corresponding to the $j$th reflection for the $p$ periodic orbit.

When the incident angle is larger than the critical angle the modulus of the reflection coefficient equals 1 (see Eq. (2)), but if a periodic orbit hits a piece of boundary with angle smaller than the critical angle, then $|r_p| < 1$ thus reducing the contribution of this orbit. Therefore, the dominant contribution to the trace formula for open dielectric cavities is given by short-period orbits ($c_p \propto 1/\sqrt{L_p}$) which are confined by total internal reflection. For a square cavity with $n = 1.5$ the diamond orbit is the only confined short-period orbit which explains our experimentally observation of its dominance.

Nevertheless, this reasoning is incomplete because the summation of contributions of one periodic orbit and its repetitions in polygonal cavities does not produce a complex pole which is the characteristics of quasi-stationary states.

In order to better understand the situation, we have performed numerical simulations for passive square cavities in a two-dimensional approximation with TM polarization (see Section II and [20]). Due to symmetries, the quasi-stationary eigenstates can be classified according to different parities with respect to the square diagonals. In Fig. 7 (a), the imaginary parts of wavenumbers are plotted versus their real part for states antisymmetric according to the diagonals (that means obeying the Dirichlet boundary conditions along the diagonals) and called here $(- -)$ states.

These quasi-stationary states are clearly organized in families. This effect is more pronounced when wave functions corresponding to each family are calculated. For instance, wave functions for the three lowest families with $(- -)$ symmetry are presented in Fig. 8. The other members of these families have similar patterns. The existence of such families was firstly noted in [21] for hexagonal dielectric cavities, then further detailed in [20].

One can argue that the origin of such families is analogous to the formation of superscar states in pseudo-integrable billiards discussed in [22] and observed experimentally in microwave experiments in [23]. In general, periodic orbits of polygonal cavities form continuous families which can be considered as propagating inside.
FIG. 8: Squared modulus of wave functions with \(- -\) symmetry calculated with numerical simulations. (a) \(ak = 68.74 - .026\) i, (b) \(ak = 68.84 - .16\) i, (c) \(ak = 69.18 - .33\) i.

FIG. 9: Squared modulus of wave functions calculated within the superscar model \(^{17}\) and corresponding to the parameters of Fig. 8.

FIG. 10: Unfolding of the diamond periodic orbit. Thick lines indicate the initial triangle.

straight channels obtained by unfolding classical motion (see Fig. \(^{11}\)). These channels (hatched area Fig. \(^{11}\)) are restricted by straight lines passing through cavity corners. In \(^{22}\), it was demonstrated that strong quantum mechanical diffraction on these singular corners forces wave functions in the semiclassical limit to obey simple boundary conditions on these (fictitious) channel boundaries. More precisely it was shown that for billiard problems \(\Psi\) on these boundaries take values of the order of \(O(1/\sqrt{k}) \to 0\) when \(k \to \infty\). This result was obtained by using the exact solution for the scattering on periodic array of half-planes. No such results are known for dielectric problems. Nevertheless, it seems natural from semiclassical considerations that a similar phenomenon should appear for dielectric polygonal cavities as well.

Within such framework, a superscar state can be constructed explicitly as follows. After unfolding (see Fig. \(^{11}\)), a periodic orbit channel has the form of a rectangle. Its length equals the periodic orbit length and its width is determined by the positions of the closest singular corners. The unfolded superscar state corresponds to a simple plane wave propagating inside the rectangle taking into account all phase changes. It cancels at the fictitious boundaries parallel to the \(x\) direction and is periodic along this direction with a periodicity imposed by the chosen symmetry class. This procedure sets the wavenumber of the state and the true wavefunction is
obtained by folding back this superscar state.

