ABSTRACT

The cosmic evolution of bias of different source populations with underlying dark matter density field in post reionization era can shed light on large scale structures. Studying the angular and spatial distribution of different compact sources using deep radio catalogue at low-frequency is essential to understand the matter distribution of the present Universe. Here, we investigate the relationship of luminous matter with their host dark matter haloes by measuring the angular and spatial clustering of sources (two-point statistics), using deep radio observation of ELAIS N1 (EN1) field with upgraded Giant Metrewave Radio Telescope (uGMRT) at 300-500 MHz. We also analyze the 612 MHz GMRT archival data of the same field to understand the cosmic evolution of clustering of different source populations. We classify the sources as star-forming galaxies (SFGs) and active galactic nuclei (AGN) based on their radio luminosity. We find that the spatial clustering length and bias to the dark matter density field of SFGs are smaller than AGNs at both frequencies. This proves that AGNs are mainly hosted by massive haloes and hence strongly clustered. However, a small decrease in the bias for both kind of sources at higher frequency indicates that we are most likely tracing the faint objects residing in less massive haloes at higher frequencies. Our results are in excellent agreement with previous findings at radio and multi-frequency surveys. However, comparison with SKADS simulation suggests that the halo mass for different populations used in the simulation is systematically lower. This work quantifies the spatial distribution of extragalactic compact objects in EN1 field.

Key words: galaxies: active ⋆ galaxies: evolution ⋆ cosmology: observations ⋆ large-scale structure of Universe ⋆ radio continuum: galaxies.

1 INTRODUCTION

Observation of the oldest light of the Universe, Cosmic Microwave Background (CMB) radiation, have shown that the early Universe (at \( z \sim 1100 \)) was remarkably smooth with tiny anisotropies of the order of \( 10^{-4} \) (Planck Collaboration et al. 2016). The Universe was almost neutral at that epoch. The linear fluctuations in the matter density grew under gravitational clustering and eventually generated luminous objects. The high energy photons emanating from the first stars and galaxies started heating and ionizing the IGM and forced the Universe to go through a global phase transition. Constraint from Gunn Peterson trough in quasar absorption spectra indicate that the gas in the intergalatic medium (IGM) became completely ionized by redshift \( z \sim 6 \) (Fan et al. 2002; Fan, Carilli, & Keating 2006). The transition of the universe from the neutral to ionized phase is called the epoch of reionization (EoR) (Field 1958; Madau 1997; Furlanetto, Oh, & Briggs 2006; Pritchard & Loeb 2012; Loeb & Furlanetto 2013; Mesinger 2016; Barkana 2016; Dayal & Ferrara 2018)). In the post reionization universe, several astrophysical parameters other than the gravitational clustering influenced the evolution of the baryonic matter density. Estimation of the clustering pattern of different radio sources and comparing it to the dark matter power spectrum holds the key to understand the astrophysical aspects of the post EoR evolution of the matter density distribution.

The extragalactic sky at low-frequency in \( \mu \)Jy to mJy flux limit is mainly dominated by Fanaroff\$\$ Riley type I (FR I), radio quiet quasars and star-forming galaxies. One of the possible way to understand these sources along with their host dark matter haloes is through their clustering. The clustering of galaxies can be quantified through counting excess number of galaxies at a certain scale to that of a random distribution of galaxies. This is known as the two-point correlation function (Lindsay et al. 2014; Hale et al. 2018). Traditionally, the two-point angular correlation function using optical galaxy surveys are studied and the redshift information is used

arXiv:2002.12383v1 [astro-ph.GA] 27 Feb 2020
to estimate the spatial clustering and the bias with the underlying matter power spectrum. However, covering a large fraction of sky is extremely difficult in the optical surveys. Furthermore, dust obscuration limits the detection of high redshift sources. Emissions in radio wavelengths from these galaxies are not attenuated by dust and hence provide a direct probe of high z galaxies (Jarvis et al. 2016). The relatively larger field of view of the radio telescopes also increase the survey speed. So, deep radio surveys allow to estimate the cross-correlation of the luminous matter distribution with CMB and shed light on how the baryons traces the underlying dark matter distribution (Planck Collaboration et al. 2014; Allison et al. 2015). Multifrequency observations can be used to understand the relationship between AGNs and star formation processes with their host dark matter haloes (Hale et al. 2018). Previous findings suggest that AGNs are mainly hosted by massive haloes and strongly clustered than SFGs. An efficient method to understand the bias of these populations to the underlying dark matter density field is the ratio of spatial correlation lengths of luminous matter and dark matter density field (Peebles 1980). This study of large scale distribution of dark matter through clustering pattern of luminous objects is important to understand the structure formation (Hale et al. 2018). Measurement of bias for different populations of sources in radio surveys allow to probe non-Gaussianity in the initial density fluctuation (Seljak 2009; Raccanelli et al. 2015).

