Shape of the zeroth Landau level in graphene with non-diagonal disorder

Rajesh K. Malla and M. E. Raikh

Department of Physics and Astronomy, University of Utah, Salt Lake City, UT 84112

Non-diagonal (bond) disorder in graphene broadens Landau levels (LLs) in the same way as random potential. The exception is the zeroth LL, \( n = 0 \), which is robust to the bond disorder, since it does not mix different \( n = 0 \) states within a given valley. The mechanism of broadening of the \( n = 0 \) LL is the inter-valley scattering. Several numerical simulations of graphene with bond disorder had established that \( n = 0 \) LL is not only anomalously narrow but also that its shape is very peculiar with three maxima, one at zero energy, \( E = 0 \), and two others at finite energies \( \pm E \). We study theoretically the structure of the states in \( n = 0 \) LL in the presence of bond disorder. Adopting the assumption that the bond disorder is strongly anisotropic, namely, that one type of bonds is perturbed much stronger than other two, allowed us to get an analytic expression for the density of states which agrees with numerical simulations remarkably well. On the qualitative level, our key finding is that delocalization of \( E = 0 \) state has a dramatic back effect on the density of states near \( E = 0 \). The origin of this unusual behavior is the strong correlation of eigenstates in different valleys.

PACS numbers:

I. INTRODUCTION

Broadening of the Landau levels (LLs) in two-dimensional (2D) electron gas by a random potential was studied more than a quarter century ago in various limits, namely, strong and weak magnetic field, and also short-range and long-range disorder [1–12].

With regard to LLs in graphene [13–15], the theories of the LL broadening of Refs. [1–12] apply. Recent experimental and theoretical studies of the LLs in graphene in the presence of disorder are reported in Refs. [16–19].

There is, however, a situation when the underlying mechanism of the LL broadening in graphene is distinctively different from that in the 2D gas. The tight-binding Hamiltonian of the disordered graphene in magnetic field has the form

\[
\hat{H} = \sum_i V_i c_i^\dagger c_i + \sum_{\langle i,j \rangle} \left( t_{i,j} e^{i\theta_{i,j}} c_i^\dagger c_j + \text{H.c.} \right),
\]

where the \( \langle i,j \rangle \) correspond to neighboring sites and the sum runs over all the sites. The Peierls phase, \( \theta_{i,j} \), is defined in such a way that the sum of the phases around a unit cell is equal to the magnetic flux (in the units of flux quantum) threading the cell. It follows from Eq. (1) that the disorder can be of two types: randomness in on-site energies, \( V_i \), describe the potential disorder, while the randomness in the hopping integrals \( t_{i,j} \) describe the bond disorder specific for graphene. To describe the LL broadening due to \( V_i \), one can use the continuous version of the bare Hamiltonian Eq. (1)

\[
\hat{H}_0 = V(r) \cdot \mathbf{I} + v_F \mathbf{\pi} \cdot \mathbf{\sigma},
\]

where \( \mathbf{\sigma} \) is the 2D vector whose projections are the Pauli matrices, and \( v_F \) is the Fermi velocity. The effective momentum operator is given by \( \mathbf{\pi} = p - eA / c \), with \( p \) being the electron momentum, and \( A = (0, Bx) \) is the vector potential with \( B \) standing for the uniform magnetic field.

To make a connection to Refs. [1,12] the Fourier component, \( V_q \), of the random potential, \( V(r) \), is expressed through the random energies, \( V_i \), used in numerical simulations, as \( \sum_i V_i \exp (i q \cdot r_i) \).

Unlike the potential disorder, the bond disorder corresponds to the randomness in \( v_F \) and \( B \) and, thus, is called non-diagonal disorder. Indeed, \( v_F \) is related to the average \( t_{i,j} = t \) as \( v_F = \frac{\sqrt{2}a}{\ell_B} \), where \( a \) is the lattice constant. In this way, the fluctuations of \( t_{i,j} \) translate into the position-dependent \( v_F \). Similarly, the fluctuations of \( \theta_{i,j} \) translate into the position-dependent magnetic field.

The broadening of LLs in graphene due to non-diagonal disorder has been studied numerically in Refs. [20–27]. The results of simulations in all the above papers are consistent with each other. The most prominent feature of these results is that the broadening of \( n \neq 0 \) levels is much stronger than the broadening of the \( n = 0 \) level. This feature can be easily understood from the continuous Hamiltonian Eq. (2). Indeed, the eigenfunctions of \( \hat{H}_0 \) are the spinors

\[
\Psi_{n,k}(x,y) = \frac{C_n}{\sqrt{L}} \exp (iky) \left( \frac{\text{sgn}(n)(-i)\phi_{|n|-1,k}}{\phi_{n,k}} \right),
\]

where \( L \) is the normalization length. The constant \( C_n \) is equal to \( 1/2 \) for \( n \neq 0 \), and \( C_0 = 1 \). The functions \( \phi_{n,k}(x) \) are the eigenfunctions of the harmonic oscillator