Superscar wave functions with \((-\cdash-\) symmetry associated with the diamond orbit (see Fig. 10) are expressed as follows:

\[
\Psi_{m,p}^{-}(x,y) = \sin\left(\kappa_m^{-}x\right) \sin\left(\frac{2\pi}{l}py\right) + \sin\left(\kappa_m^{-}x'\right) \sin\left(2\frac{2\pi}{l}py'\right)
\]

where \(x'\) and \(y'\) are coordinates symmetric with respect to square side. In coordinates as in Fig. 10

\[
x' = y, \quad y' = x
\]

In \((\ell m)\) \(m\) and \(p\) are integers with \(p = 1, 2, \ldots, \) and \(m \gg 1\). \(l = \sqrt{2}a\) is the half of the diamond periodic orbit length \(30\), \(\delta\) is the phase of the reflection coefficient defined by \(r = \exp(-2\ii \delta)\). For simplicity, we ignore slight changes of the reflection coefficient for different plane waves in the functions above. So \(\delta\) is given by \(3\) with \(\nu = 1\) for TM polarization and \(\theta = \pi/4\). And \(\kappa_m^{-}\) is the momentum defined by

\[
\kappa_m^{-}l - 4\delta = 2\pi m.
\]

This construction conducts to the following expression for the real part of the wavenumbers \(31\)

\[
n_{eff} \text{Re}(k_{m,p}) = 2\pi \sqrt{\left(m + \frac{2}{\pi} \delta\right)^2 + p^2} = 2\pi (m + \frac{2}{\pi} \delta) + O\left(\frac{1}{m}\right)
\]

To check the accuracy of the above formulae we plot in Fig. 9 scar wave functions \(17\) with the same parameters as those in Fig. 8. The latter were computed numerically by direct solving the Helmholtz equations \(6\) but the former looks very similar which supports the validity of the superscar model.

The real part of the wavenumbers is tested too. In Fig. 7 (b) the lowest loss states (with the smallest modulus of the imaginary part) with \((-\cdash-\) symmetry are presented over a larger interval than in Fig. 7 (a). The real parts of these states are compared to superscar predictions \(19\) with \(p = 1\), leading to a good agreement. To detect small deviations from the theoretical formula, we plot in the inset of Fig. 7 (b) the difference between a quantity inferred from numerical simulations and its superscar prediction from \(19\).

\[
\delta E = \left(\frac{ml}{2\pi} \text{Re}k\right)^2 - \left(m + \frac{2}{\pi} \delta\right)^2 + p^2
\]

From this curve it follows that this difference tends to zero with \(m\) increasing, thus confirming the existence of the term proportional to \(p^2\). By fitting this difference with the simplest expression

\[
\delta E = \frac{c}{m}
\]

we find that \(c \approx -6.9\). By subtracting this correction term from the difference \(20\), one gets the curve indicated with filled circles in inset of Fig. 7 (b). The result is one order of magnitude smaller than the difference itself.

All these calculations confirm that the real parts of resonance wavenumbers for square dielectric cavities are well reproduced in the semiclassical limit by the above superscar formula \(19\) and our experimental results can be considered as an implicit experimental confirmation of this statement.

### V. PENTAGONAL MICRO-CA VITY

The trace formula and superscar model arguments can be generalized to all polygonal cavities. The pentagonal resonator provides a new interesting test. In fact, due to the odd number of sides, the inscribed pentagonal orbit (indicated by solid line in Fig. 11 (a)) is isolated. The shortest confined periodic orbit family is twice longer. It is represented with a dashed line in Fig. 11 (a) and can be mapped onto the five-pointed star periodic orbit drawn in Fig. 11 (b) by continuous deformation. In this Section we compare the predictions of the superscar model for this periodic orbit family with numerical simulations and experiments.

Due to the \(C_{5v}\) symmetry, pentagonal cavities sustain 10 symmetry classes corresponding to the rotations by \(2\pi/5\) and the inversion with respect to one of the symmetry axis. We have studied numerically one symmetry class in which wave functions obey the Dirichlet boundary conditions along two sides of a right triangle with angle \(\pi/5\) (see Fig. 11 (a) in grey). The results of these computations are presented in Fig. 12.