The 21 cm signal from the EoR and post EoR universe traces the evolution of the matter density over all redshifts. The major hindrance on our quest to detect the redshifted 21 cm signal are bright dominating foregrounds. Foreground contamination due to diffuse Galactic synchrotron emission from our Galaxy (DGSE) (Shaver et al. 1999), free-free emission from Galactic and extragalactic sources (Cooray & Furlanetto 2004), faint radio-loud quasars (Di Matteo et al. 2002), synchrotron emission from low-redshift Galaxy clusters (Di Matteo et al. 2004), extragalactic point sources (Di Matteo et al. 2004), etc, are several order of magnitudes higher than the cosmological signal of interest (Zaldarriaga, Furlanetto, & Hernquist 2004; Bharadwaj & Ali 2005; Jelić et al. 2008; Bernardi et al. 2009; Jelić et al. 2010; Zaroubi et al. 2012). Di Matteo et al. (2004) have shown that spatial clustering of extragalactic sources with flux densities ≥0.1 mJy dominates the angular fluctuation at scales, θ ≳ 1 arcmin and modelling and removing these sources will allow us to detect angular fluctuation in 21 cm emission. However, to understand the systematic effects of the foregrounds on calibration and the effect of bright point sources far away from the field of view of observations, we require an accurate statistical model of the compact source distribution. The extra-galactic source counts are often modelled as single power law or a smooth polynomial (Intema et al. 2017; Franzen et al. 2019) and the spatial distribution of sources is assumed to be Poissonian (Ali, Bharadwaj, & Chengalur 2008; Trott et al. 2016) or a simple power-law clustering pattern has been implemented. The assumption of simple Poissonian distribution of sources in EoR foreground modelling is too simplistic and will effect the signal extraction gravy (Ali, Bharadwaj, & Chengalur 2008; Jelić et al. 2010; Ghosh et al. 2012; Trott et al. 2016). This demands a better observational estimate of the clustering pattern of the point sources at the lower radio frequencies.

With this motivation, here we have studied in detail the clustering pattern of different sources (AGNs and SFGs) in EN1 field using deep radio survey with uGMRT, at 300 - 500 MHz. Along with that, to understand the redshift evolution of bias of different sources we also study the clustering of different populations using 612 MHz GMRT archival data of the same field. In our previous works, we have studied the spatial and spectral properties of diffuse galactic synchrotron emission, the angular power spectrum of Galactic and extragalactic foregrounds, the differential source counts as a function of flux densities, etc in the same field (Chakraborty et al. 2019a,b). The paper is structured as follows. The details of radio and optical data used in this work is presented in Sec. 2. The pre-processing of the source catalogues to estimate the angular and spatial clustering of sources and the classification of sources based on radio luminosity is discussed in Sec. 3. The estimated angular correlation of all sources and a detailed comparison with previous findings are presented in Sec. 4.1. The results of spatial clustering and bias of the sources to the dark matter density field is discussed in Sec. 5. The clustering pattern of AGNs and SFGs along with the detail comparison with previous observations and simulations are discussed in Sec. 6. Finally, we draw conclusion in Sec. 7.

Throughout this work, we use the best fitted cosmological parameters of the Planck 2018 analysis (Planck Collaboration et al. 2018), which are: \[ \Omega_M = 0.31, \Omega_{\Lambda} = 0.68, \sigma_8 = 0.81, H_0 = 67.36 \text{ km s}^{-1} \text{Mpc}^{-1}. \]

\section{Sources of Data at Different Frequency Bands}

We use 400 MHz uGMRT observation of EN1 field along with archival GMRT 612 MHz data for cataloguing radio sources at these frequency bands. In this section, we briefly discuss the radio and optical data used in this work to estimate the angular and spatial clustering properties of sources in the EN1 field.

\subsection{2.1 uGMRT Observation at 400 MHz}

The EN1 field (\( \alpha_{2000} = 16^h10^m1^s, \delta_{2000} = 54^\circ30'36'' \)) has been observed with uGMRT in GTAC cycle 32 during May 2017 at 300 - 500 MHz for a total on source time of 25 hours. The raw data has a time resolution of 2 sec and frequency resolution of 24 KHz. This high resolution data was flagged for RFI with AOFLAGGER (Offringa, van de Gronde, & Roerdink 2012) and then averaged to 16 sec time and 97 kHz frequency resolution for further processing. The calibration, imaging and self-calibration was done in \textit{CASA} \(^1\) (Chakraborty et al. 2019b). The final image has a off-source noise of ~ 15\( \mu \)Jy beam\(^{-1} \) in the central part (Fig. 1: left panel). A source catalogue of 2528 sources with flux densities above 100 \( \mu \)Jy (6\( \sigma \)) was compiled using P-BDSF (Mohan & Rafferty 2015). In this work we use these catalogued compact radio sources in the EN1 field to estimate the angular and spatial clustering. The detail analysis of the uGMRT 400 MHz observation, calibration, source extraction and catalogue formation is presented in Chakraborty et al. (2019b).

\subsection{2.2 GMRT Archival Data at 612 MHz}

We additionally use the GMRT archival data of EN1 field, observed between 2011 to 2013 at 612 MHz (project codes: 20_044, 21_083, 22_056) in this study. Observations were carried out using seven different pointings arranged in a hexagonal pattern centered at \( \alpha_{2000} = 16^h10^m30^s, \delta_{2000} = 54^\circ35'00'' \) (Taylor & Jagannathan 2016). We perform necessary flagging and calibration of each pointing using the AIPS based automated pipeline Source peeling and

\(^1\) See: https://casa.nrao.edu; (McMullin et al. 2007)
Atmospheric Modeling (SPAM) (Intema et al. 2009, 2017). We create a mosaic of the seven pointings to create a combined image of the field. We achieve a off-source rms of $\sim 8\mu$Jy beam$^{-1}$ at the central part of the image (Fig. 1: right panel). We use p-pBDSF on the final image to compile a 612 MHz source catalog of the EN1 field having 2342 sources with flux densities above 50 $\mu$Jy ($> 6\sigma$).

