The Structure of 2D Semi-simple Field Theories

Constantin Teleman

August 9, 2011

Abstract

I classify the cohomological 2D field theories based on a semi-simple complex Frobenius algebra $A$. They are controlled by a linear combination of $\kappa$-classes and by an extension datum to the Deligne-Mumford boundary. Their effect on the Gromov-Witten potential is described by Givental’s Fock space formulae. This leads to the reconstruction of Gromov-Witten (ancestor) invariants from the quantum cup-product at a single semi-simple point and the first Chern class of the manifold, confirming Givental’s higher-genus reconstruction conjecture. This in turn implies the Virasoro conjecture for manifolds with semi-simple quantum cohomology. The classification uses the Mumford conjecture, proved by Madsen and Weiss [MW].

Introduction

This paper studies structural properties of topological field theories (TFT’s), a notion introduced by Atiyah and Witten [W] and inspired by Segal’s axiomatisation of Conformal Field Theory. A TFT extracts the topological information which is implicit in quantum field theories defined over space-time manifolds more general than Euclidean space. The first non-trivial example is in 2 dimensions, a setting which has been the focus of much interest in relation to Gromov-Witten theory: the latter captures the expected count of pseudo-holomorphic curves in a compact symplectic target manifold. The result proved here, the classification of semi-simple theories, shows that an important property of these invariants is a formal consequence of the underlying structure, rather than a reflection of geometric properties of the target manifold. Loosely stated, the property in question is that a count of rational curves with three marked points, encoded in the quantum cohomology of the target, determines the answer to enumerative questions about curves of all genera, when the quantum cohomology ring is semi-simple.

My classification leaves some important questions open (see [Te] for more discussion). One of them is to extract the Gromov-Witten classification data from the geometry of the symplectic manifold. Finding even a single semi-simple quantum cup-product (when one exists) may require infinite information, if curves are counted degree-by-degree. Another, more precise question concerns the degeneration of a semi-simple theory to the locus in its Frobenius manifold (the natural parameter space, see §7) where the algebra acquires nilpotents. An example is the discriminant locus within the deformation space of an isolated singularity: it is unclear whether the higher-genus part of the associated TFT, the Landau-Ginzburg B-model for a singularity, extends continuously there (the semi-simple classification data blow up).

1To be precise, this is true of the so-called ancestor Gromov-Witten invariants. The complete, descendent invariants require additional genus zero information, the $J$-function.
(0.1) First definition. A 2-dimensional topological field theory over a ring $k$ is a strong symmetric monoidal functor $Z$ from the 2-dimensional oriented bordism category to the tensor category of finitely generated projective $k$-modules. This means that $Z$ assigns to every closed oriented 1-manifold $X$ a $k$-module $Z(X)$, and to any compact oriented surface $\Sigma$, with independently oriented boundary $\partial \Sigma$, a linear “propagator”

$$Z(\Sigma) : Z(\partial_+ \Sigma) \rightarrow Z(\partial_- \Sigma).$$

The sign $\pm$ of a boundary component compares the orientation induced from $\Sigma$ with the independent one on $\partial \Sigma$; we call $\partial_- \Sigma$ the incoming boundary and $\partial_+ \Sigma$ the outgoing one. The above definition requires that

(i) $Z$ is multiplicative under disjoint unions, $Z(X_1 \amalg X_2) = Z(X_1) \otimes Z(X_2)$.
(ii) Sewing boundary components leads to the composition of maps.

Part (i) is the monoidal condition, while (ii) is the functorial property. Note that the cylinder “$\amalg$” with one incoming and one outgoing end represents the identity. In the simplest definition of the bordism category, morphisms are surfaces modulo oriented homeomorphism (rel boundary); more sophisticated definitions remember the topology of the diffeomorphism group (Remark 1.2).

(0.2) First classification. A folk theorem (with non-trivial proof, see [A1]) ensures that $Z$ is equivalent to the datum of a commutative Frobenius $k$-algebra structure on the space $A := Z(S^1)$. This last notion comprises a commutative $k$-algebra structure on $A$, together with an $A$-module isomorphism $i : A \longrightarrow A^* := \text{Hom}_k(A,k)$. The Frobenius structure on $Z(S^1)$ can be read from the functor $Z$ as follows:

- the multiplication map $A \otimes A \rightarrow A$ is defined by the trinion with two incoming circles and an outgoing one;
- the unit in $A$ is defined by the disk with outgoing boundary, $Z(\triangleright) : k \rightarrow A$;
- the disk $\subset$ with incoming boundary determines the vector $\theta := i(1) \in A^*$.

(My pictures represent the projection outlines of surfaces, with their boundaries omitted. Also, the reader will have noticed that surfaces are ‘read’ from right to left, matching the ordering convention for the composition of operators.) The form $\theta$, in turn, determines a symmetric pairing $\beta : A \times A \rightarrow k$, $\beta(a \times b) = \theta(ab)$, which is the partial adjoint to $i$ in one of the variables. Non-degeneracy of $\beta$ — equivalently, the isomorphy condition on $i$ — is also known as Zorrø’s lemma and is proved by the diagram wherein a “$\amalg$”-shaped identity cylinder is factored into a “right elbow” $\ominus$ (that is, a cylinder with two outgoing ends), sewed on to a left elbow $\ominus$ at one of its outputs: $Z(\ominus)$ represents $\beta$, and $Z(\ominus)$ provides an inverse co-form.

(0.3) Semi-simple case. An easy but important special case concerns semi-simple algebras $A$ over $k = \mathbb{C}$. As algebras, these are isomorphic to $\mathop{\bigoplus}_{i} \mathbb{C} \cdot P_i$ for projectors $P_i$, uniquely determined up to reordering. From the definition and non-degeneracy of $\beta$, the projectors are $\beta$-orthogonal and their $\theta$-values $\theta_i = \theta(P_i)$ must be non-zero complex numbers. Up to isomorphism, $A$ is classified by the (unordered) collection of the $\theta_i$. The TFT is easy to describe in the normalised canonical basis of rescaled projectors $p_i := \theta_i^{-1/2} P_i$, as follows. For a connected surface $\Sigma$ with $m$ incoming and $n$ outgoing boundaries, the matrix of the propagator $Z(\Sigma)$ has entry $\theta_i^{\chi(\Sigma)/2}$ linking $p_i^{\otimes m}$ to $p_i^{\otimes n}$, while all entries involving mixed tensor monomials in the $p_i$ are null. I leave it to the reader’s care to supply the correct reading of this rule when $m$ or $n$ are zero.

\footnote{I believe the name was coined by Jacob Lurie.}
Example: the Euler class. A Frobenius algebra contains a distinguished vector, the Euler class $\alpha$, which is the output of a torus with one outgoing boundary. When $A$ is the cohomology ring of a closed oriented manifold with coefficients in a field and $\beta$ the Poincaré duality pairing, $\alpha$ is the usual Euler class. (Of course, $A$ will be a skew-commutative, if there is any odd cohomology.) By contrast, in the semi-simple case, $\alpha$ is the invertible element $\sum_i \theta^{-1}P_i$. The endomorphism of $A$ defined by a two-holed surface of genus $g$ is the multiplication by $\alpha^g$: in matrix form, $\text{diag}[\theta^{-g}]$. In the semi-simple case, this observation allows the recovery of low-genus $Z$ from high genus, and will play a key role in the paper.

There is actually a converse: invertibility of $\alpha$ implies semi-simplicity of $A$. (The trace on $A$ of the operator of multiplication by $x$ is $\theta(ax)$, so $\text{Tr}_A$ defines a non-degenerate bilinear form on $A$; it follows that, over any residue field of the ground ring $k$, $A$ is a sum of separable field extensions.) This, and the importance of an invertible $\alpha$, were perhaps first flagged by Abrams, also in connection with quantum cohomology; the reader is referred to the nice paper [A2].

What this paper does. Here, I give an algebraic classification for family TFTs (FTFTs), in which the surfaces vary in families and the functor $Z$ takes values in the cohomology of the parameter spaces, with coefficients in the space of maps between tensor powers of $A$. These theories are variants of the Cohomological Field Theories (CohFT’s) introduced by Kontsevich and Manin [KM1]. “Families” consisting of single surfaces recover the previous TFT notion, detecting the underlying Frobenius algebra $A$. My classification applies whenever $A$ is semi-simple and $k$ is a field of characteristic zero; I use $\mathbb{C}$ for simplicity.

The Gromov-Witten case. The theories of greatest interest involve nodal surfaces, the stable curves of algebraic geometry, and come from Gromov-Witten invariants. In this setting, I provide a structure formula for the Gromov-Witten invariants of manifolds whose quantum cohomology is generically semi-simple. Such theories have additional structure, a grading which stems from the fact that spaces of stable maps have topologically determined (expected) dimensions. This structure limits the freedom of choice considerably: the full FTFT is determined by the Frobenius algebra and the grading information. This affirms a conjecture of Givental’s [G1] on the reconstruction of higher-genus invariants, and in particular, as pointed out in [G3], the Virasoro conjecture for such manifolds. Verification of this conjecture involves tracing through Givental’s construction, with an improvement to the formulation which (I think) is originally due to M. Kontsevich, and which we review in §6.

Relation to “open-closed” theories. With different starting hypotheses, a vast extension of my classification has been reached by Kontsevich and collaborators in the framework of open-closed FTFTs (see [KKP] and sequels in preparation). From that perspective, I show that any semi-simple (closed string) CohFT might as well be assumed to come from an open-closed FTFT with a semi-simple category of boundary states. In Gromov-Witten theory, this statement could even follow from a sufficiently optimistic formulation of Homological Mirror Symmetry: semi-simplicity of quantum cohomology suggests a Landau-Ginzburg B-model mirror with isolated Morse critical points of the potential, since (in the case of isolated singularities) the quantum cohomology ring is meant to be isomorphic to the Jacobian ring of the potential. In this situation, the mirror category of boundary states (B-branes) is also semi-simple. Assuming all this, we could then invoke Kontsevich’s classification.

However, while it seems clear that the open-closed framework (or some related 2-categorical approach) is the right setting, Gromov-Witten theory is not quite ready for it, as the requisite assumptions on the Fukaya category of boundary states have only been checked in special cases;
whereas the CohFT axioms are well-established. Examples of varieties with generically semi-simple quantum cohomology include: toric manifolds, most Fano three-folds with no odd Betti numbers \[\text{[Ci]}\], as well as blow-ups of such varieties at any number of points \[\text{[B]}\]. Of these, only for toric ones does the open-closed theory seem to be in convincing shape, thanks to work by Fukaya and collaborators \[\text{[FOOO]}\].

Acknowledgements

I have lectured on successive approximations of this work since the fall of 2004. Comments from colleagues were essential in correcting and re-shaping the results, and it is a pleasure to thank them here. Early on, K. Costello suggested a link between my classification and Givental’s conjecture; T. Coates, Y. Eliashberg, S. Galatius, E. Getzler, M. Kontsevich, Y. Manin, J. Morava and D. Sullivan all contributed useful comments. Y.-P. Lee offered numerous helpful comments on the early form of the manuscript. Special thanks are due to A. Givental for patient explanation of his work, as well as to the anonymous referees for careful reading and numerous suggestions for improvement.

Substantial portions of this work were completed during the 2006 programme on “New Topological structures in physics” at MSRI and much of the initial writing was done during a visit to the Max Planck Institute in Bonn in August 2007. Partial support was provided by NSF grant DMS-0709448.

1. Summary of definitions and results

This section outlines the definition and classification of the various versions of FTFT’s used throughout the paper, as well as the background of the two key results, Theorems 1 and 2, formulated towards the end of the section. It is not possible to cover all the details in the space suited to an opening section, and the reader will often be referred to later paragraphs for clarification. For instance, classifying spaces of surface bundles are discussed in \[\text{\S}2\]; a refresher on \(\kappa\)- and \(\psi\)-classes is found in \[\text{\S}\text{2.15}\] and the list of axioms for a DMT is only truly completed by spelling out the ‘nodal relations’ in \[\text{\S}\text{4.5}\].

(1.1) Functorial definition. Family TFT’s admit a categorical definition in the style of the introduction. I give it here for logical completeness; its meaning and use, in the several variants outlined in \[\text{\S}\text{1.3}\] below, will be spelt out more clearly in Section 2.

Consider the following two contra-functors \(\mathcal{C}\) and \(\mathcal{F}\), defined over the category of topological spaces and continuous maps, and taking values in symmetric monoidal categories. On a topolog-

A FTFT is a symmetric monoidal transformation $Z$ from $\mathcal{C}$ to $\mathcal{F}$. Variants of this notion are obtained by changing the defining features of $\mathcal{C}$: we can require all circles in $\mathcal{C}(X)$ to be parametrised (1.3i) or not (1.3ii), allow Lefschetz fibrations as morphisms (1.3iii), and finally, impose the Deligne-Mumford stability condition on the surface fibrations (1.3iv).

1.2 Remark. The objects of $\mathcal{C}$ and $\mathcal{F}$ form sheaves over the site of topological spaces, but the morphisms do not. Morphisms of $\mathcal{F}$ are the cohomologies of a differential-graded version of $\mathcal{F}$, in which the objects are complexes of local coefficient systems over $X$ and the morphisms are cocycles, instead of cohomology classes. There is a similar enhancement of $\mathcal{C}$ to a sheaf of categories enriched over topological spaces: morphisms are classifying spaces of the homeomorphism groupoids of surface bundles. A (symmetric monoidal) natural transformation between these sheaves of categories is a possible definition of chain-level FTFT’s, and is closely related to Segal’s definition of topological conformal field theory $\mathbb{S}[\mathbb{C}]$. We will not use this more refined notion in the paper.

1.3 FTFT variants and their classification. We will consider several versions of family field theories; their classification increases in complexity. All four variants below are relevant to the eventual focus of interest, semi-simple cohomological field theories.

(i) In the simplest variant, the surfaces have parametrised boundaries. These theories are classified by a single, group-like class $\tilde{Z}^+$ in the $A$-valued cohomology of the stable mapping class group of surfaces (1.2.20). As a result of the Mumford conjecture $\mathbb{MW}$, such a class is necessarily of the form $\exp\{\sum_{j>0}a_j\kappa_j\}$, with arbitrary elements $a_j \in A$ coupled to the Morita-Mumford classes $\kappa_j$. The class $\tilde{Z}$ associated to a surface bundle acts diagonally on tensor monomials of the normalised canonical basis, as follows. if $a_j = \sum a_{ij}p_\alpha$, then the entry $\theta_i^{j/2}$ in the propagator matrix (1.3) which the Frobenius algebra assigns to a single surface is now multiplied by the factor $\exp\{\sum_{j>0}a_{ij}\kappa_j\}$. Note that, as $\chi = -\kappa_0$, we could also account for the $\theta_i$ by including in our sum a term $j = 0$, with $a_0 = \frac{1}{2}\log a$.

(ii) The second FTFT variant allows the boundaries to rotate freely. This introduces a new classification datum, a $\mathbb{C}$-linear map $E : A \to A[z] / (z)$ with $E \equiv \text{Id}$ (mod $z$). A free boundary theory is determined by $E$ and the earlier $\tilde{Z}^+$ as follows: twist the incoming states by $E^{-1}$ and the outputs by $E$, with $z$ specialised to the sign-changed Euler classes of the respective boundary circle bundles. (The awkward sign is reluctantly adopted here to avoid worse later; it stems from the sign mismatch between Euler and $\psi$ classes for inbound circles.) In-between, the fixed-boundary propagator of (i) applies.

1.4 Remark. The meaning of $E$ is obscured by our simplified, cohomological setting; it can be reverse-engineered from the context of open-closed and chain-level FTFTs. In the functorial setting (1.1), the local system $Z(S^1)$ with fibre $A$ over $\mathbb{CP}^\infty$ defined by the universal circle bundle is necessarily trivial, because $\mathbb{CP}^\infty$ is simply connected. Our $E$ supplies a second, ‘interesting’ trivialization of the same, $(-z) \in H^2(\mathbb{CP}^\infty)$ is the universal Euler class. In the chain-level version of the theory, $A$ is the homology of a space $X$ (or a chain complex) with
circle action, and the inputs and outputs at free boundaries belong naturally to the circle-equivariant cohomology, and $E$ is here to split the latter as $A \otimes \mathbb{C}[z]$. When the circle action on $X$ is trivialized for independent reasons, as happens with the Hochschild complex of a semi-simple category of boundary states, $E$ expresses the difference between the 'obvious' splitting and the one relevant the field theory. (See [KKP] for more discussion.)

(iii) Next in line are the Lefschetz theories, where surfaces are allowed to degenerate nodally into the Lefschetz fibrations of algebraic geometry. A nodal surface can be deformed uniquely to a smooth one; the cohomological nature keeps $Z$ unchanged under this deformation, so adding single nodal surfaces to the theory involves no new information. Things are different in a family: up to homotopy, the automorphism group of the "nodal propagator" $\subset$, an incoming-outgoing pair of crossing disks, is the product $T \times T$ of the two independent circle rotation groups. This provides a new datum $Z(\subset)$, an $\text{End}(A)$-valued formal series $D(-\omega_+,\omega_-)$ in the Euler classes $\omega_\pm$ of the two universal disk bundles.

Keeping only the diagonal rotation, we can deform the node $\subset$ into a rotating cylinder. Since $Z(=) = \text{Id}$ for a fixed cylinder, and it must remain a projector when the cylinder rotates, we conclude that $D = \text{Id} \text{ mod } (\omega_+ - \omega_-)$. In addition, we will find a symmetry constraint relating $D$ and $E$; see §4 for the precise relation. These are all the data and constraints: an involved, but explicit formula for the Lefschetz theory classes is given in §4.10 from $\tilde{Z}$, $E$ and $D$, as a kind of “time-ordered exponential integral” along the surfaces in any family.

(iv) Lastly, we are interested in Deligne-Mumford theories (DMT’s): these are Lefschetz theories involving only stable nodal surfaces, the Deligne-Mumford stable curves of algebraic geometry. Excluding cylinders and disks (which are unstable) brings about the need for two additional axioms, the nodal factorisation rules and vacuum axiom, which in a Lefschetz theory follow from the other axioms (See §§2.7–2.13).