As for the square cavity, lowest loss states are organized in families. The wave functions of the three lowest loss families are plotted in Fig. 12 and their superscar structure is obvious.

The computation of pure superscar states can be per-
formed as in the previous Section. The five-pointed star periodic orbit channel is shown in Fig. 13. In this case boundary conditions along horizontal boundaries of periodic orbit channel are not known. By analogy with superscar formation in polygonal billiards [22], we impose that wave functions tend to zero along these boundaries when $k \rightarrow \infty$.

Therefore, a superscar wave function propagating inside this channel takes the form

$$\Psi_{\text{scar}}(x, y) = \exp(i\kappa x) \sin\left(\frac{\pi}{w}py\right)\Theta(y)\Theta(w - y) ,$$  \hspace{1cm} (22)

where $w$ is the width of the channel (for the five-pointed star orbit $w = a \sin(\pi/5)$ where $a$ is the length of the pentagon side). $\Theta(x)$ is the Heavyside function introduced here to stress that superscar functions are zero (or small) outside the periodic orbit channel.

The quantized values of the longitudinal momentum, $\kappa$, are obtained by imposing that the function $\Psi_{\text{scar}}$ is periodic along the channel when all phases due to the reflection with the cavity boundaries are taken into account

$$\kappa L = 2\pi \left(M + \frac{10}{\pi} \delta \right) .$$  \hspace{1cm} (23)

Here $M$ is an integer and $L$ is the total periodic orbit length. For the five-pointed star orbit (see Fig. 11) it is

$$L = 10a \cos\left(\frac{\pi}{5}\right),$$  \hspace{1cm} (24)

and $\delta$ is the phase of the reflection coefficient given by (6) with $\nu = 1$ (for TM polarization) and $\theta = 3\pi/10$. For these states the real part of the wavenumber is the following

$$n L \Re k = 2\pi \left(M + \frac{10}{\pi} \delta \right) + O\left(\frac{1}{M}\right) .$$  \hspace{1cm} (25)

Wave function inside the cavity are obtained by folding back the scar function (22) and choosing the correct representative of the chosen symmetry class. When Dirichlet boundary conditions are imposed along two sides of a right triangle passing through the center of the pentagon (see Fig. 11), $M$ must be written as $M = 5(2m)$ if $p$ is odd and $M = 5(2m - 1)$ if $p$ is even. Then the wave function inside the triangle is the sum of two terms

$$\Psi_{m,p}(x, y) = \sin(\kappa_m x) \sin\left(\frac{\pi}{w}py\right)\Theta(y)\Theta(w - y) +$$

$$+ \sin(\kappa_m x' - 2\delta) \sin\left(\frac{\pi}{w}py'\right)\Theta(y')\Theta(w - y')$$  \hspace{1cm} (26)

where the longitudinal momentum is

$$\frac{\kappa_m L}{10} = 2\pi (m + \frac{1}{2} \delta - \xi)$$  \hspace{1cm} (27)

with $\xi = 0$ for odd $p$ and $\xi = 1/2$ for even $p$. $x'$ and $y'$ in (26) are coordinates of the point symmetric of $(x, y)$ with respect to the inversion on the edge of the pentagon. In the coordinate system when the pentagon edge passes through the origin (as in Fig. 11)

$$x' = x \cos 2\phi + y \sin 2\phi , \hspace{1cm} y' = x \sin 2\phi - y \cos 2\phi$$

and $\phi = \pi/5$ is the inclination angle of the pentagon side with respect to the abscissa axis. Wavefunctions obtained with this construction are presented in Fig. 14. They correspond to the first, second, and third perpendicular excitations of the five-star periodic orbit family ($p = 1, 2, and 3$).