\[
\phi_{n,k}(x) = (2^n n! \sqrt{\pi} \ell_B)^{-1/2} e^{-\frac{(x-x_0^2)^2}{4\ell_B^2}} H_n \left( \frac{(x - k\ell_B^2)}{\ell_B} \right),
\]

where \( H_n(x) \) is the Hermite polynomial and \( \ell_B = \frac{\hbar}{cB} \) is the magnetic length. The difference between \( n = 0 \) LL and other LLs is that the matrix element of non-diagonal disorder between the states \( k \) and \( k' \) is zero for \( n = 0 \). This is because one of the two components of the spinor Eq. (3) is zero. In fact, this matrix element remains zero even when the admixtures of higher
in Ref. [21] One has to add to the bare $4 \times 4$ Hamiltonian of graphene
\begin{equation}
\hat{H}_0 = v_F \begin{pmatrix}
0 & \pi_x - \pi_y & 0 & 0 \\
\pi_x + \pi_y & 0 & 0 & 0 \\
0 & 0 & 0 & \pi_x + \pi_y \\
0 & 0 & \pi_x - \pi_y & 0
\end{pmatrix}
\end{equation}
a perturbation
\begin{equation}
\hat{U}_i(r) = \begin{pmatrix}
0 & z_A^* z_B & 0 & z_A^* z_B' \\
z_B z_A & 0 & z_B' z_A & 0 \\
0 & z_A^* z_B & 0 & z_A^* z_B' \\
z_B z_A & 0 & z_B' z_A & 0
\end{pmatrix} u(r - r_i),
\end{equation}
where $u(r - r_i)$ encodes the change of the hopping parameter upon the alternation of the bond, $i$. Then the matrix, describing the bond disorder, takes the form $\sum_i \hat{U}_i$.

Note that the Hamiltonian Eq. (5) represents the continuous limit of the microscopic Hamiltonian Eq. (1), and its matrix form captures only the low-energy states close to the points $K$ and $K'$ in the momentum space. The general form of the four-component eigenvectors of $\hat{H}_0$ is $(\psi^A_K, \psi^B_K, \psi^K', \psi^B')$. In the absence of disorder, the $n = 0$ eigenvector has only one nonzero component corresponding to $B$-sites in the valley $K$ and to $A$-sites in the valley $K'$. The randomness in the hopping parameter couples $B$-sites in the valley $K$ to $A$-sites in the valley $K'$.

The fact that there are three types of bonds in graphene is captured in the perturbation $\hat{U}_0$ by nondiagonal matrix element $z_B z_A$, where, with proper choice of axes, $(z_B z_A)$ takes three values, namely, 1, $\exp(2\pi i/3)$, and $\exp(-2\pi i/3)$, depending on the position of the bond.

Upon introducing the random function
\begin{equation}
h(r) = \sum_{bonds \ i} c_i u(r - r_i) + e^{2\pi i} \sum_{bonds \ j} c_j u(r - r_j) + e^{-2\pi i} \sum_{bonds \ l} c_l u(r - r_l),
\end{equation}
where the coefficients $c_i$, $c_j$, and $c_l$ take the values 0 or 1 depending on whether or not the corresponding bond is perturbed, we rewrite a system of equations for the components of the spinor in the form
\begin{align}
E \psi^K_A &= v_F (\pi_x - i\pi_y) \psi^K_B + h(r) \psi^K_B \\
E \psi^K_B &= v_F (\pi_x + i\pi_y) \psi^K_A + h(r) \psi^K_A \\
E \psi^K' &= v_F (\pi_x + i\pi_y) \psi^K' + h'(r) \psi^K_B \\
E \psi^K' &= v_F (\pi_x - i\pi_y) \psi^K' + h'(r) \psi^K_A.
\end{align}

In this system we have kept only the terms responsible for the inter-valley scattering. In the absence of this scattering, the amplitudes $\psi^K_B$ and $\psi^K'$ correspond to the $\phi_{0,k}(x)$, i.e. to zeroth LL, while the amplitudes $\psi^K_A$ and $\psi^K''$ are zero. When the disorder strength is much smaller
than the distance between the LLs, the system Eq. \[8\] simplifies to the \(2 \times 2\) system

\[
\begin{align*}
E \psi^K_B &= h(r) \psi^K_A, \\
E \psi^{K'}_B &= h^\ast(r) \psi^K_B.
\end{align*}
\]

We can write the amplitude \(\psi^K_A\) and \(\psi^K_B\) as a linear combination of \(\phi_{0,k}\),

\[
\begin{align*}
\psi^K_B &= \sum_\kappa e^{i \kappa y} \phi_{0,\kappa}(x) B^K_\kappa, \\
\psi^{K'}_A &= \sum_q e^{i q y} \phi_{0,q}(x) A^{K'}_q.
\end{align*}
\]

Substituting Eq. \[10\] into Eq. \[9\], we get

\[
\begin{align*}
E B^K_\kappa &= \sum_q h_{\kappa,q} A^{K'}_q, \\
E A^{K'}_\kappa &= \sum_q h^\ast_{\kappa,q} B^K_q,
\end{align*}
\]

where \(h_{\kappa,q}\) is matrix element of \(h(r)\) between the eigenfunctions, \(e^{i \kappa y} \phi_{0,\kappa}(x)\) and \(e^{i q y} \phi_{0,q}(x)\), of \(n = 0\) LL.