The best-known DMT’s are the Cohomological Field theories à la Kontsevich and Manin, which satisfy $D = \text{Id}$. It is more customary to state their structure in terms of surfaces with inputs only, but that is a matter of convenience. In CohFT’s, the compatibility constraint on $E$ will become Givental’s symplectic constraint $E(z) \circ E^*(-z) = \text{Id}$. The main examples of CohFT’s are the Gromov-Witten cohomology theories of compact symplectic manifolds, which carry even more structure and constraints: see §§1.6–1.8 below.

Functors of the types (i), (ii) and (iii, iv) shall be denoted by $\tilde{Z}$, $Z$ and $\bar{Z}$, respectively. In the semi-simple case, we will find that (iii) and (iv) have the same classification.

(1.5) Idea of proof. For the first two types of FTFTs, the classification is an easy consequence of the Mumford conjecture, proved by Madsen and Weiss [MW]. (We will also use an older result of Looijenga’s on $\psi$-classes, [L].) In the limit of large genus surfaces, the sewing axiom becomes an equation in the complex cohomology of the stable mapping class group. The latter is a power series ring in the tautological classes (see §2.15), and we solve the equation there. Semi-simplicity of $A$ lets us retrieve the low-genus answer from high genus thanks to invertibility of the Euler class $\alpha$.

DMT’s require an additional argument. The universal families of stable nodal surfaces are classified by orbifolds with a normal-crossing stratification. The argument above determines the classes $Z$ on each stratum, but there could be ambiguities and obstructions in patching these classes together. However, the Euler classes of certain boundary strata involving large-genus surfaces are not zero-divisors in low-degree cohomology. This ensures the unique gluing of cohomology classes over suitably chosen strata. We find enough strata to cover all Deligne-Mumford
moduli orbifolds, and prove the unique patching of the \( Z \)-classes to a global class \( \overline{Z} \). This observation is the key contribution of the paper; the remainder falls in the “known to experts” category.

A more natural resolution of the gluing ambiguity involves the use of chains, instead of homology classes. This point of view, pioneered by Kontsevich in the context of homological mirror symmetry, fits naturally with the notion of open-closed field theories and their \( A_\infty \)-categories, and was successfully developed by Costello, leading in that setting to a beautiful classification result [C]. It also ties in nicely with the string topology example of Chas and Sullivan [Su]. From this angle, my result shows that the semi-simple case is considerably easier: open strings and chain-level structures are not needed.

(1.6) Example: Gromov-Witten theory. Here, the Frobenius algebra \( A \) is the quantum cohomology of a compact symplectic manifold \( X \), at some chosen point \( u \in H^{2\gamma}(X) \). To apply my classification, we must choose a point \( u \) where this ring is semi-simple (assuming such a point exists, which is a strong restriction on the manifold \( X \)). This \( u \) may be the generic point — which indeed may be the only option, if the series defining the quantum cup-product turns out to diverge. Semi-simplicity confines \( H^\bullet(X) \) to even degrees, because odd classes are necessarily nilpotent. (More is true: it turns out that semi-simplicity of the even part \( H^{2\gamma} \) of the quantum cohomology ring forces the vanishing of odd cohomology [HMT].)

The Gromov-Witten theory of \( X \) is constructed as follows. Denote by \( X^n_{g,\delta} \) the space of Kontsevich stable maps to \( X \) with genus \( g \), degree \( \delta \in H_2(X) \), and \( n \) marked points. We obtain maps

\[
GW^n_{g,\delta} : H^\bullet(X)^{\otimes n} \to H^\bullet(\overline{M}^n_g)
\]

to the cohomology of Deligne-Mumford spaces \( \overline{M}^n_g \) by pulling back classes on \( X \) via the evaluation map \( X^n_{g,\delta} \to X^n \), and then integrating along the forgetful map \( X^n_{g,\delta} \to \overline{M}^n_g \). This last step uses the virtual fundamental class of \( X^n_{g,\delta} \). The degree of each map \( GW_{g,\delta} \), in the natural grading on \( H^\bullet(X) \), is determined by the relative (virtual) dimension of moduli spaces:

\[
\deg GW_{g,\delta} = 2(\dim C M^n_g - \dim C X^n_{g,\delta}) = 2(g - 1) \dim C X - 2(c_1(X)\delta).
\]

Summing over homology degrees \( \delta \) yields a class

\[
GW^n_g := \sum \delta GW^n_{g,\delta} \cdot e^\delta,
\]

with coefficients in (a completion of) the group ring \( \mathbb{Q}[H_2] \), called the Novikov ring of \( X \). For a fixed \( u \in H^2(X; \mathbb{C}) \), sending \( e^\delta \mapsto \exp \langle u|\delta \rangle \) furnishes a ring homomorphism \( \mathbb{Q}[H_2] \to C \), and subject to convergence we get a \( u \)-dependent family of complete cohomology classes \( GW^n_{u,g} \). We recall in Section 2 below why this is equivalent to a family of DMT’s \( GW_u \), in the sense of [CG]. It is no accident that we obtain an entire family of DMT’s: in fact, a general deformation construction (Definition 1.7 below) produces a family parametrised by all \( u \) in (an open, or possibly formal subset of) \( H^{2\gamma}(X) \). Example 7.17 spells this out in the case of Gromov-Witten cohomology.

(1.8) Gromov-Witten cohomology constraints. The theories \( GW \) just described meet three additional constraints. They are specifically traced to the use of ordinary cohomology (for instance, they do not apply in this form to the exotic Gromov-Witten theories of Coates and Givental [CG]).

(i) The Cohomological Field Theory (CohFT) condition \( D = \text{Id} \);

(ii) The flat vacuum condition: inserting the identity \( 1 \in A \) as the first input in \( GW^n_u \) leads to the same class as the pull-back of \( GW^n_{u,-1} \) along the first forgetful morphism \( \overline{M}^n_g \to \overline{M}^{n-1}_g \),
(iii) Homogeneity of the family $GW_u$ under the Euler vector field $\xi$ on $H^{ev}(X)$. Along $H^2(X)$, $\xi$ is the constant vector field $c_1(X)$, but more generally

$$\xi_u := c_1(X) + \sum (i-1) u_{2i} \quad \text{at} \quad u = \sum u_{2i} \in \bigoplus_i H^{2i}(X).$$

In GW theory, condition (i) reflects the factorisation of the (virtual) fundamental class of $X^n_g \delta$ at the boundary of Deligne-Mumford space $\overline{G^2}$. Condition (ii) is the base change formula in the square of forgetful morphisms $\overline{M^n_g} \rightarrow \overline{M^{n-1}_g}$.

Readers may know that (ii) implies the flatness of the identity in the associated Frobenius manifold $[M, III]$; we will revisit this in §7.12. Finally, the homogeneity condition (iii), to be reviewed in more detail in §7.15 (see also [M, §I.3]), encodes the degrees (1.7) of the maps $GW^n_{g, \delta}$; see Example 7.17.

These constraints can be axiomatised in the setting of abstract DMT’s, and imposing them narrows down the classification of semi-simple theories. In CohFT’s, the operator $E$ of §1.3 ii satisfies $E(z) \circ E^*(z) = \Id$. The flat vacuum condition determines the $\tilde{Z}^+$ (of §1.3 ii) from $E$, as in Proposition 3.14 below. Confirming a prediction of Givental’s [G1], we will see that semi-simple CohFT’s are determined by their genus-zero part, the restriction to families of genus zero curves, save for an ambiguity related to the Hodge bundle. (See §8.6 for the precise statement.) Homogeneous theories (iii) have no such ambiguity, and we can then give an explicit reconstruction procedure from the Frobenius algebra $A$ alone and the homogeneity constraint, as we explain after reviewing the following example.

(1.9) Example: the Manin-Zograf conjecture. A simple illustration of the classification concerns the cohomological field theories of rank one: $\dim A = 1$, so $A$ is necessarily semi-simple. (These theories are the units for a natural tensor structure on the category of CohFT’s.) In this case, my classification affirms an older conjecture of Manin and Zograf [MZ]: $\tilde{Z}$ is an exponentiated linear combination of $\kappa$- and $\mu$-classes (the latter being the Chern character components of the Hodge bundle). The coefficients of the $\mu$-classes are easily related to those of $\log E(z)$ (§8.8), and this example illustrates nicely the ambiguities in reconstruction, as follows. Genus zero CohFT’s of rank one are described using $\kappa$-classes alone, [M, §III.6], because the Hodge bundle is trivial in genus zero, where the $\mu$-classes are therefore invisible. On the other hand, the flat vacuum CohFT’s are precisely those involving $\mu$-classes only (Proposition 8.10). Imposing all three conditions in §1.8 leads to $\tilde{Z}^+ = 1$ and $E = \Id$, leaving only one choice: the Frobenius algebra structure on $A$, determined by the single complex number $\theta(1)$.

(1.10) Reconstruction from genus zero. We now outline the reconstruction result of semi-simple homogeneous CohFTs from their underlying Frobenius algebra; full details are given in §7 and §8.

For any CohFT $\tilde{Z}$, a formal construction (Definition 7.1) produces a family $\tilde{Z}_u$ of CohFT’s, parametrised by $u \in U$, an open (or formal) neighbourhood of $0 \in A$. In Gromov-Witten theory, the $H^2$ part of this family was described in §1.6. The Frobenius algebra structure on $A$ varies in this family and leads to a so-called Frobenius manifold structure on $U$; see §7.3 below for a minimal discussion, or [D, M, LP] for an extensive one. A reconstruction theorem [M] determines the

---

5This is not altogether trivial, because the square is not quite Cartesian, due to the contractions of the universal curve. Again, it is conditioned by our use of ordinary cohomology.
genus-zero part of the CohFT from this Frobenius manifold. This fact has no known analogue for the higher-genus part of the theory, largely because the cohomologies \( H^\bullet(\overline{M}_g^\nu) \) are unknown.

However, for semi-simple theories, Givental [G1] conjectured a formula for the classifying datum \( E \) from genus-zero information. (The conjecture was framed in the slightly different setting of potentials, to be recalled in (1.12) below.) Specifically, he characterised \( E \) by a system of linear ODE’s on \( U \) (Dubrovin’s first structure connection), and from there, the homogeneity constraint (1.8) iii led to a unique solution. In the final sections of this paper, I verify the ODE’s for \( E \) in the abstract setting of CohFT’s (along with a companion ODE for \( \tilde{Z} \)) and conclude

**Theorem (1).** A semi-simple Cohomological Field theory satisfying the homogeneity constraint (1.8) iii is uniquely and explicitly reconstructible from genus zero data. For homogeneous theories with flat vacuum, the Euler vector field and the Frobenius algebra structure suffice for reconstruction.

Reconstruction takes the form of a recursion for the Taylor coefficients of \( E(z) = \sum_k E_k z^k \). Let us spell this out in Gromov-Witten cohomology, when \( A = H^\bullet(X) \) with the quantum cup-product at some point \( u \in H^{2\nu}(X) \), assumed to define a semi-simple multiplication. Denote by \( \mu \) the shifted degree operator \( (\deg - \dim(X))/2 \) on \( A \), and by \( (\xi_u \cdot ) \) that of quantum multiplication by the Euler vector \( \xi_u \) at \( u \). Then, the recursion

\[
[(\xi_u \cdot ), E_{k+1}] = (\mu + k) \cdot E_k
\]

determines \( E(z) \) uniquely form \( E_0 = \Id \). (See the proof of Theorem 8.15.) Thus, all Gromov-Witten classes \( GW_{g,\delta}^u \in H^\bullet(\overline{M}_g^\nu) \) are constructible from \( c_1(X) \) and the quantum multiplication operator \( (\xi_u \cdot ) \) at a single (semi-simple) point \( u \).

1.11 Remark. The series \( E(z) \) has an interpretation already flagged by Dubrovin [D]. Namely, the formal expression \( E(z) \cdot \exp(-\xi_u \cdot / z) \) gives the asymptotics at \( z=0 \) of solutions of an ODE with irregular (quadratic) singularities there (see (8.1). In the case of quantum cohomology, genuine solutions have unipotent, but non-trivial monodromy around 0. (The monodromy logarithm is the operator of classical multiplication by \( c_1(X) \), cf. [D], which does not vanish for manifolds with semi-simple quantum cohomology.) Because the asymptotic formula is single-valued, it cannot represent a genuine solution and so the series \( E(z) \) cannot converge. This makes the prospect of expressing \( E \) in terms of immediate geometric data of the symplectic manifold problematic; this last question is very much open.

(1.12) Potential of a DMT. Let \( \overline{Z}^n : A^{\otimes n} \to H^\bullet(\overline{M}_g^\nu) \) be the class associated by the DMT to the universal stable curve over the Deligne-Mumford space \( \overline{M}_g^\nu \). The primary invariants are the integrals of the \( Z \)’s on the \( \overline{M}_g^\nu \’s \). However, \( \overline{M}_g^\nu \) also carries the Euler classes \( \psi_1, \ldots, \psi_n \) of the cotangent lines to the universal curve at the marked points, and more information about \( Z \) is recovered by including \( \psi \’s \) before integration. The resulting numbers are encoded in a generating series, the (ancestor) potential, a function of a series \( x(z) = x_0 + x_1 z + \cdots \in A[[z]] \):

\[
A(x) = \exp \left\{ \sum_{g,n} h^{g-1} / n! \int_{\overline{M}_g^\nu} \overline{Z}^n_0 (x(\psi_1), \ldots, x(\psi_n)) \right\} ; \tag{1.13}
\]

the sum excludes the values \((g,n) = (0,0), (0,1), (0,2) \) and \((1,0) \) for which \( \overline{M} \) is not an orbifold. The series in (1.13) need not converge analytically, but converges at least formally as a power series in \( \{x, h, x^3/h\} \); so its exponential is well-defined in some space of \( \mathbb{C}((h)) \)-valued functions of \( x \).
1.14 Example. The trivial 1-dimensional theory has \( A = \mathbb{C} \) and \( \mathbb{Z} = 1 \) for all \( g \) and \( n \); the integrand is \( x(\psi_1) \land \cdots \land x(\psi_n) \) and \( \mathcal{A} \) is the \( t \)-function of Kontsevich and Witten.

More generally, any Frobenius algebra \( A \) can be coupled to the trivial cohomological field theory, by letting each \( \mathbb{Z}^p_g \) be the degree zero class specified by the surface of genus \( g \) with \( p \) inputs and \( q \) outputs. The potential is then expressible in terms of Kontsevich integrals.

The potentials \( A_u \) corresponding to the family \( GW_u \) of Gromov-Witten cohomology theories of a compact symplectic manifold are parametrised by \( u \in A = H^{cv}(X) \) — or in a formal version thereof, since the convergence question seems open in general. They are known as the ancestor GW potentials of \( X \). Their relation to the more customary descendent potential, defined using the \( \psi \)-classes and integration over the spaces \( X^g_{u,v} \), was determined\(^4\) by Kontsevich and Manin [KM2]. The ancestor-descendent relation was reframed by Givental in the setting of loop group actions, which we now recall.

(1.15) Givental’s loop group conjecture. For clarity, let us focus here on Cohomological Field Theories \( (D = \text{Id}) \), postponing discussion of the general case until §6. Let \( F((h)) \) be the space of \( C((h)) \)-valued polynomials on \( A[[z]] \); the potentials \( A \) in (1.13) live in some completion of this, such as the space of power series described in (1.12). (The choice of completion is not material, as our constructions and group actions will reduce to recursively defined operations on power series coefficients; see §6.) Define a symplectic form on the space \( A((z)) \) of formal Laurent series,

\[
\Omega(x, y) = \oint \beta(x(-z), y(z)) \, dz,
\]

using the Frobenius bilinear form \( \beta \). We view \( F((h)) \) as a Fock representation of the Heisenberg group \( H \) built on \( \{ A((z)), h\Omega \} \). The symplectic group \( Sp \) on \( A((z)) \) acts projectively on suitably chosen completions of \( F((h)) \) by the intertwining metaplectic representation. (The Lie algebra acts on \( F((h)) \), and the portion of the action which we will need is integrable on a space containing the potentials; see §6.) The Laurent series loop group \( GL(A)((z)) \) acts point-wise on \( A((z)) \). Consider the following subgroups of \( Sp \):

- \( Sp_L := Sp \cap GL(A)((z)) \), the symplectic part of \( GL(A)((z)) \);
- \( Sp^+_L := Sp \cap (\text{Id} + z \cdot \text{End}(A)[[z]]) \).

The term “symplectic loop group” is sometimes used for \( Sp_L \), but it really is the twisted form of the loop group of \( GL(A) \). The subgroup \( Sp^+_L \) contains the matrix series \( E(z) \) of §1.8. In [G1] [G3], Givental described the Kontsevich-Manin relation between descendent and ancestor potentials of Gromov-Witten theory in terms of the action of \( Sp_L \), without assuming semi-simplicity. In addition, he proposed (and proved, for toric Fano manifolds) a formula for the value of the GW ancestor potential \( A_u \) at a semi-simple point \( u \) of quantum cohomology. This was formulated in terms of the action \( Sp^+_L \), using ingredients which appear in Dubrovin’s isomonodromy description [D] of semi-simple Frobenius manifolds.

Call \( A^{DM} \) the subspace of those vectors in the cohomology \( \prod_{g,n} H^*(M^g_{\bar{g}}; (A^*)^n) \) of all Deligne-Mumford spaces which are invariant under the symmetric groups. A DM field theory \( \mathcal{Z} \) defines a vector in \( A^{DM} \), by restricting to surfaces with no output points. (Furthermore, if the nodal factorisation rule \( D \) is specified, \( \mathcal{Z} \) is in turn determined by this vector.) A distinguished vector \( I_A \in \prod H^0 \) represents the trivial CohFT based on \( A \). Let \( H^+, H^{++} \) denote the subspaces \( zA[[z]] \) and \( zA[[z]] \), respectively.

\(^4\)For clarification, recall that the descendent potential carries additional “calibration” information from the 1-point, or \( f \)-function, a choice of solution of the quantum ODE, which is not contained in our notion of a CohFT.
denote the translation by \( x \) the category of boundary states, versus deformation of the cyclic trace. \( \frac{\partial}{\partial x} \) which we will derive in §1.10. The interaction of these translations with the group \( \text{Sp} \) is rather complicated, given by a system of ODE’s which we will derive in §7.4. For instance, \( A \)-translations and \( H^+ \)-translations do not commute. In the setting of open-closed theories, translation along the Frobenius manifold and that by \( H^+ \) correspond to deformations of the TFT coming from independent sources: to wit, deformation of the category of boundary states, versus deformation of the cyclic trace.

\[ z^2 A[z] \] in the Heisenberg group \( H \), acting on \( F(h) \) by translation. In §6.18 we describe an action of \( \text{Sp}_L^+ \ltimes H^+ \) on \( A_{DM} \), which lifts the metaplectic and translation actions on potentials.\(^6\) Let \( T_x \) denote the translation by \( x \in H^+ \), \( (T_x F)(y) = F(y-x) \), and write \( T_z \) short for \( T_{z^1} \), for the unit \( 1 \in A \). My classification of DMT’s will imply the following.