To check the agreement between numerically computed real parts of the wavenumbers and the superscar prediction (25) and (27), we plot in Fig. 12 (b) the following...
For pure scar states $\zeta = p^2$. As our numerical simulations have not reached the semiclassical limit (see scales in Figs. 7 and 12), we found it convenient to fit numerically the $\zeta$ constant. The best fit gives $\zeta \approx 0.44$, 2.33, and 5.51 for the three most confined families (for pure scar functions this constant is 1, 4, 9 respectively). The agreement is quite good with a relative accuracy of the order of $10^{-4}$ (see Fig. 12 (b)). Irrespective of precise value of $\zeta$ the total optical length, $nL$, is given by (25) and leads to an experimental prediction twice longer than the optical length of the inscribed pentagon, which is an isolated periodic orbit and thus can not base superscar wavefunctions.

Comparison with experiments confirms the superscar nature of the most confined states for pentagonal resonators. In fact, the spectrum and its Fourier transform in Fig. 16 correspond to a pentagonal micro-laser with side $a = 80 \mu m$, and show a periodic orbit with optical length $1040 \pm 30 \mu m$ to be compared with the five-star optical length $n_{full} 10a \cos(\pi/5) = 1061 \mu m$. The agreement is better than 2%. This result is reproducible for cavities with the same size.
Other sizes have been tested as well. For smaller cavities, the five-pointed star orbit is not identifiable due to lack of gain, whereas for bigger ones it is visible but mixed with non-confined periodic orbits. This effect, not specific to pentagons, can be assigned to the contribution of different periodic orbit families which become important when the lasing gain exceeds the refractive losses. We will describe this phenomenon in a future publication [24].

The good agreement of numerical simulations and experiments with superscar predictions gives an additional credit to the validity of this approach even for non-trivial configurations.

VI. MICRO-DISKS

Micro-disk cavities are the simplest and most widely used micro-resonators. In the context of this work, they are of interest because of the coexistence of several periodic orbit families with close lengths. For low index cavities (n ∼ 1.5) each regular polygon trajectory with more than four sides is confined by total internal reflection.

In the two-dimensional approximation passive circular cavities are integrable and the spectrum of quasistationary states can be computed from an explicit quantization condition

\[
J^r_m (nkR) J_m (nkR) = \nu \frac{H^r_m (nkR)}{H^r_m (nkR)}.
\]

Here \( R \) is the radius of the disk, \( n \) the refractive index of the cavity, and \( \nu = 1 \) (resp. \( \nu = n^2 \)) for the TM (resp. TE) polarization. For each angular quantum number \( m \), an infinite sequence of solutions, \( k_{m,q} \), is deduced from [29]. They are labeled by the \( q \) radial quantum number.

For large \( |k| \) the \( k_{m,t} \) wavenumbers are obtained from a semiclassical expression (see e.g. [25]) and the density of quasi-stationary states [15] can be proved to be rewritten as a sum over periodic orbit families. The derivation of this trace formula assumes only the semi-classical approximation (|\( k | R \) >> 1) and can be done in a way similar to that of the billiard case (see e.g. [27]), leading to an expression close to [16]

\[
d(k) \propto \sum_p \frac{A_p}{\sqrt{L_p}} |r_p|^N_p \cos (nL_p k - N_p (2\delta_p + \pi) + \pi/4).
\]

Here the \( p \) index specifies a periodic orbit family. This formula depends on periodic orbit parameters: the number of bounces on the boundary, \( N_p \), the incident angle on the boundary, \( \chi_p \), the length, \( L_p = 2N_p R \cos (\chi_p) \), and the area covered by periodic orbit family, \( A_p = \pi R^2 \cos^2 (\chi_p) \), which is the area included between the caustic and the boundary (see Fig. 17 (b)). \( 2\delta_p \) is the phase of the reflection coefficient at each bounce on the boundary (see Eq. (30)) and \( |r_p| \) is its modulus.