2.3 BOSS spectroscopic survey

The Baryon Oscillation Spectroscopic Survey (BOSS) is the dark time survey of the third phase of the Sloan Digital Sky Survey or SDSS-III (SDSS; York et al. 2000). This survey primarily aims to determine Baryon Acoustic Oscillation feature (BAO) in large scale structure (Cole et al. 2005; Eisenstein et al. 2005). It has measured redshift of 1.5 million galaxies and have obtained distance-redshift relation $d_A(z)$ and the Hubble parameter $H(z)$ with highest precision till date. Four plates were granted to observe spectra of the radio sources identified in the EN1 field by LOFAR, GMRT, JVLA and FIRST. After data reduction, spectra of sources observed in each plate along with their position and redshift is made available as a part of SDSS DR12. We use this spectroscopic redshift catalogue released by SDSS team to identify the redshift of the radio sources in our catalogues discussed above.

2.4 SWIRE photometric survey

The revised Spitzer Wide Area Infrared Extragalactic survey (SWIRE) catalogue incorporates Two Micron All Sky Survey (2MASS) and UKIRT Infrared Deep Sky Survey (UKIDSS) near-infrared data, which essentially reduces the fraction of catastrophic outliers and gives a more reliable photometric catalogue (Rowan-Robinson et al. 2008; Rowan-Robinson, Gonzalez-Solares, Vaccari & Marchetti 2013). The SWIRE survey covers a sky of 49 deg$^2$ at 3.6, 4.5, 5.8, 8.0, 24.0, 70.0 and 160.0 $\mu$m using Spitzer. This survey covers $\sim 8.72$ deg$^2$ of EN1 field in five bands ($U', g', r', i', Z'$). Together with this, the additional information of JHK magnitude from 2MASS and UKIDSS results in the most reliable photometric redshift catalog publicly available for this field.

We use the spectroscopic redshifts in the SDSS catalogue and the photometric redshifts in the SWIRE catalogue complimentarily to get redshifts of the sources identified in the radio frequencies.

2.5 Semi-empirical extra galactic radio source catalogue

Wilman et al. (2008) performed semi-empirical simulation to generate extragalactic radio continuum sky where they model the statistical distribution of different sources to be seen in radio continuum with the next generation radio telescope. Their conical simulation volume covers a sky area of 20 $\times$ 20 deg$^2$ to a redshift of $z = 20$ with sources to a flux density limit of 10 mJy. They use five distinct source types, the radio quiet quasars (RQQ), the radio loud AGNs with FRI and FRII morphology, the star forming galaxies with quiescent and starbursts (SB). They use a numerical Press-Schechter (Press & Schechter 1974) formalism to identify high density halos in the dark matter distribution. A source type is identified with the given halo mass and the luminosity of the source drawn from an observed luminosity function of the given source type. In this work we use the corresponding source catalogue, statistical inference of the variation of angular and spatial clustering of different source types over the redshift. We shall use $S^3$ simulation or $S^3$ (SKA Simulated Skies) to denote results of this simulation henceforth.

3 PREPROCESSING OF THE SOURCE CATALOGUE

To generate radio catalogue at 400 MHz and 612 MHz with redshift information and source characteristics we proceed with the steps given in this section. These catalogues are used to estimate the angular and spatial clustering of the radio sources.

3.1 Merging multi-component sources

In a high resolution radio map, such as here ($-5''$), many sources resolve into multiple components. These are mostly radio galaxies with a central nucleus; accompanied by hotspots along or at the end of, one or two jets (Prandoni et al. 2018). As a result, a single radio source may split into multiple sources in the catalogue (Magliocchetti, Maddox, Lahav & Wall 1998). It is important to identify these separate components as a single source to unbiasedly quantify the angular clustering. Oort (1987) finds a strong correlation between the angular size $\theta$ of the radio sources with their flux densities $S$. This relation, $\theta \propto \sqrt{S}$, usually known as the $\theta - S$ relation, is used to identify multiple resolved components of radio sources in various earlier surveys (Magliocchetti, Maddox, Lahav & Wall 1998).

We use the following two criteria to associate multiple nearby objects in our initial catalogue as a single source in the final catalogue. We first estimate the total flux $S_{\text{total}}$ and angular separations $\theta$ of each pair of sources and identify the pairs to a maximum angular separation $\theta_{\text{max}}$. The choice of maximum separation is hard on the $\theta - S$ relation discussed above and is given as $\theta_{\text{max}} = 20(S_{\text{total}})^{0.5}$, where $\theta_{\text{max}}$ is given in arcsec and $S_{\text{total}}$ in mJy (Huynh, Jackson, Norris & Prandoni 2005; Prandoni et al. 2018). We consider the above identified pairs to come from a single source if their flux densities differ by a factor of less than 4 (Huynh, Jackson, Norris & Prandoni 2005). Fig. 2 shows the summed flux of each nearest pair as a function of distance between them in black filled circles. The pairs above the blue dashed line have angular separation lesser than $\theta_{\text{max}}$ Sources satisfying both the criteria discussed above are shown as red triangles and are considered as single sources in the final catalogue. Using this method we have 2253 and 2153 sources in our final radio catalogue at 400 MHz and 612 MHz respectively.