**Theorem (2).** The CohFT’s with underlying semi-simple Frobenius algebra \( A \) constitute the \( \text{Sp}_L^+ \ltimes H^+ \)-orbit of the trivial theory \( I_A \). The theories with flat vacuum form the orbit of the subgroup \( T_z \circ \text{Sp}_L^+ \circ T_z^{-1} \).

The group element of \( \text{Sp}_L^+ \ltimes H^+ \) taking \( I_A \) to the theory with classification data \( \{ A, E(z), \tilde{\mathcal{Z}}^+ \} \) in \( \{1.3\} \) is \( E(z) \cdot \zeta \), with

\[
\zeta = z \exp \left( - \sum_{j>0} a_j z^j \right) - z \in H^+.
\]

This formula is closely related to the coordinate changes studied by Kabanov and Kimura.\(^5\)\(^\text{[KK]} \).

Note that this \( \zeta \) contains no \( z \)-linear term. Adding a term \( \zeta_1 z \), with \( \zeta_1 = \sum_i \zeta_{i1} P_i \) turns out to change the structure constants \( \theta_i \) of \( A \), scaling them by \( (1 + \zeta_{i1})^2 \) (Proposition 6.13). Every complex semi-simple Frobenius algebra can be obtained in this way from a sum of copies of the trivial one, \( C \) with \( \theta(1) = 1 \). It is tempting to say that all semi-simple CohFT of the same rank constitute a single \( \text{Sp}_L^+ \ltimes H^+ \)-orbit, but there is trouble when some \( \zeta_{i1} = -1 \): in other words, the action of the linear modes \( zA \in H^+ \) on \( A_{DM} \) has some singularities, so this re-formulation of the first part of Theorem 2 requires some care.

Translation by \( z \) is the *dilaton shift* of the literature; it encodes the expression of \( \zeta \) from \( E \) in flat vacuum theories. With a general vacuum vector \( v(z) \) (as in §3.12), we are instead looking at the set \( T_{v(z)} \circ \text{Sp}_L^+ \circ T_z^{-1} \). Even more generally, abandoning the CohFT condition to allow \( D \neq 1d \) enlarges the space of DM theories to the orbit of a larger subgroup \( \text{Sp}_L^+ \subset \text{Sp} \); this requires a slightly different setup and will be discussed in §6 where the proof of Theorem 2 is completed.

**1.16 Remark.** The translation action of \( H^+ \) on the space of CohFT’s has an analogue for the zero-modes \( A \in A[z] \): this leads to the Frobenius manifold mentioned in §1.10. The interaction of these translations with the group \( \text{Sp}_L^+ \ltimes H^+ \) is rather complicated, given by a system of ODE’s which we will derive in §7.4. For instance, \( A \)-translations and \( H^+ \)-translations do not commute.

2. Field Theories from universal classes

We now review the definitions of FTFTs from the perspective of classifying spaces of oriented surface bundles. In the process, we complete the definition of Cohomological Field theories; however, the list of axioms for more general DM theories is only completed in §4.5 after listing some explicit conditions.

We may switch between oriented topological, smooth, metric and Riemann surfaces as convenience dictates, because these structures are related by contractible spaces of choices (the spaces of Riemannian metrics, or metrics up to conformal equivalence), so their classifying spaces — the bases of universal surface bundles — are homotopy equivalent. Similarly, we can describe boundary circles more economically as follows.

\(^5\)A construction along similar lines was alluded to in \( \text{CKS} \).

\(^6\)I am grateful to V. Tonita for pointing this out.

\(^7\)Unfortunately, the author does not know of a written reference detailing this point of view.
(2.1) Points versus boundaries. Call a surface \((m, n)\)-pointed if it carries a set of \(m + n\) distinct unordered points, separated into \(m\) incoming and \(n\) outgoing ones. Given a vector space \(A\), the base \(X\) of an \((m, n)\)-pointed surface bundle \(\Sigma_X\) carries local systems \(A^{(m)}, A^{(n)}\) with fibres \(A^\otimes m, A^\otimes n\), permuted by the monodromy in the base. Removing open disks centred at the special points shows that, up to a contractible space of choices, points contain the same information as un-parametrised boundary circles. Moreover, since \(\text{Diff}_+(S^1)\) is homotopy equivalent to its subgroup of rigid rotations, we may capture the parametrisation information, again up to a contractible space of choices, by specifying unit tangent vectors, or tangent rays. More precisely, there is a torus bundle \(\tilde{X} \rightarrow X\) with fibre \(T^m \times T^n\), the product of unit tangent spaces at the special points.\(^8\) Up to homotopy, \(\tilde{X}\) parametrises the surfaces in the family \(\Sigma_X\), together with all parametrisations of their boundary circles.

(2.2) FTFT’s reviewed. Let us recall the functorial definition of FTFT’s, and then convert the data to a collection of cohomology classes on the classifying spaces of surface bundles. This is especially necessary for DMT’s, where we must formulate the nodal factorisation and vacuum axioms mentioned in §1.3.iv.

- A family TFT with fixed boundaries and coefficients in \(A\) assigns to each family \(\Sigma_X \hookrightarrow X\) of closed oriented \((m, n)\)-pointed surfaces a class

\[
\tilde{Z}(\Sigma_X) \in H^\bullet(\tilde{X}; \text{Hom}(A^{(m)}, A^{(n)})).
\]

This must be functorial in \(\tilde{X}\) and subject to the condition that sewing together any collection of incoming-outgoing boundary pairs gives the corresponding composition of linear maps.

- In a free boundary FTFT, the class \(Z(\Sigma_X)\) lives in \(H^\bullet(X; \text{Hom}(A^{(m)}, A^{(n)}))\), is functorial in \(X\), and the sewing condition must hold for any given identification over \(X\) of an incoming-outgoing boundary pair.

- A Lefschetz FTFT assigns such \(\tilde{Z}\)’s functorially to (chiral) Lefschetz fibrations of closed oriented pointed surfaces.

- Finally, a Deligne-Mumford FTFT is a Lefschetz FTFT for stable surfaces, satisfying a nodal factorisation rule and a vacuum axiom. We describe these in §§2.9–2.13 below, after introducing the universal classes \(p_\mathcal{Z}^q\).

2.3 Remark. (i) Single surfaces define a commutative Frobenius algebra structure on \(A\).

(ii) “Sewing” of pointed surfaces in a family is well-defined, up to homotopy, from an identification of tangent rays at the matched points.

(iii) As usual, nodes and special points must avoid each other.

(iv) Stability of surfaces leads to an orbifold description of the moduli of nodal surfaces, but this does not play a role here. More important is the connection with Gromov-Witten theory, which forces us into the setting of Deligne-Mumford spaces and cohomological field theories. The classification of semi-simple theories remains unchanged for Lefschetz theories, which allow pre-stable curves.

(2.4) Reformulation using universal classes. Let \(\mathcal{M}^p_\mathbb{S}\) denote the classifying space of the universal surface with \(p + q\) distinct ordered points, and denote by \(\mathcal{M}^p_\mathbb{S}\) (or alternatively, \(\mathcal{M}^p_\mathbb{S,p}\), as is common in the literature) the principal torus bundle defined by all choices of tangent rays at those points.

\(^8\)\(\tilde{X}\) is a principal bundle only if there is no monodromy, that is, if the special points can be ordered over \(X\).
Functoriality reduces a fixed-boundary FTFT to the specification of universal classes

\[ q\mathcal{Z}_g^p \in H_{\mathfrak{g} \times \mathfrak{g}}^q(\mathcal{M}_g^p; \text{Hom}(A^{\otimes p}; A^{\otimes q})) , \]

where the symmetric groups \( S_p, S_q \) act on \( q\mathcal{M}_g^p \) by permuting marked points and simultaneously on \( A^{\otimes p,q} \) by permuting the factors. Over \( C \), equivariance under finite groups simply means invariance. With free boundary theories, we obtain classes \( \mathcal{Z}_g^p \) over \( \mathcal{M}_g^p \), and in the case of DM theories, \( \mathcal{Z}_g^p \) over the Deligne-Mumford compactifications \( \mathcal{M}_g^p \).

The classifying space for the universal Lefschetz fibration has model which is perhaps less familiar, as a finite-dimensional complex algebraic Artin stack \( \mathcal{A}_g^p \) of infinite type, classifying nodal curves with arbitrary chains and trees of rational curves. This has an infinite descending normal-crossing stratification, reflecting the unlimited bubbling that can occur in families.

(2.5) Sewing conditions. Sewing two specified boundary components together defines maps, uniquely up to homotopy (with \( x = x' + x'' \) for \( x = g, p, q \))

\[ s : q\mathcal{M}_g^{p'} \times q''\mathcal{M}_g^{p''} \to q^{-1}\mathcal{M}_g^{p-1} , \]

and similar maps where several pairs of boundaries are simultaneously identified. The FTFT sewing condition is

\[ s^* \left( q^{-1}\mathcal{Z}_g^{p-1} \right) = q'\mathcal{Z}_g^{p'} \circ q''\mathcal{Z}_g^{p''} , \]

with composition of the appropriate entries. Self-sewing in a family of single surfaces is also permitted, but the result could be re-expressed by means of sewing on elbows.

Free boundary FTFT’s are different, in that the sewing maps (2.6) does not descend to the base moduli spaces \( M, M', M'' \) for surfaces with free boundaries: sewing requires an identification of the boundaries. A natural circle bundle \( \pi : \partial N \to M' \times M'' \) parametrises the possible identifications. This \( \partial N \) is also (the pull-back to \( M' \times M'' \)) of the circular neighbourhood of a divisorial boundary stratum in \( M \), image of \( \partial M \times \partial M \) under a boundary map (see (2.10) below). Functoriality stipulates that, after contracting out the \( A, A^* \) factors of the two sewing indices, the pull-back \( \pi^*(q'\mathcal{Z}_g^{p'} \times q''\mathcal{Z}_g^{p''}) \) agrees with the restriction of the class \( q^{-1}\mathcal{Z}_g^{p-1} \) to \( \partial N \).

(2.7) Nodal factorisation in Lefschetz theories. Every Lefschetz theory carries a nodal factorisation rule, which describes \( \mathcal{Z}(\Sigma) \), for a nodal surface family \( \Sigma \), in terms of the normalised family \( \tilde{\Sigma} \). This rule is a consequence of the sewing condition: cutting out the pair of crossing disks near a chosen node expresses \( \mathcal{Z}(\Sigma) \) as a contraction of \( \mathcal{Z}(\tilde{\Sigma}) \) with the crossing disk family. Functoriality describes the latter by a universal formula in the Euler classes of the two tangent spaces at the node. Thus, for of a pair of marked points of opposite type, the relevant operator is the nodal propagator \( Z(\infty) = D(-\omega_+, \omega_-) \in \text{End}(A)[[\omega_{\pm}]] \) mentioned in (1.3). Similarly, the effect of attaching two output points of \( \tilde{\Sigma} \) into a node is controlled by a bilinear form \( B \) on \( A \) with values in \( k[[\omega_{\pm}]] \), while inputs involve a co-form \( C \in (A \otimes A)[[\omega_{\pm}]] \).

The tensors \( B, C \) and \( D \) are not independent: each of them determines the other two, by a formal game with connecting elbows. In addition, \( B \) and \( C \) are symmetric under a switch of the two disks, and this also translates into a symmetry constraint on \( D \). We will list the explicit formulae in (4.1) below.

2.8 Remark. When lifted from \( M' \times M'' \) to \( \partial N \), the nodal factorisation law becomes precisely the smooth surface sewing axiom, by virtue of the identity \( D(-\omega, \omega) = 1d \).
(2.9) Deligne-Mumford factorisation rules. The nodal factorisation condition can also be formulated in a DMT, but as the pair of crossing disks is an unstable surface, the cutting argument used to derive it in Lefschetz theories is no longer valid. We therefore adopt these rules as an additional DMT axiom, and now spell them out.

Universally on Deligne-Mumford spaces, attaching marked points define the following boundaryary morphisms, differing only in the type of the attaching points:

\[ b^D_2 : q^{-1} M^n_g × q^{-1} M^n_g → q^{-1} M^{n-1}_g, \quad b^D_1 : q^{-1} M^n_g → q^{-1} M^{n-1}_{g+1}, \]
\[ b^C_2 : q^{-1} M^n_g × q^{-1} M^n_g → q^{-2} M^n_g, \quad b^C_1 : q^{-1} M^n_g → q^{-2} M^n_{g+1}, \]
\[ b^B_2 : q^{-1} M^n_g × q^{-1} M^n_g → q^{-2} M^n_g, \quad b^B_1 : q^{-1} M^n_g → q^{-2} M^n_{g+1}. \]  

(There are corresponding maps for the Artin classifying stacks \( q^{-1} \overline{A}^p \) of Lefschetz fibrations.)

DMT’s are required to satisfy a factorisation rule under each of these maps, involving contraction with specified tensors \( B, C \) and \( D \). Thus, for \( b^B_2 : M^n_g × M^n_g → M^n_g \), we require

\[ (b^B_2)^* Z^n_g = B(\omega', \omega'') \left( Z'^n_g × Z''^n_g \right), \]

where \( \omega', \omega'' \) are the two Euler classes at the node; similarly for the other maps, with \( D(-\omega', \omega'') \) and \( C(-\omega', -\omega'') \), respectively. (The choice of signs here is adapted to our later use of \( \psi \)-classes, in lieu of Euler classes.)

The tensors \( B, C, D \) should satisfy the consistency constraints already mentioned (and spelt out in §4.1), which are guaranteed in a Lefschetz theory. As it turns out, these constraints are also guaranteed in a semi-simple DM theory; so we could omit them from the axiom in this case. Refer to §4.5 below for more detail.

2.12 Remark. In the familiar case of CohFT’s, we require that \( D = \text{Id}, B = \beta, \) and \( C \) is the inverse co-form. Factorisation rules with interesting \( B \) appear in generalised-cohomology Gromov-Witten theory [CG] (although the dependence on \( \omega', \omega'' \) has a very special form there, \( D \) is scalar).

(2.13) Vacuum axiom. In a Lefschetz theory, a distinguished vector \( v(\zeta) ∈ A[[\zeta]] \), defined by the universal sphere with a single output, has the following property: for any Lefschetz fibration \( \Sigma_X \) with \( n > 0 \) input points and the associated family \( \Sigma'_X \) which ignores the first input, we have

\[ Z(\Sigma_X)(v(\omega_1), x_2, \ldots, x_n) = Z(\Sigma'_X)(x_2, \ldots, x_n), \]

where \( \omega_1 \) is the the first input Euler class. This is the smooth surface sewing rule at work.

Again, this story fails in a DMT, so our final DMT axiom is the specification of a “vacuum” vector \( v(\zeta) \), which must satisfy the following condition in the case of a CohFT. Let \( \phi : \overline{M}^n_g → \overline{M}^{n-1}_g \) be the morphism of Deligne-Mumford spaces induced by forgetting the first marked point. Then,

\[ Z^{n+1}(\zeta v(\omega_1), x_2, \ldots, x_n) = \phi^* Z^n_g (x_2, \ldots, x_n). \]

The vacuum condition is more complicated in general DMT’s with \( D ≠ \text{Id} \), where it gets corrected by boundary terms. The reason is that \( \phi \) does not classify the point-forgetting map on nodal surfaces: the universal curve over \( \overline{M}^{n-1}_g \) lifts to a contraction of the one over \( \overline{M}^n_g \). This contraction turns out to be inoffensive for \( Z \) in a CohFT, but not so in general. We will not use the vacuum in general DMT’s, so will not spell out the correction terms.

Later, we will concentrate on the special class of CohFT’s with flat vacuum, when \( v = 1 \).
The sewing maps \((2.6)\) assemble to a **PROP structure** on the spaces \(\hat{M}_g^p\), which carries over to their homology. In this language, an FTFT is equivalent to an algebra over the homology PROP. Similarly, the Deligne-Mumford boundary morphisms \((2.10)\) give a PROP structure on \(H_*(\bar{M}_g^m)\). In this case, self-sewing of single surfaces enhances this to a **wheeled PROP** (a notion introduced in [MMS]). Cohomological field theories are algebras over the associated homology PROP of DM spaces, but to capture the full CohFT structure, we must add a cyclic structure, permuting inputs and outputs. (We lost the ability to switch inputs and outputs by means of elbows.) DMT’s with general \(D\) are algebras over a twisted form of the DM homology PROP. Free boundary FTFT’s do not fit into PROP language, for the reason explained in \((2.5)\).

(2.15) **Tautological classes.** The classification will describe the various field theories in terms of the **tautological classes** on the moduli of surfaces. We briefly recall the generating tautological classes on \(\bar{M}_g^m\), those on \(M_g^m, \hat{M}_g^m\) are obtained by restriction. Let \(\varphi : \bar{M}_g^{n+1} \to \bar{M}_g^n\) be the map forgetting the last marked point. The marked points define \(n\) sections \(\sigma_i\) of \(\varphi\), with smooth divisors \([\sigma_i]\) as their images. Let \(T_\varphi^n\) be the relative cotangent complex of \(\varphi\) and define

\[
\psi_i := \sigma_i^* c_1(T_\varphi^n), \quad \kappa_j = \varphi_*(\psi_{n+1}^{j+1}),
\]

(where \(\psi_{n+1}^{j+1}\) on \(\bar{M}_g^{n+1}\) is defined using \(\sigma_{n+1}\) and \(\bar{M}_g^{n+2}\)). These classes satisfy the relations

\[
[\sigma_i] \cdot \psi_i = [\sigma_i] \cdot \psi_{n+1} = 0,
\]

\[
\psi_i^j = \varphi^* \psi_{i+1}^j + \sigma_*(\psi_{i+1}^{j-1}), \quad \kappa_j = \varphi^* \kappa_{j+1} + \psi_{n+1}^j.
\]

The correction term \(\sigma_*(\psi_{i+1}^{j-1})\) in the first relation is only visible on \(\bar{M}_g^n\), but the one for \(\kappa\) also appears on \(M_g^n\). Thus defined, the \(\kappa_j\) are primitive: that is, under the boundary maps \((2.10)\),

\[
b_2^* (\kappa_j) = \kappa_j + \kappa_j', \quad b_1^* (\kappa_j) = \kappa_j.
\]

Additional tautological classes on Deligne-Mumford spaces arise by the recursive pushing forward of polynomials in the \(\kappa\)– and \(\psi\)–classes from boundary divisors.