For orbits confined by total internal reflection \( \delta_p \) does not depend on \( kR \) in the semi-classical limit, and \( r_p \) is exponentially close to 1 [25, 26]. From (30) it follows that each periodic orbit is singled out by a weighing coefficient \( c_p = \frac{A_p}{\sqrt{L_p}} |r_p|^N_p \). Considering the experimental values \( |k| R \sim 1000, |r_p| \) can be approximated to unity with a good accuracy for confined periodic orbits, and thus \( c_p = \frac{A_p}{\sqrt{L_p}} \) depends only on geometrical quantities. Fig. 15 shows the evolution of \( c_p \) for polygons when the number of sides is increasing. As the critical angle is close to 45°, the diameter and triangle periodic orbits are not confined and the dominating contribution comes from the square periodic orbit. So we can reasonably conclude that the spectrum (15) of a passive two-dimensional micro-disk is dominated by the square periodic orbit.

The experimental method described in the previous Sections has been applied to disk-shaped micro-cavities. A typical experimental spectrum is shown on Fig. 19 (a). The first peak of its Fourier transform (see Fig. 19 (b)

![FIG. 16: Experimental spectrum of a pentagonal micro-laser of 80 µm side length. Inset: Normalized Fourier transform of the spectrum expressed as intensity versus wavenumber.](image)

![FIG. 17: (a) Two examples of periodic orbits: the square and the pentagon. (b) Two representations of the square periodic orbit and the caustic of this family in red.](image)
inset) has a finite width coming from the experimental conditions (discretization, noise, etc...) and the contributions of several periodic orbits. This width is represented as error bars on graph 11(b). The continuous red line fitting the experimental data is surrounded by the dashed green line and the dotted blue line corresponding to the optical length of the square and hexagon respectively, calculated with $n_{full} = 1.64$ as in the previous Sections. The perimeter (continuous black line) overlaps with a large part of the error bars which evidences its contribution to the spectrum, but it is not close to experimental data.

These experimental results seem in good agreement with the above theoretical predictions. But actually these resonances, usually called whispering gallery modes, are living close to the boundary. Thus both roughness and three-dimensional effects must be taken into account. At this stage it is difficult to evaluate and to measure correctly such contributions for each periodic orbit. For micro-disks with a small thickness (about 0.4 µm) and designed with lower roughness, the results are more or less similar to those presented in Fig. 19(b).

### VII. CONCLUSION

We demonstrate experimentally that the length of the dominant periodic orbit can be recovered from the spectra of micro-lasers with simple shapes. Taking into account different dispersion corrections to the effective refractive index, a good agreement with theoretical predictions has been evidenced first for the Fabry-Perot resonator. Then we have tested polygonal cavities both with experiments and numerical simulations, and a good agreement for the real parts of wavenumbers has been obtained even for the non-trivial configuration of the pentagonal cavity.

The observed dominance of confined short-period orbits is, in general, a consequence of the trace formula and the formation of long-lived states in polygonal cavities is related to strong diffraction on cavity corners. Finally, the study of micro-disks highlights the case of several orbits and the influence of roughness and three-dimensional effect.

Our study opens the way to a systematic exploration of spectral properties by varying the shape of the boundary. In increasing the experimental precision even tiny details of trace formulae will be accessible. The improvement of the etching quality will suppress the leakage due to surface roughness and lead to a measure of the diffractive mode losses which should depend on symmetry classes. From the point of view of technology, it will allow a better prediction of the resonator design depending on the applications. From a more fundamental physics viewpoint, it may contribute to a better understanding of open di-
electric billiards.

VIII. ACKNOWLEDGMENTS

The authors are grateful to S. Brasselet, R. Hierle, J. Lautru, C. T. Nguyen, and J.-J. Vachon for experimental and technological support and to C.-M. Kim, O. Bohigas, N. Sandeau, J. Szeftel, and E. Richalot for fruitful discussions.