3.2 Adding Redshift information of sources

We use the BOSS spectroscopic survey and the SWIRE photometric survey for optical identification of sources in our radio catalogue. The positional accuracy of the uGMT observation is less than 1'' (Chakraborty et al. 2019b). Hence, we use a simple nearest-neighbour match between the sources in optical and radio catalogue. The search is performed within a radius of $r_s$ from the sources. Lindsay et al. (2014) show that the rate of contamination $P_c$ of the remaining sources due to closeness to optical sources can be expressed as:

$$P_c = \pi r_s^2 \sigma_{\text{opt}}^2,$$

where $r_s$ is the search radius cut-off and $\sigma_{\text{opt}}$ is the surface density of optical catalogue. We have chosen $r_s$ as 3'' . For $\sigma_{\text{opt}} = 1.4 \times 10^4$deg$^{-2}$, a 3'' search radius results in a contamination rate of 3.1%. This search radius allows us to include a large number of radio samples as well as ensures valid optical identification. We use this search radius for cross-matching.

We find 761 (30%) and 822 (35%) sources with spectroscopic redshifts and 1470 (58%) and 1391 (59%) sources with photometric redshifts for the 400 MHz and 612 MHz catalogues respectively. Fig. 3 shows the correlation plots to compare the photometric and
3.3 Classification of sources

In this work we classify the catalogued sources at 400 MHz and 612 MHz with redshift information as AGNs or SFGs using their radio luminosity as a sole indicator. McAlpine et al. (2013) show that the luminosity function evolves as $(1 + z)^{2.5}$ for SFGs but for AGN powered galaxies as $(1 + z)^{1.2}$. Further, Magliocchetti et al. (2014, 2016, 2017) showed that AGN powered galaxies become dominant beyond the radio power $P_{\text{cross}}(z)$, which scales with redshift $z$ as:

$$\log_{10} P_{\text{cross}} = \log_{10} P_{0,\text{cross}} + z,$$

(2)

to $z \sim 1.8$, where radio power $P$ is in WHz$^{-1}$sr$^{-1}$. In the local Universe $P_{0,\text{cross}} = 10^{21.7}$ [WHz$^{-1}$sr$^{-1}$] and nearly coincides with the break in the radio luminosity function of star-forming galaxies (Magliocchetti et al. 2002). Beyond that the luminosity function of SFGs decreases rapidly and their population is drastically reduced. The possibility of contamination between the AGNs and SFGs using a luminosity based selection is quite low (Magliocchetti et al. 2017).
The radio luminosities of sources in EN1 field with redshift information can be calculated from their flux using (Magliocchetti et al. 2014):

\[ P_{1.4\,\text{GHz}} = S_{1.4\,\text{GHz}}D^2(1 + z)^{3+\alpha}, \]

where \( P_{1.4\,\text{GHz}} \) is in [\text{WHz}^{-1}\text{sr}^{-1}] units, \( D \) is the angular diameter distance and \( \alpha \) is the spectral index of radio emission (\( S_\nu \propto \nu^{-\alpha} \)). Note that, we do not have pre-measured spectral index values for all the sources in our catalogue. Chakraborty et al. (2019b) compared the flux densities of matched sources in EN1 field with high frequency catalogues and found a median spectral index of 0.8. Since we are probing the faint sources here, the probability of finding a large number of bright, flat spectrum AGNs is low (Magliocchetti et al. 2017). We consider the spectral index for all the sources as 0.8 to estimate their radio luminosities.

We classify the catalogued sources with redshifts \( z \leq 1.8 \) as AGNs if their luminosity is greater than the threshold given in Eqn. 2 and SFGs otherwise. For higher redshifts, we fix \( P_{1.4\,\text{GHz}} = 10^{23.5} \) [\text{WHz}^{-1}\text{sr}^{-1}] (McAlpine et al. 2013). Following this procedure, out of 1503 sources at 400 MHz (with redshift information), 314 (20.9%) and 1189 (79.1%) sources has been identified as AGNs and SFGs respectively. Whereas, at 612 MHz, out of 1429 sources (with redshifts) 290 (20%) and 1139 (79%) sources has been identified as AGNs and SFGs respectively. The redshift distributions of AGNs and SFGs are shown in Fig. 4. The median value of redshift for SFGs is 0.64 and that for the AGNs is 0.91 at 400 MHz. For 612 MHz catalogue the median redshift for SFGs is 0.57 and for AGNs it is 0.85.

\[ \delta P = n[1 + w(\theta)]d\Omega, \]

where \( n \) is the density of sources per unit solid angle and \( d\Omega \) is a solid angle element. A detailed discussion on different estimators of \( w(\theta) \) can be found in literature (see: Kerscher, Szapudi & Szalay 2000). In this work, we use the LS estimator proposed by Landy & Szalay (1993):

\[ w(\theta) = \frac{DD(\theta) - 2DR(\theta) + RR(\theta)}{RR(\theta)}. \]

Here, \( DD(\theta) \) and \( RR(\theta) \) are the average count of pair of objects separated by an angle \( \theta \) in original catalogue and in a random catalogue, respectively. \( RR(\theta) \) is calculated from a large simulated catalog constructed by distributing sources randomly across the same survey area as the real data. This estimator also includes the count of cross-pair separation, \( DR(\theta) \), between real and random catalogue, which effectively reduces the large scale uncertainty in source density (Cress et al. 1996; Overzier et al. 2003).