III. DENSITY OF STATES

A. Perturbative approach

From Eq. \[10\] it becomes apparent that the problem of the broadening of \(n = 0\) LL by the bond disorder reduces to the model introduced by S. Hikami, M. Shirai, and F. Wegner, in Ref. [29]. The Hamiltonian of Ref. [29]

\[
\hat{H}_{HSW} = \left( \frac{1}{2m} \left( \mathbf{p} - \frac{\nu}{\varepsilon} \mathbf{A} \right)^2, \ h_0(x,y) + i h_2(x,y), \ \frac{1}{2m} \left( \mathbf{p} - \frac{\nu}{\varepsilon} \mathbf{A} \right)^2 \right),
\]

pertains to parabolic spectrum with effective mass, \(m\). The random fields, \(h_0(x,y)\) and \(h_2(x,y)\), are assumed uncorrelated. When the states are restricted to zeroth LL, the eigenvectors of the Hamiltonian \(\hat{H}_{HSW}\) are the spinors with components

\[
\alpha(x,y) = \sum_k A_k e^{i k y} \phi_{0,k}(x,y), \ \beta(x,y) = \sum_k B_k e^{i k y} \phi_{0,k}(x,y),
\]

where \(A_k\) and \(B_k\) satisfy the system Eq. \[10\].

In the paper Ref. [29] the Hamiltonian Eq. \[12\] was introduced to describe the effect of a specific type of disorder on electron states in \(n = 0\) LL. It was assumed that the bare states were of \(N = 2\) types, and the disorder scattering was allowed only between the states of different type. Upon examination the expansion of the diffusion coefficient in powers of disorder, it was concluded that the state, \(E = 0\), with \(E\) measured from \(\delta h_{\text{free}}\), is delocalized. With regard to the density of states, the self-consistent Born approximation\[30\] for the Hamiltonian Eq. \[12\] yields a semicircle shape. Taking the large-\(N\) limit, the authors concluded that the density of states diverges logarithmically at \(E = 0\). Later\[31\] upon employing the semiclassical description, D. K. K. Lee demonstrated that, in addition to \(E = 0\) delocalized state, the model of Ref. [29] contains two additional delocalized states of the conventional quantum Hall type. Subsequent numerical simulation\[31\] confirmed the existence of all three delocalized states, see however Ref. [32].

In graphene, the role of states of two types, considered in Ref. [29] is played by the states at \(K\) and \(K'\) points, while the scattering between them is provided by the bond disorder.

Below we propose an alternative approach to describe the eigenstates of Eq. \[12\]. We start by introducing the new variables

\[
a_k = \frac{1}{2} (A_k + B_k), \quad b_k = \frac{1}{2} (A_k - B_k).
\]

With these variables, the system Eq. \[11\] takes the form

\[
\begin{align*}
E a_k - \sum_q (h_1)_{\kappa,q} a_q &= -i \sum_q (h_2)_{\kappa,q} b_q, \\
E b_k + \sum_q (h_1)_{\kappa,q} b_q &= i \sum_q (h_2)_{\kappa,q} a_q.
\end{align*}
\]

Our main assumption in analyzing the eigenstates of the system Eq. \[15\] is that the magnitudes and statistical properties of \(h_1(x,y)\) and \(h_2(x,y)\) fields are completely different. In particular, we assume that the magnitude of \(h_2(x,y)\) is much smaller than the magnitude of \(h_1(x,y)\) and treat \(h_2(x,y)\) perturbatively.

In zeroth order, the eigenfunctions, \(\chi_0^\nu(x,y)\) and \(\chi_0^\nu(x,y)\), of the system Eq. \[15\] are the states of \(n = 0\) LL in the potentials \(h_1(x,y)\) and \(-h_1(x,y)\), respectively.
Upon switching on the field $h_2(x,y)$, the eigenfunctions, $\chi_{\nu}^+(x,y)$ and $\chi_{\nu}^-(x,y)$, get coupled. The coupling amplitude is equal to $\int d \mathbf{r} \left( \chi_{\nu}^+ \right)^* h_2(x,y) \left( \chi_{\nu}^- \right)$. To proceed, we further assume that the correlation length, $R_c$, of $h_2(x,y)$ is much bigger than $\ell_B$. Then $h_2(x,y)$ in the integrand can be treated as a constant. Consequently, the coupling amplitude reduces to the overlap integral of $\chi_{\nu}^+$ and $\chi_{\nu}^-$. Our prime observation is that this integral is nonzero only when $\chi_{\nu}^+$ and $\chi_{\nu}^-$ correspond to energy $E$ in potential $h_1(x,y)$ and to $-E$ in potential $-h_1(x,y)$, respectively. Then the functions $\chi_{\nu}^+$ and $\chi_{\nu}^-$ are the same. Any other function $\chi_{\nu}^-$ in potential $-h_1(x,y)$ has its counterpart in potential $h_1(x,y)$, which corresponds to energy different from the state $\chi_{\nu}^+$. Thus, it is orthogonal to $\chi_{\nu}^+$. This situation is illustrated in Fig. 1.