(2.16) **The stability theorems.** The key to the classification are two stability theorems, due to Harer [H] (later improved by Ivanov [I]), and to Madsen and Weiss [MW], respectively. For the first theorem, let \(M^n_{g,m}\) be the base family of the universal surface of genus \(g\) with \(m + n\) ordered points, equipped with unit tangent vectors at the first \(m\) special points.

2.17 **Theorem** (“Harer stability” [H, I]). The maps \(M^n_{g,m} \to M^n_{g,m-1}\) and \(M^n_{g,m} \to M^n_{g+1,m}\), defined (up to homotopy) by sewing in a disk, respectively by sewing on a two-holed torus, induce homology isomorphisms in degree less than \((g - 1)/2\).

An important consequence describes the homological effect of adding marked points:

2.18 **Corollary** (Looijenga, [L]). In the stable range of total degree \(< (g - 1)/2\), we have

\[
H^*(M^n_g; \mathbb{Q}) \cong H^*(M^n_{g}; \mathbb{Q})[\psi_1, \ldots, \psi_n].
\]

We reproduce the easy proof. The circle bundle \(\pi : M_{g,1} \to M_1^n\) presents \(H^*(M_{g,1}; \mathbb{Q})\) as the cohomology of the differential graded algebra \(\{H^*(M_1^n; \mathbb{Q})[\eta], d\}\), with \(\deg \eta = 1\) and \(d \eta = \psi_1\). Now, thanks to Harer, a right inverse of \(\pi^* : H^*(M_1^n; \mathbb{Q}) \to H^*(M_{g,1}; \mathbb{Q})\) in the stable range is
provided by the forgetful pull-back $H^\bullet(M_g; \mathbb{Q}) \to H^\bullet(M^1_g; \mathbb{Q})$. Therefore, $\pi^*$ is onto, in the stable range. But then, $\psi_1$ is not a zero-divisor in that range: if $\psi_1 x = 0$, then $\eta x$ is a class which is not in the image of $\pi^*$. From the DGA presentation, we conclude that, in the stable range,

$$H^\bullet(M_g; \mathbb{Q}) \cong H^\bullet(M^1_g; \mathbb{Q})/(\psi_1)$$

so that $H^\bullet(M_g)[\psi_1]$ surjects and injects to $H^\bullet(M^1_g)$, giving the corollary for $n = 1$. Repeat for the other $\psi$.

2.19 Theorem ("Mumford conjecture" [MW]). In the stable range, we have

$$H^\bullet(M_g; \mathbb{Q}) = \mathbb{Q}[\kappa_j], \quad j = 1, 2, \ldots.$$ 

(2.20) Primitive and group-like classes. We conclude by spelling out the role of $\kappa$-classes in our context. Genus-stabilisation $M^3_{g,m} \to M^3_{g+1,m}$ defines a limiting homotopy type $M^3_{\infty,m}$. This agrees with the classifying space of the stable mapping class group $\Gamma^3_{\infty,m}$ of a surface with $m$ fixed and $n$ free boundaries. Harer stability makes the fixed boundaries invisible in the homology of the classifying space, while the homological effect of free boundaries is described by Corollary 2.18, so we focus on $M^3_{\infty,1}$. Sewing two surfaces, with one fixed boundary each, into a fixed pair of pants defines a map

$$m : M^3_{g,1} \times M^3_{h,1} \to M^3_{g+h,1}, \quad (2.21)$$

which gives a homotopy-commutative monoidal structure on $\coprod_g M^3_{g,1}$ and, in the limit, on $M^3_{\infty,1}$. The latter becomes a group-like topological monoid, and its cohomology $H^\bullet(M^3_{\infty,1}; \mathbb{Q})$ acquires a (commutative and co-commutative) Hopf algebra structure. By the Milnor-Moore theorem, this must be the free power series algebra in the primitive cohomology classes, that is, the classes $x$ satisfying $m^*(x) = x \otimes 1 + 1 \otimes x$. The $\kappa$’s do have that property (2.15), so the Madsen-Weiss theorem has the following important consequence.

2.22 Corollary. All primitive rational cohomology classes on $M^3_{\infty,1}$ are linear combinations of the $\kappa$’s.

2.23 Remark. Corollary 2.22 is equivalent to the rational Mumford conjecture. Madsen and Weiss prove an integral version, identifying the homotopy type of the group completion of the topological monoid $\coprod_g M^3_g$ with the infinite loop space $\Omega^\infty \mathbb{C}P^\infty_1$ of the Madsen-Tillmann spectrum [MT]. An integral, in fact spectrum version of Looijenga’s theorem was found earlier by Bödigheimer and Tillmann [BT].

Another important notion is that of a group-like class $X \in H^\bullet(M^3_{\infty,1}; \mathbb{Q})$, a non-zero class for which $m^*X = X \otimes X$. It is easy to see that the group-like classes are precisely those of the form $\exp(x)$, with primitive $x$.

3. Smooth surface theories

Armed with the boundary maps between the $M_g$ and the tautological classes, we proceed to classify TFT’s of the first two types, involving smooth surfaces with parametrised or with free boundaries. This might be the place to confess to a minor gap in the classification: the definitions do not seem to determine the value of the universal $Z^\text{g}$ without marked points, although a valid choice can always be made from my data. For free boundaries, the same ambiguity applies to $Z^0_1$. This last, genus one problem persists for Lefschetz theories, but not for DMT’s, since $M^3_1$ does not exist.
(3.1) Fixed boundary theories. With \( g = g' + g'' \), consider the effect on \( \tilde{Z} \)-classes of the operation of sewing onto the general surface of genus \( g' \) a fixed 2-holed surface of genus \( g'' \):

\[
1\tilde{Z}_g = \alpha^{g''} \cdot 1\tilde{Z}_{g'} \quad \text{on } 1\tilde{M}_{g'}
\]

where \( \alpha \in A \) is the Euler class of \( \{1,4\} \) and the left-hand side has been restricted to \( 1\tilde{M}_{g'} \). When \( \alpha \) is invertible, it follows that \( \alpha^{-g} \cdot 1\tilde{Z}_g \) stabilises, as \( g \to \infty \), to a class \( \tilde{Z}^+ \in H^* (M_{g\infty}; A) \). The sewing axiom, applied to the multiplication map \( (2.21) \) and corrected by the same power \( \alpha^{-(g+h)} \) on both sides, implies that \( \tilde{Z}^+ \) is group-like. It follows that

\[
\tilde{Z}^+ = \exp \left\{ \sum_{j>0} a_j \kappa_j \right\}, \quad \text{for certain } a_j \in A.
\]

We have used the superscript "+" to flag the lack of a \( \kappa_0 \)-contribution, present in the classes \( \tilde{Z} \).

3.2 Remark. Integrially, \( \tilde{Z}^+ \) would be a group-like class in the \( A \)-valued cohomology of \( \Omega^\infty \mathbb{C}P^\infty \). Additively, there exist additional primitive classes, the Dyer-Lashof descendants of the \( \kappa' \)'s \( \{11\} \); quite likely, analogous group-like classes exist as well. The new classes could perhaps be ruled out by imposing the FTFT axioms at chain level.

Clearly, \( 1\tilde{Z}_g \) is the restriction to \( 1\tilde{M}_g \) of \( \alpha^g \cdot \tilde{Z}^+ \); let us find \( m\tilde{Z}_g^n \). Sewing on large genus surfaces to one boundary allows us to assume \( g \) is large, without loss of information. Map now \( 1\tilde{M}_g \) to \( m\tilde{M}_g^n \) by sewing on to the universal surface a fixed sphere with \( n + 1 \) inputs and \( m \) outputs. This sphere determines the map \( mS_{n+1} : A^\otimes(n+1) \to A^\otimes m \), multiplication to \( A \) followed by the \( m \)th co-power \( A \to A^\otimes m \). Thanks to Harer, the map \( 1\tilde{M}_g \to m\tilde{M}_g^n \) is a homology equivalence in a range of degrees, so we detect \( m\tilde{Z}_g^n \) by pulling back to \( 1\tilde{M}_g \), where we see the result of feeding \( 1\tilde{Z}_g \) as one of the inputs in \( mS_{n+1} \). Thus,

\[
m\tilde{Z}_g^n = mS_1 (\alpha^g \cdot \tilde{Z}^+ \cdot 1S_n)
\]

and we conclude the desired classification, with freely chosen elements \( a_j = \sum_i a_{ij} P_i \) of \( A \):

3.3 Proposition (Fixed-boundary FTFTs). If \( m, n \) do not both vanish, then the matrix for \( m\tilde{Z}_g^n \) is diagonal in the tensor monomials of the normalised canonical basis. All entries are null, save for those relating \( p_i^\otimes n \) to \( p_i^\otimes m \); these have the form

\[
\theta_i^{g/2} \cdot \exp \left\{ \sum_{j>0} a_{ij} \kappa_j \right\},
\]

for fixed complex numbers \( a_{ij} \). Each \( p_i^0 \) stands for \( 1 \in \mathbb{C} \), if \( m \) or \( n \) (but not both) vanish.

Finally, every choice of numbers \( \{a_{ij}\} \) gives rise to an FTFT by this rule, if, in addition, we define \( \tilde{Z}_g \) defined by summing the above expression over \( i \).

3.4 Remark. The argument fails when \( m = n = 0 \), and the axioms don't seem to determine \( \tilde{Z}_g \) for closed surfaces, except in the stable range of homology, where we can detect it by lifting to \( M_{g,1} \).

(3.5) Free boundaries and \( E \). Restricting to surfaces with fixed boundaries determines a \( \tilde{Z} \) as above. Let now \( 1Z_{g,1} \) denote the lift of \( 1Z_1 \) to \( 1M_{g,1} \). Recall that the latter is a circle bundle over \( 1M_{1} \) and classifies surfaces with a fixed incoming boundary and a free outgoing one. Sewing a fixed surface of genus \( g'' \) into the fixed incoming boundary of the general surface over \( 1M_{g',1} \) tells us that

\[
1Z_{g,1} \in H^* \left( 1M_{g,1}; \text{End}(A) \right) \quad \text{restricts to} \quad 1Z_{g',1} \circ (\alpha^g \cdot .) \in H^* \left( 1M_{g',1}; \text{End}(A) \right),
\]
and the Frobenius trace \( \theta \) large as needed, and lift (3.9) to freely generated over \( \partial N \). Minding that \( \kappa \) result is co-multiplied out to \( A \otimes \) at the node. On the total space \( \partial N \) we have

\[
\partial N = 1 M_{g',1} \times 1 M_{g''}
\]

where the circle \( T \) simultaneously rotates the two boundaries being sewn together. The sewn surface is classified by a map \( \partial N \to 1 M_{g} \). Pull-backs to \( \partial N \) being understood, we have

\[
1 Z^1_g \circ 1 Z^1_{g''} = 1 Z^1_g.
\]

In a moment, we will proceed by fixing the incoming or outgoing boundaries, as convenient. In any case, \( \partial N \to 1 M_{g'}^1 \times 1 M_{g''}^1 \) is a circle bundle with Chern class \( -(\psi' + \psi'') \), using the \( \psi \)-classes at the node. On the total space \( \partial N \), \( \psi'' = -\psi' \), the common value representing the Euler class of the sewing circle. The Leray sequence and our knowledge of stable cohomology show that \( H^*(\partial N) \), below degree \( (g' - 1)/2 \), is freely generated over \( H^*(1 M_{g}^1) \) by the \( \kappa'' \). Similarly, it is freely generated over \( H^*(1 M_{g'}^1) \) by the \( \kappa' \), below degree \( (g'' - 1)/2 \). Let now both \( g' \) and \( g'' \) be as large as needed, and lift (3.9) to \( 1 M_{g,1} \); we obtain from (3.6) and (3.7), after cancelling powers of \( \alpha \):

\[
1 Z^{+1}(\kappa', \psi') \circ 1 Z^+(\kappa'', -\psi') = \bar{Z}^+(\kappa).
\]

Using the relation \( \kappa = \kappa' + \kappa'' \) and the algebraic independence of \( \kappa', \kappa'', \psi' \), we obtain the second formula in the lemma by setting \( \kappa'' = 0 \), and from there, the first formula by setting \( \kappa' = 0 \).

For the final and more general formula, return to (3.9) and let only \( g'' \) be large. Fixing the incoming circle leads to

\[
1 Z^1_{g''} = 1 Z_{g,1} \circ (1 Z^1_{g''})^{-1}
\]

with both factors on the right now known. Minding that \( \psi' = -\psi'' \) gives the formula.

3.11 Proposition (Free boundary FTFTs). For \( (g, m, n) \neq (1, 0, 0) \), we obtain "\( Z^m_g \) as follows: each input is transformed by \( E^{-1}(\psi) \), with the respective \( \psi \) class; the product of these is multiplied by \( \alpha^\delta \cdot \bar{Z}^+(\kappa) \), the result is co-multiplied out to \( A^\otimes n \), where each factor is transformed by the respective \( E(\psi) \). The unit \( 1 \) substitutes for the empty input, and the Frobenius trace \( \theta \) is applied if there is no output.
Proof. If at least one marked point is present, we can repeat the final argument in the proof of the previous lemma: for each output or input point, compose with a large-genus \(1Z^1_G\) or \(1Z_{G,1}\), respectively, to arrive at the known operator \(m_{Z_{G,n}}\). Since \(1Z^1_G\) is invertible and known, we are done. The case \(m = n = 0\) is handled as follows. Pull back \(Z_g\) along the forgetful map \(\varphi : M^1_g \to M_g\). The universal closed surface bundle splits, when lifted to \(M^1_g\), into an open surface and a disk sewed along their common (moving) boundary, and we can compute \(\varphi^* Z_g\) from the known formulae to get the desired

\[
\varphi^* Z_g = \theta (a^\delta \cdot Z^+(\varphi^* \kappa)),
\]

having used the primitivity of \(\kappa\)-classes. (More precisely, the \(\kappa\)-classes of the unpointed disk precisely undo the \(\varphi^*\)-correction of \(\|2.15\) see the discussion of the vacuum below, if more help is needed.) Now, when \(g \neq 1\), the map \(\varphi^*\) is split in rational cohomology by integration against the \(\psi\)-class down to \(M_g\), so we recover \(Z_g\) as hoped. \(\Box\)

(3.12) The vacuum. The universal disk with outgoing boundary defines the vacuum vector \(v(z) \in A[z]\), where we take \(z\) to be the opposite of the boundary Euler class (and of the \(\psi_{out}\) at the output, in the pointed sphere model). Let \(\varphi : pM^2_g \to pM^2_g\) be the map which forgets the first input; capping the first boundary in the universal surface with a disk shows that

\[
pZ_g^{g+1}(v(\psi_1), \ldots) = \varphi^*(pZ^2_g)(\ldots).
\]

(3.13)

Fixing the disk shows that \(v \equiv 1\) (mod \(z\)). We say that that \(Z\) has flat vacuum if in fact \(v = 1\).

3.14 Proposition. In the semi-simple free boundary FTFT build from data \(\{E, Z\}\), the vacuum is given by

\[
v(z) = E(z) \left( \exp \left\{ - \sum_{j > 0} a_j z^j \right\} \right),
\]

and \(Z\) has a flat vacuum precisely when \(\exp \left\{ - \sum_{j > 0} a_j z^j \right\} = E(z)^{-1}(1)\).

Proof. This is the formula in Lemma \(\|3.8\) together with the equality \(\kappa_j = -(-\psi_{out})^j \) on \(1M_0\). One way to see the latter is to use the correction formula in \(\|2.15\) for the pull-back to \(1M_0\), on which space all \(\kappa\)’s vanish, and the two \(\psi\)-classes are opposite. \(\Box\)

3.15 Remark. Unlike Harer stability and Looijenga’s result on \(\psi\)-classes, the Mumford conjecture has not seriously been used: in the discussion so far, the \(\kappa\)’s could have been replaced by the primitives in the Hopf algebra \(H^*(M_{\infty,1})\). However, later on, unknown primitive classes would break the argument for reconstruction from genus 0.

(3.16) Comment on stable surfaces Deligne-Mumford theories, which we aim to classify, can be restricted to families of smooth curves and they define free boundary FTFTs for stable surfaces only; so we must track the role of stability in the arguments of this section. The discussion applies with two exceptions: the construction of the vacuum, and the determination of \(Z^0_g\) (in the proof of Proposition \(\|3.11\)). In a general DMT, the vacuum (specified in an extra axiom) can be used to determine \(Z^0_g\). In semi-simple theories, we can detect \(v\) — and establish its existence — by going to large-genus surfaces in the contraction formula \(\|3.13\); invertibility of \(\hat{Z}^+\) allows us to replicate the conclusion of Proposition \(\|3.14\) This helps explain why there will be no distinction later between classification of semi-simple Lefschetz and DM theories.
4. Lefschetz and DM theories: construction

Restricting a Lefschetz theory to families of smooth surfaces gives a free-boundary theory. In the semi-simple case, this is parametrised by

(i) the Frobenius algebra $A$,
(ii) the class $Z^+ = \exp \{ \sum_{j>0} a_j k_j \}$ of §3.1
(iii) the formal Taylor series $E(z) = \text{Id} + zE_1 + z^2 E_2 + \cdots \in \text{End}(A)[[z]]$ of §3.5

New information arises from the universal pairs of crossing disks, in the form of

(iv) the “nodal propagator” $Z(\infty) = D(-\omega_+, \omega_-)$ and the companion quadratic tensors $B, C$ of §2.7 all of which are formal series in the Euler classes of the two disks.