The statistical error due to random data sets is negligible if an average over a large number of random catalogues or a single densely populated random catalogue is used. In that case the uncertainty on \( w(\theta) \) is governed by Poissonian error of \( DD(\theta) \) counts only and is given by (Lindsay et al. 2014):

\[ \Delta w(\theta) = \frac{1 + w(\theta)}{\sqrt{DD(\theta)}}. \]

In practice, \( w(\theta) \) is calculated in bins of the variable \( \theta \). As each object may contribute to counts across a range of separation bins, value of \( w(\theta) \) in adjacent bins are expected to be correlated. Consequently, Poissonian error underestimates the uncertainties in \( w(\theta) \). A more rigorous ‘bootstrap’ re-sampling method can be used to estimate the errors in \( w(\theta) \) (Ling, Frenk & Barrow 1986). In this method, a large number of ‘bootstrap’ catalogues, each of same size as the original catalogue, is generated by randomly sampling the original catalogue. Variance of \( w(\theta) \) across these bootstrap catalogues can be used as a estimate of uncertainty in \( w \) at each \( \theta \) (Cress et al. 1996).

**Figure 3.** The comparison between photometric and spectroscopic redshift of sources with both for 400 MHz (left panel) and 612 MHz (right panel) catalogue. The histogram of redshifts are also plotted here. The redshift distribution of sources for both the catalogues are nearly identical.

4 ESTIMATION OF THE CORRELATION FUNCTIONS

4.1 The angular correlation function

The angular two-point correlation function, \( w(\theta) \), quantifies clustering of sources on angular scale in sky-plane. It is defined as the excess probability \( \delta P \) of finding a source pair separated by an angle \( \theta \) due to clustering as compared with an unclustered Poisson distribution (Peebles 1980):

\[ \delta P = n[1 + w(\theta)]d\Omega, \]

where \( n \) is the density of sources per unit solid angle and \( d\Omega \) is a solid angle element. A detailed discussion on different estimators of \( w(\theta) \) can be found in literature (see: Kerscher, Szapudi & Szalay 2000). In this work, we use the LS estimator proposed by Landy & Szalay (1993):

\[ w(\theta) = \frac{DD(\theta) - 2DR(\theta) + RR(\theta)}{RR(\theta)}. \]

Here, \( DD(\theta) \) and \( RR(\theta) \) are the average count of pair of objects separated by an angle \( \theta \) in original catalogue and in a random catalogue, respectively. \( RR(\theta) \) is calculated from a large simulated catalog constructed by distributing sources randomly across the same survey area as the real data. This estimator also includes the count of cross-pair separation, \( DR(\theta) \), between real and random catalogue, which effectively reduces the large scale uncertainty in source density (Cress et al. 1996; Overzier et al. 2003).

The statistical error due to random data sets is negligible if an average over a large number of random catalogues or a single densely populated random catalogue is used. In that case the uncertainty on \( w(\theta) \) is governed by Poissonian error of \( DD(\theta) \) counts only and is given by (Lindsay et al. 2014):

\[ \Delta w(\theta) = \frac{1 + w(\theta)}{\sqrt{DD(\theta)}}. \]

In practice, \( w(\theta) \) is calculated in bins of the variable \( \theta \). As each object may contribute to counts across a range of separation bins, value of \( w(\theta) \) in adjacent bins are expected to be correlated. Consequently, Poissonian error underestimates the uncertainties in \( w(\theta) \). A more rigorous ‘bootstrap’ re-sampling method can be used to estimate the errors in \( w(\theta) \) (Ling, Frenk & Barrow 1986). In this method, a large number of ‘bootstrap’ catalogues, each of same size as the original catalogue, is generated by randomly sampling the original catalogue. Variance of \( w(\theta) \) across these bootstrap catalogues can be used as a estimate of uncertainty in \( w \) at each \( \theta \) (Cress et al. 1996).
Here, we have generated 100 ‘bootstrap’ to estimate the variance to quote uncertainty in $w(\theta)$ measurement.

4.2 Random Catalog

The noise is not uniform across the map of the EN1 field. This results in systematic non detection of fainter sources at the regions of the field of view with higher noise and hence introduces a bias in the estimate of the angular two point correlation function. The effect of inhomogeneous noise in the image needs to be incorporated in the generation of random catalogue to avoid this bias. We use the following procedure to generate random catalogue in order to estimate the angular correlation function unbiasedly.

We use PvBDSF to estimate the noise map for the EN1 field. Assuming that the radio sources follow the flux distribution of $S^3$ catalog (Wilman et al. 2008), we randomly choose 1000 sources from the $S^3$ catalog with flux densities in a given range. We simulate a radio map with compact sources with the above scaled flux densities distributed randomly in the EN1 field. We generate a mock sky map with these sources and add the above noise map. We use PvBDSF with same parameters as that used to estimate the EN1 catalogue (see Sec.4 in Chakraborty et al. 2019b) to construct the random catalogue from this map. This gives us one realization of the random catalogue that can be used to estimate the angular correlation function unbiasedly. We use 100 statistically independent realizations of such random catalogues to reduce the statistical uncertainty associated with it.

Since the noise map of the 400 MHz and 612 MHz data are different we generated separate random catalogues for them following the procedure described above. For the 400 MHz catalog we draw sources with flux densities in the range between $75 \mu Jy$ to $1 Jy$ from the $S^3$ catalog, whereas for the 612 MHz catalog the sources were selected within flux density range of $40 \mu Jy$ to $1 Jy$, where lower flux density threshold corresponds to the $5\sigma$ limits of the corresponding maps.