We conclude that, upon switching on the random field $h_2(x,y)$, the modified states are determined upon diagonalizing the $2 \times 2$ matrix

$$
\begin{pmatrix}
E_{\nu} & i \langle h_2 \rangle_{\nu,\nu} \\
-i \langle h_2 \rangle_{\nu,\nu} & -E_{\nu}
\end{pmatrix},
$$

where $E_{\nu}$ is the bare energy, and the non-diagonal element, $\langle h_2 \rangle_{\nu,\nu}$, stands for the coupling amplitude. The modified energies are given by

$$
\tilde{E}_{\nu} = \pm \left[ E_{\nu}^2 + \langle (h_2)_{\nu,\nu} \rangle^2 \right]^{1/2},
$$

Overall, the effect of $h_2(x,y)$ amounts to the repulsion of the states $E_{\nu}$ away from the center $E = 0$. From the fact that the values $E_{\nu}$ and $\langle h_2 \rangle_{\nu,\nu}$ are statistically independent, we readily arrive to the general expression for the modified density of states

$$
\rho(\tilde{E}) = \int dE \rho_{\nu_1}(E) \int dh_2 \mathcal{P}(h_2) \delta \left[ \tilde{E} - (E^2 + h_2^2)^{1/2} \right],
$$

with $\mathcal{P}(h_2) = 1/\pi^{1/2} \Gamma \exp \left( -h_2^2/\Gamma^2 \right)$, where $\rho_{\nu_1}(E)$ is the average density of states in the potential $h_1(x,y)$. The form of this density of states depends on whether the correlation length of $h_1(x,y)$ is bigger or smaller than the magnetic length. For long-range disorder $\rho_{\nu_1}(E)$ is Gaussian

$$
\rho_{\nu_1}(E) = \frac{1}{2\pi^{3/2} \ell_B^2 \Gamma} \exp \left( -E^2/\Gamma^2 \right),
$$

where the width, $\Gamma$, is simply $\Gamma = \langle h_1(x,y)^2 \rangle^{1/2}$, i.e. the r.m.s. value of the potential. In the opposite limit of short-range disorder with a correlator

$$
\langle h_1(\mathbf{r})h_1(\mathbf{r}) \rangle = w \delta (\mathbf{r} - \mathbf{r}_1)
$$

the exact density of states found by F. Wegner in Ref. [3] has the form

$$
\rho_{\nu_1}(E) = \frac{1}{2\pi^{3/2} \ell_B^2} \frac{\partial}{\partial E} \left\{ \text{arctan} \left[ G(E/\Gamma) \right] \right\},
$$

with $G(z) = \int_0^z dt t^{1/2}$,

$$
(21)
$$

the integral over $E$.

FIG. 3: (Color online) A cartoon illustrating the suppression of the repulsion of energies $E$ and $-E$ near zero energy. Although the correlation radius, $R_c$, is bigger than the magnetic length, $\ell_B$, the extension, $\mathcal{L}(E)$, of the wave-functions grows with decreasing $E$, and, eventually, exceeds $R_c$. Then the matrix element, $\langle h_2 \rangle_{\nu,\nu}$, responsible for repulsion, can be viewed as a sum of $(R_c/\mathcal{L}(E))^2$ random contributions.

Following our assumption that $h_2(x,y)$ is smooth, we choose the Gaussian form for $\mathcal{P}(h_2)$

$$
\mathcal{P}(h_2) = \frac{1}{\pi^{1/2} \Gamma} \exp \left( -h_2^2/\Gamma^2 \right),
$$

with $\Gamma = \Gamma_s = (w/2\pi \ell_B^2)^{1/2}$. While $\Gamma_s$ grows with magnetic field and $\Gamma_L$ does not, the shape Eq. (21) is close to Gaussian.

Upon substituting Eq. (20) and Eq. (23) into the expression Eq. (19) for the density of states, we introduce polar coordinates $E = R \cos \varphi$ and $h_2 = R \sin \varphi$ and cast it in the form

$$
\rho(\tilde{E}) = \frac{1}{2\pi^{3/2} \ell_B^2 \Gamma \gamma} \int_0^\infty dR E R 2\pi 
$$

$$
\times \exp \left[ -R^2 \left( \frac{\cos^2 \varphi}{\Gamma^2} + \frac{\sin^2 \varphi}{\gamma^2} \right) \right] \delta(\tilde{E} - R).
$$

Integration over $R$ is performed using the $\delta$-function, and the integral over $\varphi$ reduces to modified Bessel function, $I_0(z)$. Final result reads

$$
\rho(\tilde{E}) = \frac{|\tilde{E}|}{\pi \ell_B^2 \Gamma \gamma} \exp \left[ -\frac{\tilde{E}^2}{2} \left( \frac{1}{\Gamma^2} + \frac{1}{\gamma^2} \right) \right]
$$

$$
\times I_0 \left[ \frac{\tilde{E}^2}{2} \left( \frac{1}{\Gamma^2} - \frac{1}{\gamma^2} \right) \right].
$$