Ingredients (iii) and (iv) are subject to consistency constraints. In particular, we will see that $B, C$ and $D$ determine each other in any Lefschetz theory, whether or not $A$ is semi-simple. After spelling out the constraints on $B, C, D$ — and the compatibility condition with $E$, in the semi-simple case — we will construct a Lefschetz theory from those data. Restriction to stable curves gives a DMT. Unlike the proof of uniqueness in the next section, the construction does not require semi-simplicity of $A$.

We will switch henceforth from the Euler classes $\omega$ of boundary circles to the $\psi$-classes at the node, and in doing so must mind the signs: $\omega = -\psi$ at the center of an outgoing disk, but $\omega = \psi$ for an incoming one. We use $z$’s to denote universal $\psi$ classes.

(4.1) Relating on $B, C$ and $D$. The discussion in this sub-section applies to any Lefschetz theory, not necessarily semi-simple. The pairing

$$B : A \otimes A \to k[[z_{1,2}]]$$

defined by two disks with incoming boundaries and crossing at their centres must be symmetric under simultaneous swap of the $A$ factors and of the nodal $\psi$-classes $z_{1,2}$. The same symmetry holds for the co-form output by two crossing disks,

$$C \in (A \otimes A)[[z_{1,2}]].$$

Each of these pairs of disks can be constructed from $\infty$ and from the left or right elbows $\in$, $\exists$. To simplify notation in converting to algebra, we use the Frobenius pairing $\beta$ to express quadratic tensors as endomorphisms: define $B'$ by $\beta(a_1, B'(a_2)) = B(a_1 \otimes a_2)$, and similarly define $Z'(\in) \in \text{End}(A)[[z]]$ from $Z(\in)$, with $z$ standing for the Euler class of the second input circle. We then have

$$B'(z_1, z_2) = Z'(\in)(z_1) \circ D(z_1, z_2); \quad (4.2)$$

similarly, defining the operator $C'$ by $\beta(a_1, C'(a_2)) = \beta^{\otimes 2}(a_1 \otimes a_2, C)$, and $Z'(\exists)(z)$ by the same rule (with $z$ the Euler class of the second circle) leads to

$$C'(z_1, z_2) = D(z_2, z_1) \circ Z'(\exists)(z_1), \quad (4.3)$$

and these endomorphisms must satisfy $B'(z_2, z_1) = B'(z_1, z_2)^*$ and $C'(z_2, z_1) = C'(z_1, z_2)^*$.

We can eliminate the operators $Z'(\in)$ and $Z'(\exists)$ from formulas (4.2) and (4.3):

4.4 Proposition. We have

$$Z'(\in)(z) = B'(z, -z) = D^*(0, z) \circ D^{-1}(z, 0) = C'(-z, z)^{-1} = Z'(\exists)(-z)^{-1}.$$
Proof. The first identity arises by setting \( z = z_2 = -z_1 \) in (4.2): this results in the specialisation 
\[ D(z, -z) = \text{Id}, \] 
as in \( \text{§1.3.iii.} \) For the second, set one of the arguments to 0 and the other to \( z \) in (4.2) to get 
\[ B'(0, z) = D(0, z), \quad B'(z, 0) = Z'(\langle \rangle)(z) \circ D(0, z), \] 
and now use the symmetry of \( B \). The last two identities are reached by the same route, but using equation (4.3). Incidentally, equality of the outer terms in (4.4) is the equivariant form of Zorro’s lemma.

Equations (4.2), (4.3) and (4.4) allow us to express \( B, C \) and \( D \) in terms of each other. In particular, note the equivalent 
\[ \text{Cohomological Field theory constraints} \quad B' = \text{Id} \iff C' = \text{Id} \iff D = \text{Id}. \] 

(4.5) Deligne-Mumford data and constraints. In a DMT, the data \( B, C \) and \( D \) are supplied in the nodal factorisation axioms, controlling the behaviour of \( \bar{Z} \)-classes at the boundary of \( \overline{M}_g \). The arguments of (4.1) are now disallowed, because the elbows \( \in, \inj \) are unstable surfaces. Instead, the relations between \( B, C, D \) are imposed as consistency constraints on the data. (In the process of interpreting the formulas from the previous section, we define \( Z(\in), Z(\inj) \) from \( B \) and \( C \) by Proposition 4.4.)

Equivalent constraints can be formulated for each datum separately, as follows:

(i) symmetry of \( B \);
(ii) symmetry of \( C \);
(iii) the identity \( D(z, -z) = \text{Id} \), together with an awkward adjointness condition on \( D \).

(We shall not use this adjointness condition on \( D \), and leave it to the reader to spell it out.) With these constraints, the list of axioms of a DMT is finally complete!

Let us note, on the side, that it is unnecessary to impose the constraints in semi-simple theories, as they can be inferred from the other axioms by a different method. Namely, one considers the universal curve with a single node and two components of large genus, each carrying a marked point, and computes its \( \bar{Z} \)-class in the three possible nodal factorisations, using \( B, C \) and \( D \). This suffices to detect the identities of (4.1) for the usual reasons: the surface operators are invertible, and the nodal \( \eta \)-classes are free algebra generators in the stable range. (The details of the argument closely parallel the proof of Lemma 3.8 and are left to the reader.)

(4.6) Constraint on \( E \), and the CohFT condition. Thanks to Proposition 3.11 in a semi-simple theory we have 
\[ Z'(\langle \rangle)(z) = E^{-1}(-z)^* \circ E^{-1}(z), \] 
whence equation (4.4) gives the compatibility constraint between \( E \) and each datum \( B, C \) and \( D \). For example, fixing a symmetric \( B \) subjects \( E \) to the constraint
\[ B'(z, -z) = E^{-1}(-z)^*E^{-1}(z), \] 
and determines \( E \) up to left multiplication by any \( \text{End}(A) \)-valued Taylor series \( F(z) = \text{Id} + O(z) \) which preserves the symplectic form on \( A([z]) \)
\[ \Omega_B(a_1, a_2) = \text{Res}_{z=0} B(-z, z)(a_1(-z), a_2(z)) \, dz. \]

In particular, in a CohFT with \( B = \text{Id} \), (4.7) becomes the standard symplectic condition
\[ E^*(z) = E^{-1}(-z), \]
which says that $E(z)$ preserves the symplectic form
\[ \Omega(a_1, a_2) := \text{Res}_{z=0} \beta (a_1(-z)a_2(z)) \, dz. \]

The constraint on $E$ must apply in any semi-simple DMT: we can detect the requisite identity in the tubular neighbourhood of a nodal stratum in large genus.

\[ \text{(4.8) Alternative parameters for semi-simple theories.} \] The following alternative description will be useful in §6. Since $D(z,-z) \equiv \text{Id}$, we can write
\[ C'(z_1, z_2) = E(z_1) \circ (\text{Id} + (z_1 + z_2)W'(z_1, z_2)) \circ E^*(z_2) \]
for a uniquely determined $W'$ satisfying the straightforward symmetry constraint
\[ W'(z_1, z_2)^* = W'(z_2, z_1), \]
corresponding to a symmetric $W \in (A \otimes A)[z_1, z_2]$. The triple $(\tilde{Z}^+, W, E)$ will be an alternative set of parameters for a semi-simple DMT or Lefschetz theory, with symmetry of $W$ as the only constraint. For example, in these parameters, the CohFT condition becomes
\[ W'(z_1, z_2) = \frac{E^{-1}(z_1)E^{-1}(z_2)^* - \text{Id}}{z_1 + z_2}, \]
which can be met precisely for symplectic $E$.

Finally, we give the promised construction of a Lefschetz theory with compatible data (i)–(iv).

\[ \text{4.10 Proposition.} \text{ Given any Frobenius algebra } A \text{ and data } \tilde{Z}^+, E \text{ and } B, \text{ subject to the constraint } (4.7), \text{ there exists a Lefschetz theory with nodal bilinear form } B, \text{ and which on smooth surface families is given by Proposition } 3.11. \]

\[ \text{Proof.} \text{ Here is a recipe to produce a field theory; for definiteness, we write it on } \bar{M}^n_g \text{ but } \overline{A}^n_g \text{ would work as well. For a single surface } \Sigma, \text{ the smooth-surface and nodal factorisation rules leave no choice: resolve the surface, viewing all nodal points as outgoing say, then apply the free boundary formula to each component, and finally use } B(\psi', \psi'') \text{ to contract the two factors of } A \text{ at each node (formula 2.11). Clearly, this recipe works in any family which does not vary the topological type of the surface, and in particular over any stratum of } \bar{M}^n_g. \text{ However, patching these classes together when attaching the strata requires more comment.} \]

For any boundary stratum, the recipe just given can also be applied to nearby smoothings of our nodal surface $\Sigma$. These smoothings have a distinguished handle which degenerates to the node; we can cut this handle and use, in contracting with $B$, the Euler class of the cutting circle, with the two choices of sign, in lieu of the nodal $\psi$-classes. Let us call this the nodal recipe. The nodal recipe is unavailable as we move farther into the bulk of Deligne-Mumford space, where the handle is lost; the smooth recipe, based on the true topology of the surface, must take over. Constraint (4.7) ensures the agreement of the smooth and nodal recipes, at the level of cohomology, in the region where both can be used. However, to produce a well-defined cohomology class on $\bar{M}^n_g$, we must exhibit cocycle-level representatives, such as differential forms, for the local $\tilde{Z}$-classes, and check their agreement on overlaps. (Choose the overlaps to be (poly-) annular neighbourhoods of the Deligne-Mumford strata.)

For this purpose, we choose differential forms $\tilde{\psi}$ representing the $\psi$’s over $\bar{M}^{n+1}_g$, such that:

(i) $\tilde{\psi}_{n+1}$ vanishes near the sections $[\sigma_i]$ and near the nodes of the universal curve
(ii) The closed forms $\tilde{\psi}', \tilde{\psi}''$ at a node are also defined on a tubular neighbourhood of the locus of nodal curves, and $\tilde{\psi}' = -\tilde{\psi}''$ in an annular neighbourhood.

This is possible because the line bundle $\det\sigma^*_{n+1}T^*_x$ is trivial near the $[\sigma]$ and flat near the nodes, so its curvature forms in any metric which is constant near $[\sigma]$ and near the nodes will work.

Apply now the nodal recipe for $\overline{Z}$ with differential forms, using $\int_{\sigma} \tilde{\psi}'_{n+1}$ for each occurrence of $\kappa_i$ in the cohomological formula. Vanishing of $\tilde{\psi}_{n+1}$ near the nodes allows us to omit nodal neighbourhoods of the surface when computing the integral, and gives a well-defined differential form expression for $Z$ of the cut surface $\Sigma^{cut}$ with values in $A \otimes A$, over a small neighbourhood of the boundary of $\overline{\mathcal{M}}^n_{g'}$. We can then contract with $B(\tilde{\psi}', \tilde{\psi}'')$. In other words, we can continue to use the nodal recipe in a neighbourhood of any given boundary stratum, using $\Sigma^{cut}$ and the forms $\tilde{\psi}', \tilde{\psi}''$ as substitutes for the boundary Euler classes. Moving now a little further away, into the annular neighbourhood where $\tilde{\psi}' = -\tilde{\psi}'''$, constraint [3.7] shows that contraction with $B$ simply has the effect of cancelling the output $E(\tilde{\psi})$-twists in the formula for $Z(\Sigma^{cut})$. As a result, the nodal and smooth recipes agree at the level of forms. This gives the desired patching. 

4.11 Remark. Another construction of the classes $Z$ will be given in [6] in terms of a group action on cohomology of the Deligne-Mumford spaces.

(4.12) The vacuum in Lefschetz theories. Existence of a vacuum ([2.13]) follows from the Lefschetz theory sewing rule. In the theory of Proposition 4.10, the flat vacuum condition $v(z) = 1$ amounts to

$$\exp \left\{ - \sum_{j>0} a_j z^j \right\} = E^{-1}(z)(1).$$

In the semi-simple case, large genus surfaces detect the vacuum, so the restricted Deligne-Mumford theory will also have a flat vacuum precisely when (4.13) holds.

5. Deligne-Mumford theories: uniqueness

This section contains the key argument of the paper: we show that semi-simple DMT’s are uniquely determined by the nodal propagator $D$ and by the associated free-boundary theory on smooth curves. The argument also applies to Lefschetz theories, but we focus on the DM case. A reformulation of the main result, suggested by one of the referees, is found in the appendix to this section.

(5.1) Extending $Z$-classes over Deligne-Mumford strata. Let $j : S \rightarrow M$ be the divisor parametrising a (locally versal) nodal degeneration of a family $\Sigma_M \rightarrow M$ of marked Riemann surfaces. The normal bundle $\nu_S$ to $S$ in $M$ is the tensor product $L' \otimes L''$ of the complex tangent lines at the two exceptional points $p', p''$ of the normalised surface $\bar{\Sigma}$ over $S$; as to its Euler class, $\text{eul}(\nu_S) = -(\psi' + \psi'')$.

Since $p'$ and $p''$ may be switched by the monodromy over $S$, we view them both as outgoing. Over $S$, and hence over a tubular neighbourhood $N$, $Z(\Sigma)$ is the contraction of $Z(\bar{\Sigma}) \in H^*(\partial N; A^{(2)})$ by $B(\psi', \psi'')$. The Mayer-Vietoris sequence

$$\cdots \rightarrow H^{*-1}(\partial N) \rightarrow H^*(M) \rightarrow H^*(M \setminus N) \oplus H^*(N) \rightarrow H^*(\partial N) \rightarrow \cdots$$

In the context of chain-level theories, this fact is true without the semi-simplicity assumption; but in that situation, it can be made obvious with the right definitions.
shows that cohomology classes over \( M \setminus S \) and \( N \) patch into one over \( M \), if they agree over the circular neighbourhood \( \partial N \); but an ambiguity arises from the \( \delta \)-image of \( H^{\bullet -1}(\partial N) \). More precisely, if \( \eta \) is a connection form on the circle bundle \( \partial N \to S \), then \( H^\bullet(\partial N) \) is computed as the cohomology of the DGA \( H^\bullet(S)[\eta] \), with differential \( d\eta = \text{eul}(\nu_S) \). For \( a \in H^{\bullet -1}(\partial N) \), \( \delta(a) \) is given by the differential of any extension of \( a \) to \( N \) as a co-chain. This kills classes pulled back from \( S \), while a class \( b\eta \), with \( b \) from \( S \), is sent to \( j_*(b) \). Now, \( b\eta \) is a co-cycle iff \( b \cdot \text{eul}(\nu_S) = 0 \), so the patching ambiguity is precisely the Thom push-forward \( j_* \), of the annihilator of \( \text{eul}(\nu_S) \) in \( H^{\bullet -2}(S) \).

This observation applies to Deligne-Mumford strata \( S \) of any co-dimension \( c \): a class in \( H^\bullet(M) \) with known restrictions to \( M \setminus S \) and \( S \) is ambiguous only up to addition of some \( j_*(b) \), with \( b \in H^{\bullet -2c}(S) \) annihilated by \( \text{eul}(\nu_S) \). We see this from the long exact cohomology sequence

\[
\cdots \to H^{\bullet -2c}(S) \xrightarrow{j_*} H^\bullet(M) \to H^\bullet(M \setminus S) \xrightarrow{\delta} H^{\bullet -2c+1}(S) \to \ldots,
\]

(where we have used the Thom isomorphism \( j_* : H^{\bullet -2c}(S) \cong H^\bullet(M,M \setminus S) \)) and from the fact that \( j_*(b)|_S = \text{eul}(\nu_S) \cdot b \). Note that \( \text{eul}(\nu_S) \) is the product of Euler factors for the Deligne-Mumford divisors containing \( S \).

(5.2) Uniqueness for large genus: the main idea. If \( M \setminus S \) is the universal family of smooth surfaces of large genus and \( S \) a boundary divisor in its DM compactification, Looijenga’s theorem \( (2.18) \) ensures that \( \text{eul}(\nu_S) = -\psi' - \psi'' \) is not a zero-divisor within a range of degrees, as one component of \( \Sigma \) must have large genus. Classes then patch uniquely. This applies to strata of any co-dimension, and even if the family \( M \) includes nodal and reducible surfaces, the only requirement being that each node defining the degeneration to \( S \) should belong to at least one large genus component. This is the germ of an inductive proof of unique extension of \( Z(\Sigma_M) \) to the Deligne-Mumford boundary. The induction requires a careful stratification of the Deligne-Mumford spaces \( \overline{M}_g^n \).

(5.3) Stratification of \( \overline{M}_g^n \). Assume that \( n > 0 \), and call the irreducible component of the universal curve containing the marked point \( n \) special. We now decompose \( \overline{M}_g^n \) following the topological type \( \tau \) of the special component. A partial ordering on the resulting strata is defined by stipulating that higher special types can only degenerate to lower ones (plus extra components, which cease to be special). We extend this to some complete ordering; an example is the dictionary order on geometric genus, number of nodes and total number of marked points of the special component. (Nodes linking the special component to other components should be counted for this purpose as marked points, not nodes.) The smooth stratum \( M_g^n \) is by itself. Every stratum in the decomposition is isomorphic to \( (M^\nu_\gamma \times \overline{M})/F \), where \( \gamma \) and \( \nu \) pertain to the special component, while \( \overline{M} \) parametrises the complementary components, and \( F \) is the group of symmetries of the modular graph describing the topological type our curves.

5.4 Example. With \( g > 2 \) and \( n = 1 \), if we split off an elliptic curve crossing the special component at two nodes, \( \gamma = g-2, \nu = 2, \overline{M} = \overline{M}_2^2 \) and \( F = \mathbb{Z}/2 \), switching the two nodes.

Our decomposition \( M_\tau \) of \( \overline{M}_g^n \) is not a stratification in the strict sense: it is not compatible with the dimensional ordering. However, we have the following:

(i) Each \( M_\tau \) is a union of Deligne-Mumford strata.
(ii) Every descending union \( \Pi_{\tau \geq \tau'} M_{\tau'} \) of strata is open.
(iii) Each \( M_\tau \) is a closed sub-orbifold of \( \Pi_{\tau \geq \tau} M_{\tau'} \).
(iv) The normal bundle to \( M_\tau \) is (locally) a sum of lines \( L' \otimes L'' \) for tangent line pairs at the nodes which belong to the special component (and possibly one other component).
Parts (i) and (ii) are clear by construction. To see (iv), choose a surface \( \Sigma \) in \( M_\tau \). It belongs to a DM stratum \( M_\Sigma \), which is wholly contained within \( M_\tau \). The deformation space of \( \Sigma \) is smooth, and its tangent space is the sum of the lines \( L' \otimes L'' \), over all nodes, with the tangent space to \( M_\Sigma \). The nodes which lie on the special component give deformations changing the topology of the special component, hence they represent normal directions to \( M_\tau \); whereas the other nodes correspond to deformations of the complement of the special component, which are tangent to \( M_\tau \). An automorphism of \( \Sigma \) preserves the special component, and cannot interchange tangent and normal lines. This shows that the symmetry group \( F \), acting on the tubular neighbourhood of \( M_\tau \), preserves the decomposition into tangent and normal directions; so \( M_\tau \) has no self-intersections, proving smoothness in (iii).