4.3 Results of clustering pattern of compact sources at 400 MHz and 612 MHz

We use the publicly available code TreeCorr \(^2\) (Jarvis et al. 2004) to find the angular correlation function of the sources in the 400 MHz and 612 MHz catalog in 15 equal logarithmically spaced bins between $\theta \sim 18\"$ $- 1.5\"$. The left panel of Fig. 5. shows

\(^2\) https://github.com/rmjarvis/TreeCorr
the estimated value of $w(\theta)$ at 400 MHz as a function of $\theta$ with (orange) filled circles. The error bars are estimated by ‘bootstrap’ re-sampling method as described earlier. We fit $w(\theta)$ with a power law of the form $w(\theta) = A\theta^{-\gamma}$. We use Markov Chain Monte Carlo (MCMC) simulation for this fitting and parameter estimation. We use Metropolis-Hastings algorithm to simulate 10^6 data points in the $A-\gamma$ parameter space and use $\chi^2$ to estimate the most likely values of the parameters. The best fitted values are $\log(A) = -2.03_{-0.08}^{+0.08}$ and $\gamma = 1.75 \pm 0.06$, where the error bars are $1-\sigma$ error bars corresponding to 68.3% MCMC points.

The right panel of Fig. 5 shows the angular correlation function at 612 MHz as estimated in 15 equally spaced logarithmic bins between $\theta \sim 25''$ to 1$''$. The best fit values of the parameters are $\log(A) = -2.22_{-0.15}^{+0.12}$ and $\gamma = 1.81 \pm 0.06$.

### 4.4 Comparison to previous observations

The results of angular clustering from various studies along with the findings in this paper is summarized in Table 1. Column (7) and (8) in the Table 1 gives the projected flux density cut offs at 400 and 612 MHz (assuming a spectral index of 0.8; $S_\nu \propto \nu^{-0.8}$ ) for different catalogues used to calculate the angular correlation function. The best fit estimate of the parameter $\gamma$ is found to be consistent with all the previous observations at different frequency bands as well as with its theoretical prediction (Peebles 1980).

Given similar types of sources in a population, the less luminous sources are expected to be found in weakly clustered less massive haloes. This results in measurement of lower value of the amplitude of the correlation function for deeper catalogues. We believe this the reason of higher clustering amplitude in the 400 MHz catalogue as compared to the 612 MHz catalogue.

Hale et al. (2018) measured angular two-point correlation function of radio sources in Cosmological Evolution Survey (COSMOS) field at 3 GHz (Smolčić et al. 2017A,B). Hale et al. (2018) reports estimation of clustering amplitude of all sources as $\log(A) = -2.83_{-0.1}^{+0.1}$ in this field using a $\sim 13 \mu Jy$ beam^{-1} flux density limit. The amplitude for this deep survey suggests less clustering of the fainter sources as expected. However, it needs to be noted that at 3 GHz, COSMOS is also likely to look at different population of sources and a direct comparison of the clustering
5 SPATIAL CLUSTERING

Spatial clustering of sources is quantified by the two-point correlation function $\xi(r)$. The probability $\delta P$ of finding a pair of sources at a separation $r$ within a volume $\delta V$ in a given distribution is given as:

$$\delta P = n [1 + \xi(r)] \delta V,$$

where $n$ is the average number of sources in the volume. In principle, if we have redshift information of all the sources in the catalog, spatial correlation function $\xi(r)$ can be estimated. However, it is unlikely to have a complete redshift knowledge of all sources detected at low frequency radio survey. However, if the redshift distribution of sources, $N(z)$, is known, it is possible to use the Limber inversion (Limber 1953) method to estimate spatial correlation function $\xi(r)$ from the measured angular correlation function. We briefly discuss this technique here.

Due to gravitational clustering, the spatial clustering of sources changes with redshift. We assume an epoch-dependent power-law (Overzier et al. 2003) spatial correlation function as:

$$\xi(r, z) = (r_0/r)^{\gamma + 3\epsilon},$$

where $r$ is in comoving units, and $\epsilon$ quantifies different clustering models (Overzier et al. 2003). The parameter $r_0$ gives the spatial clustering length at $z = 0$. In this work we use comoving clustering model with $\epsilon = \gamma - 3$. In this model, the correlation function remains unchanged in comoving coordinates and the cluster has fixed comoving size. The spatial correlation length in comoving coordinates can be estimated as (Peebles 1980):

$$A = r_0^2 H_0 \int_0^\infty N(z)(1 + z)^{-\gamma} \chi^{-1}(z)E(z)dz,$$

where, $H_\gamma = [\Omega_{m0}(1 + z)^3 + \Omega_{k0}(1 + z)^2 + \Omega_{\Lambda0}]^{1/2}$, $E(z) = [\Omega_{m0}(1 + z)^3 + \Omega_{k0}(1 + z)^2 + \Omega_{\Lambda0}]^{1/2}$, $N(z)$ is the redshift distribution of sources and $\chi(z)$ is the line-of-sight comoving distance. We use Eqn. 9 to estimate the spatial correlation length, $r_0$, from the estimated clustering amplitude of angular correlation function $A$, slope of correlation function $\gamma$ and redshift distribution $N(z)$ (Lindsay et al. 2014).