(25)
The fact that \( \rho(\tilde{E}) \) behaves as \( |\tilde{E}| \) at small energies is a natural consequence of the level repulsion. It is also natural that, for symmetric disorder \( \Gamma = \gamma \), Eq. (25) reduces to the Wigner-Dyson distribution, as in Ref. 31. Under the assumption adopted above, that the disorder \( h_2(x, y) \) is weak, the shape of the density of states develops a sharp feature at small energies, as illustrated in Fig. 2, which is somewhat reminiscent of the numerical data, but does not capture the robust low-energy behavior revealed in these papers. We argue that the reason of the discrepancy lies in the fact that we disregarded the energy dependence of the matrix element \( \langle h_2 \rangle_{\nu, \nu} \). Namely, when we assumed the correlation length, \( R_c \), of \( h_2(x, y) \) is much bigger than \( \ell_B \), we overlooked the fact that, upon approaching to \( \tilde{E} = 0 \) the eigenfunctions \( \chi_+^\nu \) and \( \chi_-^\nu \) become progressively extended.

\[
\langle (h_2)^2 \rangle_{\nu, \nu} = \int dr_1 |\chi_+^\nu(r_1)|^2 dr_1 \int dr_2 |\chi_-^\nu(r_2)|^2 dr_2 \times \langle h_2(r_1) h_2(r_2) \rangle \sim \gamma \left( \frac{R_c}{\mathcal{L}(E)} \right)^2 ,
\]

where \( \mathcal{L}(E) \) is the energy-dependent localization length of the wavefunctions \( \chi_+^\nu \) and \( \chi_-^\nu \). We see that the repulsion of energy levels from the band-center, \( E = 0 \), gets strongly suppressed at \( E \to 0 \). This observation is illustrated in Fig. 3. The area corresponding to the \( \mathcal{L}(E)^2 \) state, \( E \), contains \( \left( \frac{\mathcal{L}(E)}{R_c} \right)^2 \) squares within which \( h_2(r) \) is constant. Since the contributions of these squares to \( \langle h_2 \rangle_{\nu, \nu} \) are random, the typical value of \( \langle h_2 \rangle_{\nu, \nu} \) is suppressed by a factor \( \sim \left( \frac{R_c}{\mathcal{L}(E)} \right)^2 \). This is certainly a hard-waving argument. Strictly speaking, with \( h_2(r) \) changing in space, the state \( \chi_-^\nu \) gets coupled to all the states \( \chi_+^\nu \). It is, however, important that the contributions to the matrix element from positive and negative energies almost cancel each other at small \( E \).

B. Shapes of the density of states

A minimal ansatz to incorporate the suppression of the repulsion of the levels \( E \) and \( -E \) into the density of states Eq. (19) is to assume that the matrix element \( \langle h_2 \rangle_{\nu, \nu} \) still obeys the Gaussian distribution, but the r.m.s. value, \( \gamma \), is a function of \( E \).

Due to finite \( R_c \), the state, \( \nu \), corresponding to the energy, \( E \), will be coupled by \( h_2(x, y) \) not only to the state \(-E\) but to the states corresponding to different energies. We will still assume that only \( \langle h_2 \rangle_{\nu, \nu} \) is non-zero, since the degree of violation of the orthogonality is \( \sim \ell_B^2 / R_c^2 \), which is small. Then, performing integration over \( h_2 \) in Eq. (19), we arrive to the following expression for the density of states

\[
\rho(\tilde{E}) = \frac{|\tilde{E}|}{2\pi \ell_B^2 \Gamma} \int_0^{\tilde{E}} \frac{dE}{\gamma(E)} \left( \frac{\tilde{E}^2 - E^2}{\gamma^2(E)} \right)^{1/2} \times \exp \left[ - \left( \frac{E^2 + \tilde{E}^2 - E^2}{\Gamma^2 \gamma^2(E)} \right) \right] .
\]
Other forms of $\gamma(E)$ yielded similar results. In fact, Eq. (27) contains three independent parameters, which we varied. The first is the strength, $\gamma_0$, of the disorder, $h_2(x,y)$, as in Eq. (28), the second is the ratio $R_c/\ell_0$, which we assume to be big, and, finally, the exponent, $\kappa$, in the energy dependence of the localization length. For conventional quantum Hall critical point the value of $\kappa$ is 2.3. In analysis of the shape, $\rho(E)$, we have changed one parameter keeping the other two constant. The results are shown in Fig. 4. The main message of Fig. 4 is that, as we vary the parameters, the general shape of $\rho(E)$ remains unchanged.