(5.5) **Unique patching.** Let us now prove uniqueness of the patched class on every \( \overline{M}_g^n \) (\( n > 0 \)). Attach to the marked input point \( n \) a moving smooth surface \( \Sigma_G \) of large genus \( G \) with an incoming point marked “−” and an outgoing one marked “+” (the latter attached to \( n \)). This embeds \( S := \overline{M}_g^n \times M_1^G \) as part of the boundary of \( \overline{M}_g^n+G \). Let, as before, \( N \) be a tubular neighbourhood of \( S \) and \( \partial N \) its boundary.

**5.6 Lemma.** The projection \( \partial N \to \overline{M}_g^n \times M_1^G \) forgetting the point + gives an isomorphism in degree less than \((G-1)/2\):

\[ H^\bullet(\partial N) \cong H^\bullet(\overline{M}_g^n) \otimes H^\bullet(M_G)[\psi_-]. \]

**Proof.** The description of \( \partial N \) as a circle bundle over \( S \) gives the description of \( H^\bullet(\partial N) \) in the stable range as the cohomology of the differential graded algebra

\[ H^\bullet(\overline{M}_g^n) \otimes H^\bullet(M_G)[\psi_-, \psi_+, \eta] \]  

with \( d\eta = \psi_n + \psi_+ \),

which implies our statement. \( \square \)

Now, \( S \) parametrises nodal degenerations at \( n = + \) of those surfaces corresponding to the open union of \( U \) of DM strata in \( \overline{M}_g^n+G \), which meet \( \partial N \). We carry over our type decomposition of \( 5.3 \) to \( U \subset \overline{M}_g^n+G \) with special point “−”, and observe that properties (i)–(iv) continue to hold. In addition, the special component now has geometric genus \( G \) or higher. All the normal Euler classes in (iv) are then products of free generators of the cohomology ring. The classes \( Z \) over the \( U_\tau \) then patch uniquely. But each \( U_\tau \) factors as \( M_{g+\gamma}^U \times \overline{M}_g^n \), and \( \overline{M}_g^n \) parametrises surfaces whose type is strictly lower than that of geometric genus \( g \), with \( n \) marked points. We can inductively assume their \( Z \)-classes to be known; the factorisation rule gives the \( Z \)-class on each \( U_\tau \), therefore on all of \( U \) and then also on \( S \). The class on \( S \) is \( \overline{Z}_g^n \circ D(-\psi_n, \psi_+) \circ Z_G^n \), with \( D \) fed into the \( n \)th entry of \( \overline{Z}_g^n \). Lifting to \( \partial N \) recovers \( \overline{Z}_g^n \) by Lemma 5.6.

(5.7) **Pre-stable surfaces.** Restriction to stable surfaces may seem unnatural from the axiomatic point of view. There are Artin stacks \( \overline{A}_g^n \) parametrising all pre-stable curves, nodal curves with no condition on the rational components: they arise from stable curves by inserting chains of \( \mathbb{P}^1 \)'s at a node (leading to semi-stable curves) and trees of \( \mathbb{P}^1 \)'s at smooth points. However, these stacks also have normal-crossing stratifications à la Deligne-Mumford, and the inductive argument applies as before, ensuring uniqueness of the extension to \( \overline{A}_g^n \).

(5.8) **Appendix: An infinite-genus Deligne-Mumford space.** One referee observed that the splitting result of this section has a re-formulation in the guise of a homological splitting of a certain “infinite-genus Deligne-Mumford space” \( \overline{M}_g^n \) into its constituent strata. This space is a partial completion
of the classifying space $B\Gamma_\infty$ of the infinite-genus mapping class group, and can be obtained by the addition of certain boundary strata. Roughly speaking, $\overline{M}_{\infty}$ parametrizes infinite-genus nodal surfaces with $n$ marked points such that each irreducible component which carries a marked point has infinite genus, but the other components have finite genus.

A geometric construction of the requisite DM space, as well as its moduli interpretation, require some effort; so I shall only outline the story. While it is true that we need the spaces only up to homotopy in order to know their cohomology, we need to describe $\overline{M}_{\infty}$ as a stratified homotopy type, with normal structure to the strata. In this format, the space can be assembled from its constituent strata, which are products of various $M_{g}$ and factors of $B\Gamma_\infty$, in the manner in which $\overline{M}_{g}$ is assembled from its Deligne-Mumford strata, and with the same normal-crossing structure. Readers familiar with the structure of Deligne-Mumford boundary divisors should have no trouble supplying the details for this case.

A point in $\overline{M}_{\infty}$ represents a nodal curve $C$; to this, we associate its stable graph $\bar{\gamma}(C)$ in the usual way (a genus-labeled vertex for each component, an edge for each node, a labeled external edge for each marked point), and the modified graph $\gamma(C)$ which collapses all the edges which link vertices of finite genus. We now stratify $\overline{M}_{\infty}$ according to the modified graph. (For this purpose, one must take care that the ‘infinite’ genera of components of the curve are really very large numbers, to be stabilized later; for instance, splitting off some finite genus piece from a large genus surface changes the graph. This book-keeping must be built into the construction of $\overline{M}_{\infty}$.) For a single marked point, we recover the stratification of §5.3 by topological type of the special component (now stabilised to infinite genus). Call $c_\gamma$ the complex co-dimension of $M_\gamma$.

There is a partial ordering on strata, compatible with degeneration of the infinite-genus components: $\gamma \geq \gamma'$ if the closure of the stratum $M_\gamma$ contains $M_{\gamma'}$. (This happens as soon as the former meets the latter.) This gives an increasing filtration of $\overline{M}_{\infty}$ by the open subsets $F_\gamma := \bigsqcup_{\gamma' \geq \gamma} M_{\gamma'}$. The following proposition, suggested by the referee, has the same proof as Lemma 5.6.

5.9 Proposition. (i) The cohomology spectral sequence associated to the filtration $F_\gamma$ collapses at the first page:

$$\operatorname{gr}H^\bullet(\overline{M}_{\infty}) = \bigoplus H^\bullet(M_\gamma)[2c_\gamma].$$

(ii) Every cohomology class of $\overline{M}_{\infty}$ is uniquely determined by its restrictions to all the strata $M_\gamma$. □

6. A group action on DM field theories

This section reformulates the classification of semi-simple DMT’s in terms of the action of a subgroup of the symplectic group on the cohomology of Deligne-Mumford spaces. This construction, which lifts some of Givental’s quadratic Hamiltonians, may have been first flagged by Kontsevich [CKS] (see also the recent [KKP]), and plays a substantial role in his study of deformations of open-closed field theories. Here, it is merely a convenient way to rephrase my classification, but it does provide the link with Givental’s original conjecture, which was formulated in terms of CohFT potentials. The context is more general than in the Introduction: we allow $D \neq \operatorname{Id}$, and this requires us to review the notation.

(6.1) Definitions. Let $\Delta$ be the completed second symmetric power of $A[z]$; we may view it as the space of (symmetric) 2-variable Taylor series in $A^{\otimes 2}[z_{1,2}]$. The group $\Gamma(A)[z]$ acts on $V \in \Delta$ point-wise,

$$\operatorname{Ad}_g(V)(z_{1,2}) := (g(z_1) \otimes g(z_2)) \circ V(z_{1,2}).$$
Let $GL^+ \subset GL(A)[z]$ be the congruence subgroup $\equiv 1 \text{d} \text{d} (\text{mod } z)$, and define $Sp^+ := GL^+ \rtimes \exp(A)$, the second factor denoting the vector Lie group with Lie algebra $\Delta$. Call $F$ the space of polynomial functions on $A[z]$, introduce a formal parameter $h$ and consider, on the space $F((h))$

- the translation action of $A[z]$: $(T_z F)(y) = F(y - x);
- the geometric action of $GL^+$: $(g F)(x) = F(g^{-1} x);
- the action of $\exp(\Delta)$, exponentiating the quadratic-differentiation action of $h \Delta$.

Together, these assemble to an action of $Sp^+ \rtimes A[z]$. When $A[z]$ is doubled to a symplectic vector space, $F$ can be regarded as the Fock representation of its Heisenberg group $H$ constructed therefrom, $Sp^+$ is a subgroup of the symplectic group $Sp$, acting on $H$, and $\Delta$ is the “upper right corner” of the Lie algebra of $Sp$. The (projective) metaplectic representation of $Sp$ on $F$ induces on $F((h))$ the action of $Sp^+$ that we have just described, except that we have chosen to rescale $\Delta$ by $h$. To be precise, only the Lie algebra of $Sp$ acts on polynomial functions on $A[z]$; integrating the action to the group $Sp$ requires one to complete $F$ in some way. Nonetheless, $\Delta$-differentiation does exponentiate on $F((h))$, and our $h$ scaling will match the action we need on DMT potentials.

Note that we have not committed to an identification of the symplectic space $A[z] \oplus A[z]^*$ with $(A((z)), \Omega)$ as in (1.15) Most importantly, the geometric action of (symplectic group elements) $g \in GL^+$ does not agree with the metaplectic one, induced from its point-wise action on $A((z))$ in (1.15) rather, the latter comes from a different embedding of (the symplectic part of) $GL^+$ in $Sp^+$; see Proposition 6.17 below.

(6.2) Action on DMT’s. A Deligne-Mumford theory defines a vector in the space of $G_n$-invariant cohomologies

$$A^{DM} := \prod_{g, n} H^* \left( \overline{M}_{g, n}^n (A^*) \otimes n \right) G_n.$$

To any $Z \in A^{DM}$, not necessarily one coming from a DMT, we assign as in (1.12) its potential

$$A(x) = \exp \left\{ \sum_{g, n} \frac{h^{g-1}}{n!} \int_{\overline{M}_{g, n}^n} Z^n \left( x(\psi_1), \ldots, x(\psi_n) \right) \right\}, \quad (6.3)$$

living in a completion of $F((h))$. It converges as a formal power series in $h, x$ and $x^3 / h$, but is in fact of a very restricted kind, thanks to the dimensions $3g + n - 3$ of the spaces $\overline{M}_{g, n}^n$. Thus, the exponent is a formal series in $\{x, h, x^3 / h\}$ for $x \in A \oplus A z$, whose coefficients are polynomials in the $z^2 A[z]$ variables. This shows that the differentiation by $z^2 A[z]$ and of $h \Delta$ can be exponentiated to a linear enlargement of $F((h))$ which contains the potentials.

Let $H^+$ and $H^{++}$ be the natural lifts of $z A[z], z^2 A[z]$ in $H$. I will define an action of $Sp^+ \rtimes H^{++}$ on $A^{DM}$ which lifts the action on potentials. Now, a distinguished point $I_A \in A^{DM}$ represents the trivial theory based on $A$; its $(g, n)$-component is the $n$th co-power of $a^g$ (interpreted as the Frobenius trace, if $n = 0$). We will verify the following DMT version of Theorem 2: the semi-simple DM theories constitute the $Sp^+ \rtimes H^{++}$-orbit of $I_A$. Specializing to Cohomological Field theories will lead to the original version of Theorem 2.

As we will see, this lifted action extends infinitesimally to the larger group $Sp^+ \rtimes H^+$, but the exponentiated action of the linear modes $z A \subset H^+$ has singularities. We will compute the action explicitly in the case of semi-simple DMT’s, and will see that these linear modes vary the algebra structure of $A$, re-scaling the projectors. On the other hand, a similarly-defined translation by zero-modes is more complicated, and does not commute with the rest of $H^+$; see 8.
(6.4) Translation. Let \( \mathcal{Z} \in A^{DM} \) be any class. For \( a(z) \in z \cdot A[[z]] \), define a new class \( a\mathcal{Z} \) by setting

\[
a\mathcal{Z}^n_S(x_1, \ldots, x_n) = \sum_{m \geq 0} \frac{(-1)^m}{m!} \int_{M^m_{g+n+m}} \mathcal{Z}^{n+m}_S(x_1, \ldots, x_n, a(\psi_{n+1}), \ldots, a(\psi_{n+m})).
\]

All \( \psi \)-classes are on \( \overline{M}^{n+m} \). With \( a = 0 \), we recover \( \mathcal{Z} \). For dimensional reasons, the sum is finite if \( a \in z^2 \cdot A[[z]] \), but linear components \( zA \) can cause convergence problems, and should a priori be treated as formal variables. For semi-simple DMT’s, we will see below that \( a\mathcal{Z} \) depends rationally on \( a \in zA \).

We claim that \( a (b\mathcal{Z}) = a+b\mathcal{Z} \). Indeed, the second-order infinitesimal variation, capturing the linear effect of an infinitesimal \( b \)-translation followed by that of an \( a \)-translation, is

\[
\frac{\delta^2 \mathcal{Z}^n}{\delta a \delta b}(x_1, \ldots, x_n) = \int_{M^m_{g+1}} \int_{M^m_{g+2}} \mathcal{Z}^{n+2}_S(x_1, \ldots, x_n, a(\psi^*\psi_{n+1}), b(\psi_{n+2})),
\]

where \( \phi \) is the morphism forgetting the point \( n+2 \). The difference \( a(\psi_{n+1}) - a(\phi^*\psi_{n+1}) \) is a multiple of \( [c_{n+1}] \) (cf. (2.13)); it is killed by \( \psi_{n+2} \), therefore also by \( b(\psi_{n+2}) \). As a result, the right-hand side is symmetric in \( a, b \).

The same argument, using the presence of \( \psi \)-classes in \( a \), gives the binomial expansion

\[
\int_{M^m_{g}} \mathcal{Z}^n_S(x + a(\psi_1), \ldots, x + a(\psi_n)) = \sum_k \binom{n}{k} \int_{M^m_{g}} a\mathcal{Z}^k_S(x, \ldots, x).
\]

Defining a potential \( \mathcal{A}_a \) from \( a\mathcal{Z} \) as in (1.13) leads to

\[
\mathcal{A}_a(x) = \mathcal{A}(x - a) \quad \text{ for } \quad a \in zA[[z]].
\]

In other words, \( \mathcal{Z} \mapsto a\mathcal{Z} \) lifts to DMT classes the translation action of \( a \) on \( F((h)) \).

(6.6) The \( Sp^+ \)-action. It is clear how the action of elements \( g(z) \in GL(A)[[z]] \) can be lifted to \( A^{DM} \); the ith input of \( \mathcal{Z} \) is transformed by \( g^{-1}(\psi_i) \). The quadratic differentiations in \( \Delta \) can be implemented by the addition of boundary terms, as I now describe.

Recall first that \( \overline{M}^n_g \) has one boundary divisor \( D_{ir} \) parametrising irreducible nodal curves of genus \( g - 1 \), and additional divisors corresponding to reducible nodal curves. The latter ones are labelled by tuples \((g', g'', n', n''), (g'', n'')\), where \((g', n') + (g'', n'') = (g, n)\) and the partitions \( \sigma \) of marked points range over co-sets in \( \mathcal{S}_n/(\mathcal{S}_n \times \mathcal{S}_n) \). As usual, forbidden values of \((g', n')\) or \((g'', n'')\), giving unstable degenerations, are excluded. Our labelling double-counts the boundaries because of the interchange \((g', n') \leftrightarrow (g'', n'')\); in the case when \( g' = g'' \) and \( n' = n'' \), this becomes an involution of the respective boundary stratum, interchanging the branches at the node. In other words, a label determines a boundary stratum together with an ordering of the two branches. (This also applies to \( D_{ir} \), which is \( \mathcal{Z}/2 \)-quotient of \( \overline{M}^{g+2} \)). Denote by \( \psi', \psi'' \) the two \( \psi \)-classes at the node. Call \( \Lambda \) the set of labels for reducible degenerations, let \( \Theta_\lambda \) be the Thom class of the boundary \( D_\lambda, \lambda \in \Lambda \) and \( \Theta_\eta \), the one for \( D_{ir} \).

6.7 Definition. The infinitesimal action of \( \delta \mathcal{V} = \psi' z^p \otimes \psi'' z^q + \psi'' z^q \otimes \psi' z^p \in \Delta \) on \( \mathcal{Z} \in A^{DM} \) is given by

\[
\delta \mathcal{Z}^n_S(x_1, \ldots, x_n) = \sum_{\lambda \in \Lambda} \Theta_\lambda \land \mathcal{Z}^{n+1}_S(x_{\sigma(1)}, \ldots, x_{\sigma(n')}, \psi') \land \psi' \land \mathcal{Z}^{n+1}_S(x_{\sigma(n'+1)}, \ldots, x_{\sigma(n)}, \psi'') \land \psi'' \land \Theta_\eta \land \mathcal{Z}^{n+2}_S(x_1, \ldots, x_n, \psi'') \land \psi''.
\]
(An extension of the boundary class $\mathcal{Z}$ to a small tubular neighbourhood has been implied.)

This is a non-linear action — notice the quadratic term — that is, a vector field on $A^{DM}$. To see that this really defines an action of $\Delta$, we must check that the effects of any two $\delta V, \delta W$ commute. Now, the second variation, computed in either order, is expressed as a sum over all boundary strata of complex co-dimension 2 in $\overline{M}^{g}$. These strata are labelled by stable curves with two distinguished nodes, and a stratum $\mathcal{S}$ contributes the following term: the Thom class of $\mathcal{S}$, times the product of $\mathcal{Z}$-classes, with one factor for each irreducible component of the curve, and having the pair of entries at the two nodes contracted with $\delta V$, respectively with $\delta W$. We are exploiting the facts that nodal $\psi$-classes of boundary strata restrict to their counterparts on second boundaries, and that the Thom push-forwards, from these same second boundaries, factorise into two successive Thom push-forwards of the type appearing in Definition [6.7]. This is the desired symmetry of the second variation.