The estimated value of the parameter $\gamma$ across different surveys as mentioned in Table 1 agrees with the theoretical predicted value of 1.8 (Peebles 1980). We use $\gamma = 1.8$, the MCMC distribution of the parameter $A$ as given in section 4.1 and the redshift distribution of sources as given in section 3.2 to estimate $r_0$. Fig. 6 shows the probability density function for $r_0$ in 400 and 612 MHz. The median value of $r_0$ along with 16th and 84th percentile errors are $6.58^{+0.75}_{-0.83}$ and $3.94^{+0.65}_{-0.76}$ for 400 MHz and 612 MHz respectively.
at a median redshift of $z = 0.803$ for 400 MHz observation. For 612 MHz observation, the clustering length is $4.19^{+0.74}_{-0.64}$ at a median redshift of $z = 0.70$. The lesser value of the clustering length at the 612 MHz is a direct consequence of the lesser clustering of the fainter sources detected at this band.

5.1 Bias

The relation between clustering properties of luminous sources and underlying dark matter is described by the bias parameter. The scale independent linear bias parameter $b(z)$ is defined as the ratio of the galaxy to the dark matter spatial correlation functions (Kaiser 1984; Bardeen et al. 1986; Peacock & Smith 2000). For a standard cosmological model the bias parameter can be calculated from the spatial clustering length $r_0$ using (Lindsay et al. 2014; Hale et al. 2018):

$$b(z) = \left(\frac{r_0(z)}{\sigma_D(z)/D(0)}\right)^{1/2}$$

were, $J_2 = 72/[((3 - \gamma)^2(4 - \gamma)(6 - \gamma^2)]D(z)$ is the linear growth factor (Hamilton 2001) and $\sigma_D^2$ is the dark matter density variance in a comoving sphere of radius 8 Mpc $h^{-1}$. In this work, we have estimated the bias at the median redshift using the median value of $r_0$ corresponding to that redshift along with 16th and 84th percentile errors. We find that at 400 MHz $b_z = 2.74^{+0.27}_{-0.30}$ at median redshift of $z = 0.803$ and at 612 MHz $b_z = 1.73^{+0.27}_{-0.28}$ at a median redshift of 0.7.

6 CLUSTERING OF SFGS AND AGNS

In this section, we discuss results of our estimation of the clustering properties and corresponding bias of two different samples.
contributing to the total source counts, the AGNs and SFGs, at 400 MHz and 612 MHz. The evolution of clustering for AGNs and SFGs are expected to be different. Given that the median redshift of the two samples are different in the two observing bands, we expect to trace the hint of redshift evolution of different sources here. Following the similar procedure as described earlier, we estimate angular correlation of AGNs and SFGs and find the best fit value for the amplitude of correlation. Due to rather small sample size for statistical estimations, we fix the γ to 1.8 and kept the amplitude A as free parameter only. In Fig. 7, the estimated w(θ) and the best fit model for SFGs and AGNs are shown. These results are summarized in Table 2. The spatial clustering length for SFGs at a median redshift zmedian = 0.64 is found to be r0 = 4.62^{+0.39}_{-0.40} h^{-1} Mpc at 400 MHz, which decreases to r0 = 4.16^{+0.10}_{-0.08} h^{-1} Mpc at the median redshift of 0.57 at 612 MHz. The corresponding bias for SFGs are b = 1.65^{+0.14}_{-0.14} and b = 1.59^{+0.21}_{-0.21} at 400 MHz and 612 MHz respectively. For the AGN population the clustering length is relatively higher in general. At z = 0.91 the clustering length for the AGNs is r0 = 7.3^{+1.4}_{-1.2} h^{-1} Mpc at 400 MHz which decreases to r0 = 6.0^{+1.5}_{-1.5} h^{-1} Mpc at a redshift of z = 0.85 at 612 MHz. The bias for AGNs are b = 3.17^{+0.5}_{-0.4} and b = 2.60^{+0.6}_{-0.5} for 400 and 612 MHz catalogue respectively. We find that there is a hint of decrease of the bias parameter for both populations at higher frequency as the median redshift of these populations decreases. This indicates that we are most likely tracing the fainter less massive haloes at higher frequency. The variation of bias parameter for SFGs and AGNs along with some previous findings are shown in the Fig 9. We also show in Fig. 9, the assumed redshift evolution of bias parameters of different kind of sources in S3 simulation. The fact that the estimated bias for AGN is higher compared to that for the SFGs is consistent with results from S3 simulation. The large bias parameter indicates that the AGNs are strong biased tracers of dark matter halos than SFGs. Note that, due to uncertainties associated with measurement of redshift, clustering length and bias parameter and owing to the values of almost similar redshifts for different frequency bands, we have not observed much redshift evolution of these different populations here.

6.1 Comparison to previous observations and discussion

Compilation of the spatial clustering of AGNs and SFGs at different frequency and redshifts from the literature and this work is summarized in Table 2. The Fig. 8 shows variation of the spatial clustering length as a function of redshift. The left and the right panels show the spatial clustering length for SFGs and AGNs respectively. Note that we only mention the spatial clustering and bias parameters of radio selected samples from previous observations in the Table 2, whereas in Fig. 8 we show previous findings at radio as well as at other frequency surveys. The continuous curves gives the results from the S3 simulation for different sub-classes of sources in the S3 simulation. The individual markers with error bars corresponds to estimates of the correlation length as measured in this work and from literature.