From Fig. 4 we conclude that when the exponent $\kappa$ increases, the anomaly at $E = 0$ becomes more and more pronounced. Comparing to Fig. 2 we see that the behavior of $\rho(E) \propto |E|$ gets modified to a narrow peak. The explanation for this is straightforward: delocalization of states near $E = 0$ in the absence of $h_2(x,y)$ results in suppression of their repulsion when $h_2(x,y)$ is switched on. This suppression becomes more effective upon increasing $\kappa$. Then the origin of the peak is that, while the states with $E \sim \Gamma$ are shifted by $h_2$ either to the left or to the right, depending on the sign of $E$, the low-energy states retain their positions. Obviously, the analysis of the perturbation expansion in terms of $h_1$ and $h_2$, of the density of states up to a finite order, cannot capture this effect. This is because the finite-order expansion does not capture the delocalization of the wave functions.

Fig. 4 suggests that, the prime effect of increasing the strength of $h_2$ is the general broadening of the density of states, while the behavior at small $E$ changes weakly.

Evolution of the curves in Fig. 4 can be understood as follows. We assumed that $h_2$ couples the state $\chi^+_\nu$ only to the state $\chi^+_{\nu'}$. The bigger is $R_c$, the more accurate is this assumption. Then, the bigger is $R_c$, the more pronounced is the separation of the density of states into the central peak and two split maxima.

From all the curves in Fig. 4 the most reminiscent of the numerical simulation results is the red curve in Fig. 4.

### C. White-noise disorder

In this subsection we lift the requirement that the correlation radius, $R_c$, of the field $h_2(x,y)$ is much bigger than magnetic length. It was this requirement that ensured the repulsion of the levels $E_\nu$ and $-E_\nu$. When $h_2(x,y)$ is short-ranged, it couples the $K-K'$ level $E_\nu$ to all $K+K'$ levels, $E_{\mu'}$. Still, we will see that coupling of $E_\nu$ to $-E_\nu$ remains distinguished, since the corresponding states have the same wave functions.

For this purpose we search for the solution of the system Eqs. (15), (16) in the form of expansion,

$$
\Psi^{(K+K')} = \sum_{\nu} c_{\nu} \chi^{+}_{\nu}, \quad \Psi^{(K-K')} = \sum_{\mu} d_{\mu} \chi^{-}_{\mu},
$$

where $\chi^{+}_{\nu}$ and $\chi^{-}_{\mu}$ are the eigenfunctions of the system Eqs. (15), (16) in the absence of $h_2(x,y)$. For a finite $h_2$ we arrive to the following system for the coefficients $c_{\nu}$ and $d_{\mu}$

$$
c_{\nu}(E^{+}_{\nu} - E)\chi^{+}_{\nu} + \sum_{\nu' \neq \nu} c_{\nu'}(E^{+}_{\nu'} - E)\chi^{+}_{\nu'} = -ih_2(x,y) \left[ d_{\mu}\chi^{-}_{\mu} + \sum_{\mu' \neq \mu} d_{\mu'}\chi^{-}_{\mu'} \right],
$$

$$
d_{\mu}(E^{-}_{\mu} - E)\chi^{-}_{\mu} + \sum_{\mu' \neq \mu} d_{\mu'}(E^{-}_{\mu'} - E)\chi^{-}_{\mu'} = ih_2(x,y) \left[ c_{\nu}\chi^{+}_{\nu} + \sum_{\nu' \neq \nu} c_{\nu'}\chi^{+}_{\nu'} \right].
$$

For a given $\nu$, we treat $c_{\nu}$ and $d_{\mu}$ as zero-order terms, and express $c_{\nu}$ and $d_{\mu}$ with $\mu \neq \nu$ through them. Substituting $c_{\nu}$, $d_{\mu}$ back into the system, we get

$$
E^{+}_{\nu} - E - \frac{|(h_2)_{\nu,\nu}|^2}{E^{+}_{\nu} - E} c_{\nu} = d_{\nu} S_{\nu},
$$

$$
E^{-}_{\mu} - E - \frac{|(h_2)_{\mu,\mu}|^2}{E^{-}_{\mu} - E} d_{\mu} = -c_{\mu} S_{\mu},
$$

where $S_{\nu}$ stands for the sum

$$
S_{\nu} = \sum_{\mu \neq \nu} \frac{|(h_2)_{\nu,\mu}|^2}{E^{+}_{\mu} - E} = \sum_{\nu' \neq \mu} |(h_2)_{\nu',\mu}|^2.
$$

Multiplying Eq. (31) and Eq. (32), we get the following equation for $E$

$$
\left( (E^2 - E^2_{\nu}) - |(h_2)_{\nu,\nu}|^2 \right)^2 = (E^2 - E^2_{\nu}) S_{\nu}^2,
$$

the solution of which reads

$$
E^2 = E^2_{\nu} + \left[ |(h_2)_{\nu,\nu}|^2 + S_{\nu}^2 \right]^{1/2} \pm \frac{S_{\nu}}{2}.
$$

This equation is a generalization of Eq. (18).