Let us now show that the actions just defined on $A^{DM}$ assemble to an action of $Sp^+ \ltimes H^+$.

6.8 Proposition. The action of $GL(A)[[z]]$ intertwines naturally with those of $H^+$ and $\Delta$, which commute with each other. Moreover, the resulting action of $Sp^+ \ltimes H^+$ lifts the metaplectic action on potentials.

Proof. The statement about $GL$ is clear, as it merely transforms the input arguments. We now check the infinitesimal commutation of $H^+$ with $\Delta$. Recall that the derivative $(\partial_a \mathcal{Z})^n_S$ in the direction $a \in H^+$ is the integral along the universal curve of the a-contraction $a \mapsto \mathcal{Z}^{n+1}_S$. Call $\varphi : \overline{M}^{n+1}_g \to \overline{M}^*_{g}$ the last forgetful morphism. Omitting the obvious symbols in Definition [6.7] we have

$$\delta_a \delta_V \mathcal{Z} = \sum \Theta_\Lambda \land ((\partial_a \mathcal{Z})' \psi^p \land \mathcal{Z}' \psi'^q + \mathcal{Z} \psi^p \land (\partial_a \mathcal{Z})'' \psi''^q) + (\partial_a \mathcal{Z})^{n+2} \land \Theta_\mu \psi^p \psi''^q,$$

$$\delta_V \delta_a \mathcal{Z} = \int_\varphi a \mapsto (\sum \Theta_\Lambda \land \mathcal{Z}' \psi^p \land \mathcal{Z}'' \psi''^q) + \int_\varphi a \mapsto (\Theta_\mu \land \mathcal{Z}_{g-1} \psi^p \psi''^q);$$

we must show the agreement of the two.

Now, each $\partial_a \mathcal{Z}$ in the first formula represents an integral $\int_\varphi a \mapsto \mathcal{Z}$, but when extracting this operation out to the front of the sum, several discrepancies arise with respect to the second formula:

(i) The sum in $\delta_a \delta_V$ ranges over the boundary divisors of $\overline{M}^n_g$, that in $\delta_V \delta_a$ over those of $\overline{M}^{n+1}_g$.

(ii) The Thom classes in $\delta_a \delta_V$ are those of the boundary divisors downstairs. In $\delta_V \delta_a$, we use the Thom classes of the boundaries upstairs.

(iii) The nodal $\psi', \psi''$ classes are the ones from $\overline{M}^n_g$ in $\delta_a \delta_V$, but are those on $\overline{M}^{n+1}_g$ in $\delta_V \delta_a$.

To establish the commutation of $H^+$ with $\Delta$, we must resolve these discrepancies. Concerning (i), note that each $\varphi^{-1}(D_\lambda)$, from $\overline{M}^n_g$, is the union of a pair $D_\lambda \cup D_\lambda'$ of boundary divisors upstairs,\footnote{With the usual exception $\varphi' = \varphi''$ when we get a self-intersecting divisor, just as we do for $D_\mu$.} they correspond to the components of the universal curve $\overline{C}^n_g$, and are distinguished by the component which contains the marked point absorbing $a$. Therefore, each $\lambda$ in the first sum has two matching terms $\lambda', \lambda''$ in the second sum. Moreover, because $\varphi^* \Theta_\lambda = \Theta_{\lambda'} + \Theta_{\lambda''}$, the Thom push-forward operations in the two formulae match after integrating down along $\varphi$. We are therefore only left to account for the boundary components $[\sigma_i]$ in the second sum (the sections of $\varphi$), which have no counterparts in $\delta_a \delta_V$, as well as the discrepancy (iii). However, all of these vanish for the same reason: they are killed by the positive powers of $\psi_{n+1}$ present in $a$.

Finally, let us compare this action with the metaplectic action on potentials. Translation was checked earlier. It is clear that the $GL$-action lifts the geometric action on $F((h))$. The analogue for
the metaplectic action of $\Delta$ is seen in the following interpretation of the power series expansion of $A$: it is the integral over the moduli of all, possibly disconnected stable nodal surfaces, with individual components of the moduli space weighted down by the automorphisms of their topological type. In this expansion of the potential $A$, differentiation in the input $x$ involves replacing one $x$-entry in a $Z$-factor in each term by the direction of differentiation, and summing over all choices of doing so. Quadratic differentiation is the same procedure, but applied to all pairs of entries. Thanks to the Thom classes in formula (6.7), we can re-interpret the integral of $\delta Z''$ there over $\overline{M}_g^\text{n}$ as a sum of integrals over the relevant boundaries instead. Book-keeping confirms that we thus supply all requisite terms for the quadratic differentiation in the expansion of $A$. 

\[ 6.9 \text{ Proposition. If } Z \text{ defines a DMT, then so do all of its transforms under } Sp^+ \ltimes H^+. \text{ More precisely, upon transforming by } e^{V(z_{1,2})} \in \exp(\Delta), \text{ the nodal co-form } C \text{ is changed to } C(z_{1,2}) + (z_1 + z_2)V(z_{1,2}). \text{ H}^+ \text{-translation does not change } C. \text{ Finally, GL}^+ \text{ has the obvious effect on } C \text{ via its action on } \Delta. \]

\[ \text{Proof. For the action of } GL^+, \text{ this is clear from first definitions. For } \Delta \text{ and } H^+, \text{ we will check that the infinitesimal action gives a first-order deformation of a field theory; in the process, we spell out its effect on the co-form } C, \text{ and will do so first in the more delicate case of } \Delta. \]

More precisely, we claim that for the variation $\delta Z$ resulting from $\delta V$, $Z + e \cdot \delta Z$ is a DMT over the ground ring $k[e]/e^2$, with nodal co-form $C + \delta C$, where $\delta C(z_{1,2}) = (z_1 + z_2) \cdot \delta V(z_{1,2})$. Write the DMT factorisation rule (2.10) at a boundary divisor $D_{\lambda_0}$, corresponding to a splitting node and labelled by $\lambda_0 \in \Lambda$, as

\[ b_{\lambda}^{2}(Z) = Z' \dashv C(\psi', \psi'') \vdash Z'', \]

where the two contractions $\dashv$ and $\vdash$ absorb the left and right factors of $C$ into the nodal slots of $Z', Z''$. In a DMT over $k[e]/e^2$, the $e$-linear part of factorisation becomes a “Leibniz rule”

\[ b_{\lambda}^{2}(\delta Z) = \delta Z' \vdash C(\psi', \psi'') \vdash Z'' + \delta Z' \dashv C(\psi', \psi'') \dashv Z'' + \delta Z' \dashv C(\psi', \psi'') \dashv Z'' = \delta Z'', \]

which we must verify for our specific $\delta Z$ and proposed $\delta C$.

To do so, restrict formula (6.7) for $\delta Z$ to $D_{\lambda_0}$. Since $b_{\lambda_0}^{2} \Theta_{\lambda_0}$ is the Euler class $-(\psi' + \psi'')$ of $D_{\lambda_0}$, the term $\lambda = \lambda_0$ in the sum becomes

\[ \epsilon(\psi' + \psi'') \wedge \overline{Z}_{\sigma, \psi' + \psi''}^{\psi'}(x_{v(1)}, \ldots, x_{v(n)}, \nu') \wedge \psi'' \wedge \overline{Z}_{\sigma, \psi' + \psi''}^{\psi''}(x_{v(n + 1)}, \ldots, x_{v(n)}), \nu'' \wedge \psi'''. \]

This is precisely the contribution to (6.10) of the variation $\delta C$ we posited above. On the other hand, the $\lambda \neq \lambda_0$ and $D_{lr}$ terms in (6.7) correspond to boundary divisors on the Deligne-Mumford moduli space underlying $D_{\lambda_0}$; the nodal factorisation rule for $Z'$ or $Z''$ identifies those terms, restricted by $b_{\lambda}^{2}$, with the $Z' \dashv C \vdash Z'' + \delta Z' \dashv C \vdash Z''$ terms in our Leibniz factorisation (6.10). A similar discussion applies to the boundary divisor $D_{lr}$, proving our Leibniz rule.

For an infinitesimal translation by $a(z)$, the first variation $\delta_a Z$ is the integral $\int_{\gamma} a(\psi) \vdash Z$ along the universal curve. Restricting now to $D_{\lambda_0}$, we can split the integral into two terms, coming from the two irreducible components of the curve, to get $Z' \vdash C(\psi', \psi'') \vdash \delta Z'' + \delta Z' \dashv C(\psi', \psi'') \dashv Z''$, and there is now no additional term that could provide a $\delta C$ contribution.

This last argument argument conceals a subtlety: thanks to the presence of a $\psi$-factor, contraction with $a(\psi)$ kills the difference between the nodal $\psi', \psi''$-classes pulled back from $D_{\lambda_0}$ and those on the universal curve, over which integration is taking place. (Compare with the proof of Proposition 6.8) \[ \square \]
6.11 Remark. If \( a(z) \) contains a constant term and the co-form C carries a dependence on \( \psi', \psi'' \), there will be a \( \delta C \)-term accounting for the difference between nodal \( \psi', \psi'' \)-classes on the curve and their pull-backs from \( D_{\lambda_0} \). However, this does not happen in Cohomological Field theories, where C is constant. We will exploit this observation in \( \S 7.4 \) below.

(6.12) The action on semi-simple DMT’s. Let us now determine the action of a general group element \( g \cdot e^V \cdot \zeta \in \text{GL}^+ \ltimes (\exp(\Delta) \times H^+) \) on semi-simple DMT’s, in terms of their classification. The natural description involves the alternative parameters \( (\tilde{Z}, W, E) \) of \( (4.9) \). We will meet a restriction on the \( z \)-linear term of \( \tilde{\zeta} \).

Write \( \zeta = \sum_{j \geq 0} \zeta_j z^j \). If \( \zeta_1 = 0 \), we will not change the algebra structure on \( A \), and the reader can skip straight to the statement of the Proposition below, ignoring the primes. However, if \( \zeta_1 \neq 0 \), let \( A' \) be the Frobenius algebra which is identified with \( A \) as a vector space with quadratic form \( \beta \), but with the multiplication re-defined in such a way that the new projectors are \( P'_j = (1 + \zeta_1)P_j \). Thus, the new multiplication is \( x' \cdot y := x \cdot y \cdot (1 + \zeta_1)^{-1} \), the new identity is \( 1' = 1 + \zeta_1 \), and the Euler class is now \( \alpha' = \alpha \cdot (1 + \zeta_1)^{-1} \). However, note that the vector \( (\alpha')^{1/2} \), with the square root in the prime algebra, agrees with the old \( \alpha^{1/2} \). The construction breaks down when \( (1 + \zeta_1) \) is not a unit in \( A \), so we must exclude that case.

6.13 Proposition. The trivial DMT \( I_A \) transforms under \( g \cdot e^V \cdot \zeta \in \text{GL}^+ \ltimes (\exp(\Delta) \times H^+) \) into the semi-simple theory based on the algebra \( A' \), with alternative parameters

\[
\tilde{Z} = \exp' \left\{ \sum_{j \geq 0} a'_j \kappa_j \right\}, \quad E(z) = g(z), \quad W(z_{1,2}) = V(z_{1,2}).
\]

Here, \( \sum_{j \geq 0} a'_j z^j \) is the Taylor expansion of \( \log' \alpha^{1/2} - \log'(1 + \zeta/z) \in A'[z] \), and the logarithm and exponential are computed in \( A' \).

6.14 Remark. Since \( \log'(1 + \zeta_1) = \log'(1') = 0 \), we have \( \exp' a'_0 = \alpha^{1/2} \). In the original algebra \( A \), we can expand \( \log \alpha^{1/2} - \log(1 + \zeta/z) = \sum_{j \geq 0} a_j z^j \); the relation \( \exp' x' = (1 + \zeta_1) \cdot \exp x \) for \( x' = (1 + \zeta_1) \cdot x \) shows that the Taylor coefficients are then related by \( a'_j = (1 + \zeta_1) a_j \). The operators of multiplication by \( \exp \left\{ \sum_{j \geq 0} a_j \kappa_j \right\} \) on \( A \) and by \( \exp' \left\{ \sum_{j \geq 0} a'_j \kappa_j \right\} \) on \( A' \) coincide, when we identify the two vector spaces as above. (However, the customary relation \( a_0 = \log \alpha^{1/2} \) is broken if \( \zeta_1 \neq 0 \) since involves the ‘wrong’ \( \log \).)

Proof. Note that \( E \) and \( W \) do not change the Frobenius algebra structure, which is determined by \( \beta \) and by the tensor \( Z_0^3 : A^{\otimes 3} \to C \). The effect of \( \zeta \) will be checked in a moment. In particular, semi-simple theories remain semi-simple and we are merely looking for the change in parameters.

The effect of \( E \) is clear from its definition, while that of \( e^V \) was explained in Proposition 6.9 above: on a theory with \( E = \text{Id}, W \mapsto W + V \). To understand \( \zeta \), note first that translation cannot affect the \( E \) and \( W \) parameters of a DMT, because of the group law in \( \text{Sp}^+ \ltimes H^+ \). To find its effect on \( \tilde{Z} \), it suffices to take \( n = 1 \) and compute its first-order variation over \( M_{g,1} \) under \( \delta \zeta \). This leads to a differential equation governing the action of \( \zeta \), which we solve. We omit the \( \zeta \)-script from the notation for tidiness (so \( \tilde{Z} \) should really be \( \zeta \tilde{Z} \), etc.) and let \( C_{g,1} \to M_{g,1} \) denote the universal curve. Then,

\[
\delta \tilde{Z}(\kappa_j) = -\int_{C_{g,1}} \alpha^{-1/2} \cdot \tilde{Z}(\kappa_j) \cdot \delta \zeta(\psi_2) = -\alpha^{-1/2} \tilde{Z}(\kappa_j) \int_{C_{g,1}} \tilde{Z}(\psi_2^j) \delta \zeta(\psi_2),
\]

where \( \tilde{Z}(\kappa_j) = \exp \left\{ \sum_{j \geq 0} c_j \kappa_j \right\} \) with the \( c_j \) as yet unknown, \( \tilde{Z}(\psi_2^j) = \exp \left\{ \sum_{j} c_j \psi_2^j \right\} \) and we have used the fact that \( \kappa_j \) inside the integral is \( \kappa_j \) outside plus \( \psi_2^j \). Integration converts \( \psi_2^{j+1} \) to \( \kappa_j \).
Quadratic and higher terms in $\delta \zeta$ do not give rise to $\kappa_0$ and so do not affect the multiplication in $A$. Assuming first that $\xi_1 = 0$, we specialise to $\kappa_j \mapsto z'$:

$$\delta \tilde{Z}(z') = -\alpha^{-1/2} \tilde{Z}(z')^2 \cdot \frac{\delta \zeta(z)}{z},$$

which is solved by

$$\zeta \tilde{Z}(z') = \frac{\alpha^{1/2}}{1 + \zeta(z)/z}$$

since we know the initial value $\tilde{Z} = \alpha^{1/2}$. Now, $\log \tilde{Z}$ is linear homogeneous in the $\kappa_j$, so we recover the true $\tilde{Z}$ from our specialisation by substituting $z' \mapsto \kappa_j$ in $\log \tilde{Z}$, and then exponentiating.

Finally, the effect of $\zeta_1$-translation on the trivial $A$-theory can be determined directly from the formula

$$\int_{M^1_{g+1}} \psi_1 \wedge \cdots \wedge \psi_n = (2g + n - 2) \cdots (2g - 1),$$

giving

$$\frac{1}{\zeta} \tilde{Z} = \alpha^g \sum_n \frac{(-\zeta_1)^n}{n!} \int_{M^1_{g+1}} \psi_1 \wedge \cdots \wedge \psi_n = \alpha^g \sum_n \left(1 - \frac{2g}{n}\right) \zeta_1^n = \frac{\alpha^g}{(1 + \zeta_1)^{2g-1}}.$$

This introduces no higher $\kappa$-classes, but changes the multiplication on $A$ in the manner claimed.

\[\square\]

(6.15) Cohomological Field theories. We now deduce Theorem 1 from Proposition 6.13 by identifying the subgroup of $Sp^+ \ltimes H^+$ which preserves the Cohomological Field theory constraint (15.1). Recall from §4.6 that this constraint takes the equivalent forms $B' = \text{Id}$, $C' = \text{Id}$ and $D = \text{Id}$. In terms of $E$ and $W$, we need the identity

$$W'(z_1, z_2) = W_E := \frac{E(z_1)^{-1} E(-z_2) - \text{Id}}{z_1 + z_2}, \quad (6.16)$$

together with the symplectic condition $E(z)^* E(-z) \equiv \text{Id}$ of §4.6. In §4.15 we wrote $Sp_L^+$ for the subgroup of symplectic matrix series $E \in GL^+$. It follows from Proposition 6.9 that the group homomorphism $E(z) \mapsto E(z) \cdot e^{W_H(z_1, z_2)}$ identifies $Sp_L^+$ with the stabiliser of $C' = \text{Id}$ in $Sp^+$; it is a new, a new sheared embedding of $Sp_L^+$ in $Sp^+$. We now use the symplectic form $\Omega$ of §4.15 to identify the symplectic double of $A[z]$ with $A((z))$. The group $GL^+$ acts on $A((z))$, point-wise in $z$; its subgroup $Sp_L^+$, by definition, preserves $\Omega$ and lies in $Sp$. We write $E \mapsto \tilde{E}$ for this point-wise embedding of $Sp_L^+$ in $Sp$.