The clustering length for SFGs found here are similar to the previous findings by Hale et al. (2018), Magliocchetti et al. (2017) at redshift z < 1. Also, the estimated value is close to the clustering length of SFGs selected by different criteria in literature (Gilli et al. 2007; Starikova et al. 2012; Magliocchetti et al. 2013; Dolley et al. 2014; Hale et al. 2018). As mentioned in Hale et al. (2018), the clustering length estimates for SFGs in radio surveys can be little higher than the other wavelength surveys, due to the fact that redshift distribution for SFGs in other wavelength surveys are skewed to lower redshifts. We have seen in Fig. 4 that redshift distribution of SFGs shows a peak at lower redshift and at this redshift the estimated clustering length is in good agreement with other surveys probing the same redshift range (Magliocchetti et al. 2013; Hale et al. 2018). Dolley et al. (2014) have extensively studied the redshift evolution of clustering of SFGs using mid-IR data. They have reported a slow evolution of clustering length as a function of redshift, which is also in agreement with our results.

The spatial clustering length as well as bias parameter of SFGs are higher than S3 simulation. This may be arising for two reasons. Firstly, the comparison with the results from S3 suggests that, if the SFGs population we study here is contaminated by a few SB galaxies, both the correlation length and the bias parameter is expected to be higher. It may also be the fact that the halo mass in the S3 simulation is not a correct representation of halo mass of SFGs and is systematically lower as shown in Fig. 9. The observational evidence of higher halo mass of SFGs in previous studies (Dolley et al. 2014; Magliocchetti et al. 2017; Hale et al. 2018) suggest that the later is the likely cause of the deviation of the two parameters from the S3 predictions. In such case, a comparison of bias parameter of SFGs with bias evolution of S3 suggests that the halo masses of SFGs at the redshift range probed here are close to Mh ~ 10^{13} h^{-1} M⊙ (Fig. 9).

Our result on the clustering of the AGNs statistically similar to (see Figure 8) the earlier reports of the clustering length estimated using radio selected (Magliocchetti et al. 2017) as well as x-ray selected (Gilli et al. 2005, 2009) catalogues. Comparing with the S3 simulation suggests that the sources in our catalogue are mostly of type FRI, which agrees with the earlier results as well. Following the results of the S3 we conclude that the AGNs are mostly hosted by massive halos of the order of Mh ~ 3 - 4 × 10^{12} h^{-1} M⊙ (see Fig. 9). This range of halo masses of AGNs are larger than that of SFGs and emphasizes that fact that AGNs inhabit more massive halos than SFGs, hence more strong biased tracer of dark matter density field.

7 CONCLUSION

In this work, we investigate the clustering properties of radio sources present in EN1 field at 400 MHz and at 612 MHz and compare it to the the S3 simulation as well as previous findings at radio and other wavelengths. We use a luminosity based identifier for radio source populations as AGNs and SFGs. We find the angular correlation functions for all sources in our sample as well as for the SFGs and AGNs individually. The angular correlation function assumes a power law for angular separation ranging ~ 18'' - 1.5°. The power law index of the correlation function was found to be consistent with 1.8, a value expected from analytical calculations (Peebles 1980). Amplitude of the correlation function indicates that the AGNs are more tightly clustered and are better tracers of the dark matter halos.

We use the BOSS spectroscopic survey and SWIRE photometric survey to add redshift information to the radio sources in our catalogues and estimate the redshift distribution of the different source types. We estimate the spatial clustering length for the sources and the corresponding bias parameters at the representative redshifts.

The clustering length and bias parameter for both samples are in excellent agreement with those found in literature from earlier observations along different lines of sight. Comparing to the results from the S3 simulation, we found that our AGN population is mostly
of type FRI and are hosted by dark matter haloes of halo mass \( \sim 3 - 4 \times 10^{13} h^{-1} M_{\odot} \). We find that the halo mass used for the SFGs in the \( S^3 \) simulation is rather lower and a halo mass of \( M_{h} \sim 10^{13} h^{-1} M_{\odot} \) is likely to host the SFGs.

It is important to note that the radio sources in our catalogue are classified based on radio luminosity only, however, the clustering properties of AGNs/SFGs selected based on X-ray and mid-IR data in other surveys are consistent with our results. We shall present results based on more robust multi-frequency identification of these sources in future.

We compare estimated parameters from our work with observations from earlier surveys. Given the statistical homogeneity and isotropy at the cosmological scales, parameter estimated from different directions in the sky can be compared. It is important to note that the work presented here is the first detailed investigation of the clustering properties of different types of compact radio sources in a given field in multiple frequency bands. We find the evolution of the bias and clustering length over redshift for both AGNs and SFGs as found in the EN1 field agree with earlier results from other different fields observed in radio as well as other wavelengths.

A major science objective of the radio telescopes like LOFAR (van Haarlem et al. 2013) or SKA (Koopmans et al. 2015) is to detect the redshifted 21-cm signal from the neutral hydrogen over a large range of redshifts. Compact extragalactic radio sources are a major source of foreground for the detection of the cosmological 21-cm signal. A major effort has been to understand and characterise the distribution of the compact sources in the radio sky. Moreover, the 21-cm signal being very faint, the radio foreground structures need to be known to low flux density. In this work we use sub mJy source populations sources to estimate their clustering properties. This is the deepest catalogue used to estimate the foreground characteristics at frequencies where the redshifted 21 cm signal from the post-EoR epoch is expected.

Comparing our results with the prediction from \( S^3 \) simulation suggests that their assumption of constant halo mass bias for populating different source types is rather simplistic and needs to be reviewed. Furthermore, this emphasizes the need for further deep studies of foreground characteristics in the low frequencies. The later also would shed more light on the evolution of the clustering length and bias over redshifts and constrain structure formation models stringently.

ACKNOWLEDGEMENTS