We can now estimate the accuracy of keeping only the diagonal elements of $h_2(x,y)$. If the energy $E_{\nu}$ is in the “body” of the band broadened by the potential $h_1(x,y)$, then only the neighboring states contribute to $S$. This is because the overlap with states at distance $x \gg \ell_0$ is small as $\exp(-x^2/2\ell_0^2)$. For a neighboring state, the typical value of the denominator is Eq. (33) is $\sim \Gamma$, while the numerator is $\sim \gamma_0^2$. Thus, the relative correction to $(h_2)^2_{\nu,\nu}$ is $\sim \gamma_0^2/\Gamma^2$, i.e. it is small.
The estimate for the correction $S_\nu$ in the case where $E_\nu \ll \Gamma$ should be carried out differently. With $h_2(x, y)$ being the white-noise, the average $\langle S_\nu \rangle$ contains the combination
\[
\sum_\mu |\chi_\mu^+(r)|^2 |\chi_\mu^-(r)|^2 \frac{1}{E_\nu^+ - E_\mu^-},
\] (36)
which depends on the correlation between functions $\chi_\mu^+$ and $\chi_\mu^-$, which are the eigenfunctions in different potentials, $h_1(x, y)$ and $-h_1(x, y)$.

It is known, see e.g., Refs. [33–35], that the correlation of the critical eigenfunctions in the same potential is quantified as
\[
\int dr \ |\chi_\nu^+(r)|^2 |\chi_\nu^-(r)|^2 \delta(E_\nu^+ - E_\nu^-) \propto \frac{\Gamma}{E_\nu^+ - E_\nu^-}^{\gamma/2},
\] (37)
where $\gamma$ is the exponent characterizing the fractal structure of critical eigenfunctions. Recall now, the wavefunction $\chi_\nu^+$ and $\chi_\nu^-$ are the same when they correspond to opposite energies, $E_\nu^+ = -E_\nu^-$. Then we can use Eq. (37) to estimate $\langle S_\nu \rangle$
\[
\int dE_\mu^- \rho_{\nu,\mu}(E_\mu^-) \frac{\Gamma}{E_\mu^- + E_\mu^+}^{\gamma/2} \propto \frac{1}{|E_\nu^+|^{\gamma/2}}.
\] (38)

The above equation suggests that $\langle S_\nu \rangle$ increases upon approaching $E_\nu^+ \to 0$. Still, it loses to the diagonal term, $(h_2)_{\nu,\nu}$. This is because a typical $(h_2)_{\nu,\nu}$ is proportional to $1/L(E)$, see Eq. (26), while $S_\nu^2$ is proportional to $1/L^2(E)$.

IV. DELOCALIZED STATES

The only physically transparent description of the quantum Hall transition is the Chalker-Coddington (CC) network model of Ref. [36] which is a quantum generalization of the classical percolation. To apply this model in our case, one should assume that both fields $h_1(x, y)$ and $h_2(x, y)$ are smooth. Then the semiclassical energies [37] are determined by local values of $h_1$, $h_2$ and are equal to $E_\pm = \pm (h_1^2 + h_2^2)^{1/2}$. Within the prefactor, the distribution function, $F(E_\pm)$, of $E_\pm$ is given by Eq. (25). Then the percolation threshold, $E = E_c$, is found from the condition $\int_0^{E_c} dE_+ F(E_+) = \frac{1}{2}$. If $h_1$ and $h_2$ are statistically equivalent, then $F(E_+) = \frac{2E_c}{\pi} \exp \left(-\frac{E_c^2}{\pi E_+^2} \right)$. This yields $E_c = 0.7\Gamma$, i.e. the delocalized state lies slightly above the maximum, $0.5\Gamma$, of the density of states. This is consistent with numerical result of Ref. [31] although the simulations were performed for the short-range disorder.

Classical percolation at $E = \pm E_c$ transforms into the conventional quantum Hall transitions when the tunneling through the saddle points, defined by the conditions:

\[
\frac{\partial}{\partial x} (h_1^2 + h_2^2) = 0 \quad \text{and} \quad \frac{\partial}{\partial y} (h_1^2 + h_2^2) = 0
\] (and opposite signs of the second derivatives) are taken into account.

There is no classical picture underlying the delocalized state at $E = 0$, revealed in Ref. [29]. A peculiar feature of this delocalization established numerically in Refs. [31, 22] is that the critical exponent is anomalously small, $\nu \approx 0.3$. It is even smaller than the $\nu = \frac{1}{2}$ for classical percolation and for the random flux model [37, 31]. It is likely that the accuracy of simulations on Refs. [31, 20] and [22] was limited by the size effects.

Small critical exponent suggests that the localization length depends weakly on energy near $E = 0$. Below we invoke the CC model to explain a possible origin of this weak dependence. The explanation is based on Fig. 5. Within the CC model, the behavior of the localization length on energy, $E$, is governed by tunneling via the saddle points separating two equipotentials, see Fig. 5. Equipotentials, $h_1(x, y) = 0$, form a percolation network. Consider two blue equipotentials corresponding to $K-K'$ states. Note that, for the states corresponding to $K+K'$, the random potential is equal to $-h_1(x, y)$. Thus, the equipotentials shown in Fig. 5 in red, are rotated by $90^\circ$. Equipotentials $h_1(x, y) = E$ and $-h_1(x, y) = E$ are coupled by the random field, $h_2(x, y)$. This suggests that energy-dependent tunneling via the saddle point does not affect the structure of the low-energy states. The reason for this is that the saddle point is bypassed in the alternative channels: blue $\to$ red $\to$ blue and red $\to$ blue $\to$ red, see Fig. 5.
V. DISCUSSION AND CONCLUDING REMARKS

(i) By assuming that the bond disorder is strongly anisotropic, $h_2(x, y) \ll h_1(x, y)$, we arrived to the following scenario for the shape of the density of states of the $n = 0$ LL: the field $h_1(x, y)$ broadens the level into a band, while the field $h_2(x, y)$ is responsible for the repulsion of the levels from the center of the band facilitated by $K \rightarrow K'$ scattering. The states with $E > 0$ are shifted up, while the states with $E < 0$ are shifted down. Most importantly, the low-energy states remain unshifted, which leads to the three-peak structure of the disorder-broadened band.

(ii) Certainly, the assumption $h_2(x, y) \ll h_1(x, y)$ is artificial and does not correspond to the simulations of Refs. 20–27. However, treatment of $h_1(x, y)$ and $h_2(x, y)$ on the equal footing is possible only within the self-consistent Born approximation, leading to the semicircle shape with a width $\sqrt{\Gamma}$. This means that the diagrams taken into account within the self-consistent Born approximation do not capture properly the repulsion of the states away from the band center, $E = 0$. The picture of Ref. 30 also does not allow to make quantitative predictions about the shape of the density of states near $E = 0$.

The model of Ref. 24 is unique, in the sense, that delocalization of states has a dramatic back effect on the density of states; self-consistent Born approximation is not sensitive to the localization. Also, evaluating any particular diagram in the perturbation expansion of the density of states will not reveal an energy scale smaller than $\Gamma$. We inferred such a small scale from delocalization of $K - K'$ and $K + K'$ eigenstates in the potential, $h_1(x, y)$, assuming that $h_2(x, y)$ is absent. Note that, in the simulations of Refs. 25–26 the central peak in the density of states was hardly pronounced. Accordingly, the authors did not find any evidence for delocalization at $E = 0$.

The specifics of the Hamiltonian Eq. (12) with regard to the behavior of the eigenstates at low energies was discussed in Ref. 31. It was pointed out that this specifics originates from the reflection symmetry of the Hamiltonian, $\sigma_z \tilde{H}_{HSW} \sigma_z = -\tilde{H}_{HSW}$. Interestingly, the numerical simulations of a different model 33 of 1D hopping chain with off-diagonal disorder, described by a Hamiltonian possessing the reflection symmetry, also revealed a three-peak structure of the density of states.

(iii) We have treated the field $h_2(x, y)$ perturbatively. This implies the assumption that the perturbation theory applies even at low energies, so that $h_2(x, y)$ does not modify the structure of the wave-functions of the low-energy states. On the other hand, the argument, illustrated in Fig. 5 suggests that the order in which $h_2$ and $E$ go to zero is important. This can be also seen from the analysis of the expression Eq. (19) for the density of states. In the limit of low energies, the integral in Eq. (19) reduces to

$$\rho(E) \propto \int_0^\infty \frac{dz}{z^2} \delta \left( \frac{E}{E_c} - (z^2 + z^2)^{1/2} \right),$$

where

$$E_c = \left( \frac{\Gamma \epsilon_0}{\gamma_0 R_c} \right)^{1/2}.$$ 

Since $\gamma_0$ reflects the magnitude of $h_2$, it is seen that the result depends on the order of taking the limits $h_2 \rightarrow 0$ and $E \rightarrow 0$.

(iv) Naturally, in the opposite limit, $h_1(x, y) \ll h_2(x, y)$, we will arrive to the same result for the density of states and delocalization. In this limit, one should introduce the variables $A_k \pm iB_k$, instead of the variables $A_k \pm B_k$ Eq. (14). Then $h_2(x, y)$ will be responsible for broadening of the level, while $h_1(x, y)$ will lead to the repulsion of the states away from $E = 0$.

(v) Let us relate the fields $h_1(x, y)$ and $h_2(x, y)$ to the bond disorder in graphene: From Eq. (7) we have

$$h_1(r) = \sum_{\text{bonds } i} c_i u (r - r_i) - \frac{1}{2} \sum_{\text{bonds } j} c_j u (r - r_j) + \sum_{\text{bonds } l} c_l u (r - r_l),$$

$$h_2(r) = \frac{\sqrt{3}}{2} \sum_{\text{bonds } j} c_j u (r - r_j) - \sum_{\text{bonds } l} c_l u (r - r_l).$$

Our analysis rests on the assumptions that $h_1$ is much bigger than $h_2$. Microscopically this means that the concentration of the perturbed $i$-bonds is much bigger than the concentration of the perturbed $j$ and $l$ bonds. In principle this situation can be realized in numerical simulations.