6.17 Proposition. The two embeddings of $Sp_L^+$ into $Sp$ agree: $\tilde{E} = E \cdot e^{W_H}$.

Proof. We verify this on Lie algebras. Let $\delta E = \sum_{n>0} \delta E_n z^n$; then,

$$\delta W_E(z_1, z_2) = \frac{\delta E(-z_2) - \delta E(z_1)}{z_1 + z_2} = - \sum_{p,q \geq 0} \delta E_{p+q+1}(-z_2)^p z_1^q.$$

In the monomial decomposition $\{z^n \cdot A\}_{n \in \mathbb{Z}}$ of $A((z)) \cong A[[z]] \oplus A[[z]]^*$, the geometric action of $E$ is given by the operator with $(p, q)$ blocks

$$O_{p,q} = \begin{cases} 
-\delta E_{p-q} & \text{for } p > q \geq 0 \\
(-1)^{p+q-1} \delta E_{p-q} & \text{for } 0 > p > q \\
0 & \text{otherwise}
\end{cases}$$

32
The symplectic condition is \((-1)^{p+q} \delta E_{p-q} = \delta E_{p-q}\). On the other hand, the matrix corresponding via the symplectic form \(\Omega\) to the quadratic differentiation operator \(\delta W_E(z,1,2)\) has \((p,q)\)-blocks \(-\delta E_{p-q}\) in positions \(q < 0 \leq p\). This supplies precisely the missing \(p \geq 0 > q\) blocks for the point-wise multiplication action of the operator \(\delta E(z) : A((z)) \to A((z))\). Our statement follows. \(\Box\)

(6.18) Flat vacuum. Let us identify the vacuum vector \((\ref{2.13})\) of the theory in terms of the group element \(\hat{E} \cdot \zeta\). In particular, we will identify the subgroup of \(\text{Sp}_L^+ \times H^+\) whose action on \(I_A\) preserves the flat vacuum condition \((\ref{13}i)\) with the conjugate of \(\text{Sp}_L^+\) by the translation \(T_z\) by \(z = 1\). This will conclude the proof of Theorem 2.

By equation \((\ref{4.13})\) and Proposition \((\ref{6.1})\)
\[
E^{-1}(z)(v) = \exp\left\{-\sum_{j>0} a_j z^j\right\} = 1 + \zeta/z
\]
so \(z = z(E^{-1}(z)(v) - 1).\) Clearly, the CohFTs with vacuum \(v\) constitute the orbit
\[
\left(T_{zv(z)} \cdot \hat{E} \cdot T_z^{-1}\right)(I_A),
\]
with \(E\) ranging over the symplectic \(\text{End}(A)\)-valued series considered. (Note that the action of \(T_z\) on \(I_A\) is singular, but the conjugate \(T_z \hat{E} T_z^{-1}\) makes good sense, so that the group element in parentheses acts.) In particular, notice that changing the vacuum of a theory with fixed underlying algebra and symplectic parameter \(E\) is accomplished by \(H^+\)-translation.

7. Frobenius manifolds and homogeneity

We now enrich a given DMT \(Z\) into a family of DMT’s parametrised by a (possibly formal) neighbourhood \(U\) of 0 \(\in\ A\). When starting with a cohomological field theory, the genus zero part of this family defines on \(U\) the structure of a Frobenius manifold, a notion introduced by Dubrovin \([D]\). The family of DMT’s will allow us to incorporate the grading information of Gromov-Witten theory in the form of a homogeneity condition under a vector field on \(U\). The reader may consult \([M, \S 1]\) or \([LP]\) for a broader account of the subject.

7.1 Definition. Given a DMT \(Z\), define for \(u \in U\)
\[
_u Z^n_g(x_1, \ldots, x_n) := \sum_{m \geq 0} \frac{(-1)^m}{m!} \int_{\mathcal{M}_g} \mathcal{Z}^{n+m}_g(x_1, \ldots, x_n, u, \ldots, u).
\]
Restriction to \(U\) may be required for convergence, but for convenience we will treat \(u\) as a genuine parameter in our formulae. It is straightforward to verify the DMT axioms for \(u Z\) from those for \(Z\); the construction is formally similar to the translation \((\ref{6.4})\) but in this case we are using the subspace \(A \subset A[z]\) of the Heisenberg group. However, while the effect of translation by \(zA[z]\) was easily expressed in terms of \(\kappa\)-classes, the structure resulting now is more complicated, because the new translation interacts with the boundary terms, and fails to commute with \(H^+\). Microscopically, the absence of a \(\psi\)-factor in \(u\) breaks the calculations in the proof of Proposition \((\ref{6.9})\). Conceptually, in the case of open-closed field theories, which are controlled by linear categories with a cyclic trace, the \(u\)-parameter is related to deformations of the category of boundary states, whereas translation by \(H^+\) is tied to the (easier) deformation of the trace. There is, however, one easy fact to state, which was already mentioned in Remark \((\ref{6.11})\).

7.2 Proposition. If the DMT \(Z\) is actually a CohFT, then so is every \(_u Z\); moreover, the Frobenius bilinear form \(\beta\) remains unchanged. \(\Box\)
(7.3) Frobenius manifold of a CohFT. The previous proposition does conceal something: the product and the Frobenius trace \( \theta \) on \( A \) will vary with \( u \). We obtain a \( u \)-dependent family of Frobenius algebra structures on \( A \), viewed as a fixed vector space with bilinear form \( \beta \). Spelt out, we get for \( g = 0, n = 3 \) a map

\[
u Z^3_u : A^3 \rightarrow \mathbb{C}.
\]

Converted to a map \( A^2 \rightarrow A \) by means of \( \beta \), this gives a \( u \)-dependent multiplication \( \cdot_u \) on \( A \). This multiplication is evidently commutative, because of the symmetry of \( Z \), but must be associative as well, since it is part of a CohFT structure. (Explicitly, we can apply the nodal factorisation rule to the several boundary restrictions of the map \( u Z^3_u : A^2 \rightarrow H^*(\mathcal{M}_0^4) \). Since \( \mathcal{M}_0^4 = \mathbb{P}^1 \) is connected, these restrictions define the same map \( A^2 \rightarrow \mathbb{C} \), so that \( \beta(a \cdot_u b, c \cdot_u d) \) is symmetric in the four variables.)

We write \( A_u \) when referring to the algebra structure at \( u \), and identify each \( A_u \) with the tangent space \( T_u U \) using the linear structure. The multiplications satisfy an integrability condition, which is captured by the observation that \( u Z^3_u \) is the third total partial derivative of a function \( u Z^3 \). This function, the potential of the Frobenius manifold, is expressed by the series in Definition 7.1 with \( g = n = 0 \), after omitting the \( m \leq 2 \) terms. This integrable family of Frobenius algebras on \( U \), together with the (flat) metric \( \beta \), is called a Frobenius manifold structure. The linear structure on \( U \subset A \) is characterized by the flat coordinates under \( \beta \).

We say that the Frobenius manifold has flat identity if the unit vector field \( 1 \) is flat in the metric (constant in flat coordinates). It is shown in [M III] that this follows from the flat vacuum condition on \( Z \); we will also verify that as part of Proposition 7.13 below. A Frobenius manifold is in fact equivalent to the datum of a genus-zero CohFT (the collection of classes \( Z^3 \), satisfying the CohFT axioms), by an explicit reconstruction [M].

(7.4) The basic differential equations. Semi-simplicity of \( A \) ensures that of the nearby \( A_u \), so nearby theories are classified by \( u \)-dependent data \( Z_u, E_u, B_u \). Assuming that \( Z \) is a CohFT, I describe the changes in \( \tilde{Z} \) and \( E \) by means of differential equations.

To isolate the effect of the varying multiplication, we will express it in the (moving) normalised canonical identification \( \mathbb{C}^N \cong A_0 \), this gives the normalised canonical framing of \( T UI \). Let \( \ast_u \) denote the entry-wise multiplication of column vectors, and \( \cdot_u \) the multiplication in \( A_u \); we have

\[
\Pi_u(x \ast y) = a^{-1/2}u \cdot_u \Pi_u(x) \cdot_u \Pi_u(y).
\]

Also define the following column vector depending on \( u \) and on the \( \kappa \)-classes,

\[
Y_u = Y_u(\kappa) := \Pi^{-1}(a^{1/2}Z_u),
\]

whose entries are the eigenvalues of multiplication by \( \tilde{Z}_u \); that is, \( \Pi \circ (Y_u \ast) \circ \Pi^{-1} = (Z_u \ast) \). (The \( i \)th entry of \( Y \) is \( \exp \{ \sum_{j \geq 0} a_{ij} \kappa_j \} \), with \( u \)-dependent coefficients \( a_{ij} \).) Write \( Y_u(z) \) for the result of the substitution \( \kappa_j \mapsto z^j \). Since \( Y(\kappa) \) is linear homogeneous in the \( \kappa \)'s, \( Y(\kappa) \) determines \( Y(\kappa) \).

We can now write the propagator \( 1/2 Z^n_u : A^m \rightarrow A_n \) for smooth curves of genus \( g \), with incoming points \( \{ 1, \ldots, n \} \) and one outgoing point labelled by \( 0 \), as follows:

\[
1/2 Z^n_u(x_1, \ldots, x_n) = E_u(-\psi_0)\Pi_u \left( Y_u(\kappa) \ast \Pi^{-1}(E_u^{-1}(\psi_1)(x_1)) \ast \cdots \ast \Pi^{-1}(E_u^{-1}(\psi_n)(x_n)) \right).
\]

The contribution of \( n \) to \( k_0 = 2g + n - 1 \) gives a factor of \( a^{n/2} \) in \( u \tilde{Z} \) and has the virtue of correcting the \( n \) operations \( \ast \) into the multiplication \( \cdot_u \), cf. (7.5). We now differentiate in \( u \).
7.7 Proposition. $E_u$ and $Y_u$ verify the following systems of ODE’s in $u$, $\forall v \in T_u U$:

\[
\frac{\partial (E_u \Pi_u)}{\partial v}(z) \circ \Pi_u^{-1} = \left[ E_u(z), \frac{(\nu_u)}{z} \right];  \tag{7.7.a}
\]

\[
\frac{\partial Y_u(z)}{\partial v} \ast Y_u(z)^{-1} = -Y_u(z) \ast \Pi_u^{-1} E_u(z)^{-1} \left( \frac{v}{z} \right) + Y_u(0) \ast \Pi_u^{-1} \left( \frac{v}{z} \right).  \tag{7.7.b}
\]

Before turning to the proof, the following comments might be helpful.

7.8 Remark. (i) We use the flat structure of $TU$ to differentiate $\Pi_u$ and $E_u$.

(ii) Since $E = \text{Id} \pmod{z}$, the commutator in equation (7.7a) is regular at $z = 0$, where we obtain, with $E_{u,1}$ denoting the $z$-linear term of $E_u$,

\[
\partial_v \Pi_u \circ \Pi_u^{-1} = [E_{u,1}, (\nu_u)].
\]

By substituting this for the derivative of $\Pi$, (7.7a) can be expressed as a non-linear ODE system in $E$ alone; $\Pi$ can then be recovered from $E$.

(iii) The second term on the right in equation (7.7b) removes the pole present in the first term.

(iv) Let $C_1 := M_1 \times_{M_1} M_1$ be the universal curve over $M_1$ and note that $\int_{C_1}^{|M_1|} \psi^j = \kappa_{j-1}$, or zero if $j = 0$. Because $\partial_\nu Y(\kappa) \ast Y^{-1}$ is linear homogeneous in the $\kappa$’s, we can write the ODE’s for $Y_u(\kappa)$ explicitly:

\[
\frac{\partial Y_u(\kappa)}{\partial v} \ast Y_u(\kappa)^{-1} = -\int_{C_1}^{M_1} Y_u(\psi) \ast \Pi^{-1} E^{-1}(\psi)(v).  \tag{7.7c}
\]

Indeed, we will prove the equation in this form.

(v) A coordinate-free form of equation (7.7b) is found in Proposition 7.13 below.

Proof. Proving the proposition will require us to find the variation of (7.6) with $n = 1$. However, to keep the formulas simple, we first write out the variation with $n = 0$. It will then be straightforward to describe the additional terms for general $n$. We also drop the $u$-subscript from the notation when no confusion arises.

From (7.6),

\[
\partial_v(1Z) = \partial_v(\Pi \psi_0(Y(\kappa)) + E(-\psi_0)\Pi(\partial_\nu Y(\kappa))). \tag{7.9}
\]

This same variation is also, by definition, an integral along the universal curve:

\[
-\int_{C_1}^{M_1} E(-\psi_0)\Pi \left( Y(\kappa) \ast \Pi^{-1} E^{-1}(\psi)(v) \right) - \nu \cdot u \frac{1 - E(-\psi_0)}{\psi_0} \Pi(Y(\kappa));
\]

the second term is the boundary correction to $Z$ on the diagonal section $\sigma_0$ of $M_1 \times_{M_1} M_1$. The requisite picture for this correction attaches a three-pointed $\mathbb{P}^1$ to $C_1$ at its output $\sigma_0$; this $\mathbb{P}^1$ absorbs $v$ at the second input, and the output is read at the third point.

Using the familiar formula $\kappa_j = \psi^* \kappa_j + \psi^j$ upstairs, the integral above (without sign) becomes

\[
E(-\psi_0)\Pi \left( Y(\kappa) \ast \int Y(\psi) \ast \Pi^{-1} E^{-1}(\psi)(v) \right) + \frac{E(-\psi_0) - 1}{\psi_0} \left( \nu \cdot u \Pi(Y(\kappa)) \right);
\]

the second term comes from the correction to $\psi_0$ on the diagonal $\sigma_0$, and all the $\kappa$’s now live on the base $M_1$. All in all, we get

\[
\partial_v(1Z) = \left[ (\nu_u), \frac{E(-\psi_0)}{\psi_0} \right] \circ \Pi(Y(\kappa)) - E(-\psi_0) \circ \Pi \left( Y(\kappa) \ast \int Y(\psi) \ast \Pi^{-1} E^{-1}(\psi)(v) \right). \tag{7.10}
\]
and comparing with formula (7.9) suggests a separation into two identities, namely (7.7.a), with \( z = -\psi_0 \), and (7.7.c). However, in order to prove the proposition, we must:

- consider \( n = 1 \) in the variation of (7.6), in order to allow the insertion of arbitrary arguments in the first operator, in place of \( \Pi(Y) \);
- justify the splitting of the one resulting identity into two pieces.

Taking \( n = 1 \) changes (7.10) as follows: \( Y(\kappa) \) is replaced by \( Y(\kappa) \ast \Pi^{-1}E^{-1}(\psi_1)(x_1) \), and an additional term,

\[
E(-\psi_0) \left( \tilde{Z} \cdot u \left[ \frac{E^{-1}(\psi_1)}{\psi_1}, v \cdot u \right] \right),
\]

appears from the correction of \( \psi_1 \) along \( \sigma_1 \) and from the boundary contribution of \( \sigma_1 \) to \( \tilde{Z} \), just as explained in the case of \( \psi_0 \). Likewise, (7.9) changes by inserting \( \ast \Pi^{-1}E^{-1}(\psi_1)(x_1) \) after \( Y(\kappa) \) and \( \partial_\nu Y(\kappa) \), and by the addition of

\[
E(-\psi_0)\Pi \left( Y(\kappa) \ast \partial_\nu (E\Pi)^{-1}(\psi_1)(x_1) \right).
\]

Splitting the identity into separate ones will now complete the proof. This is accomplished by setting the \( \kappa \)'s or \( \psi \)'s, which are now independent variables, selectively to zero. A priori, this leaves a constant term ambiguity. That, however, is resolved by noting that the constant term of the first ODE, \( \partial_\nu \Pi \circ \Pi^{-1} \), is a skew matrix, whereas the operator \( \partial_\nu Y \ast \) is purely diagonal; so there is no possible mixing of constant terms. \( \square \)

(7.11) Flat vacuum preserved. If \( \tilde{Z} \) verifies the flat vacuum condition (1.8.ii), then the identity vector \( 1 \in A_0 \) remains the identity in the algebra structure at all \( u \): indeed, in the formula for \( _u\tilde{Z}_0^n(1,a,b) \) in Def. (7.1), all integrals with \( m \neq 0 \) vanish, because the integrand is lifted from the lower moduli space missing the first marked point:

\[
\tilde{Z}_0^{1+m}(1,a,b,u,\ldots) = \phi^*\tilde{Z}_0^m(a,b,u,\ldots).
\]

Moreover, each \( _u\tilde{Z} \) then satisfies the flat vacuum condition \( \phi^*_u\tilde{Z}_g^n(x_1,\ldots) = _u\tilde{Z}_g^{n+1}(1,x_1,\ldots) \), because of the “base change” identity

\[
\phi^*_u\tilde{Z}_g^{n+m}(x_1,\ldots,x_n,u,\ldots,u) = \int_{\tilde{M}_{g+1+m}}^{\tilde{M}_g^n} \phi^*_u\tilde{Z}_g^{n+m}(x_1,\ldots,x_n,u,\ldots,u)
= \int_{\tilde{M}_{g+1+m}}^{\tilde{M}_g^n} \tilde{Z}_g^{n+1+m}(1,x_1,\ldots,x_n,u,\ldots,u)
\]

confirming condition (1.8.ii) term-by-term in the sum (7.1). Note that it is the absence of \( \psi \) in \( u \) which carries the argument here: the vacuum, of course, is not preserved by \( H^+ \)-translations.

(7.12) Vacuum differential equation. The ODE’s for \( Y(z) \) have a cleaner, equivalent form in terms of the vacuum vector \( v(z) \) of the theory.

7.13 Proposition. At each \( u \in U \) and for any \( v \in T_u U \), \( \frac{\partial v(z)}{\partial v} = \frac{v}{z} \cdot u (1 - v(z)) \).
Proof. \( Y(z) \) and \( \mathbf{v}(z) \) are related by \( \mathbf{v}(z) = E(z)\Pi(Y(z)^{-1}) \) (Proposition \( \text{3.14} \)). Direct computation gives the following (we omit the argument \( z \), when it is not set to zero):

\[
\frac{\partial E\Pi(Y^{-1})}{\partial \nu} = \frac{\partial E\Pi}{\partial \nu}(Y^{-1}) + \frac{v - E\Pi(Y^{-1} \ast Y(0) \ast \Pi^{-1}(\nu))}{z} = \frac{\partial E\Pi}{\partial \nu}(Y^{-1}) + \frac{v - E(\Pi(Y^{-1}) \cdot \nu)}{z} = \frac{E(v \cdot \Pi(Y^{-1})) - v \cdot E\Pi(Y^{-1}) + v - E(\Pi(Y^{-1}) \cdot \nu)}{z} = \frac{v - v \cdot \nu}{z},
\]

having used \( \text{(7.5)} \) and the relation \( \Pi(Y(0)) = \alpha \) to convert \( \ast \) to the product in \( A_u \).

Proposition \( \text{7.13} \) provides the following formula for \( \mathbf{v}(z) \) in terms of derivatives of \( 1 \). Let \( \partial_1 \) be the operator of differentiation, in flat coordinates, along the vector field \( 1 \).

\[ \text{7.14 Corollary.} \quad \mathbf{v}(z) = (1 + z\partial_1)^{-1}(1) = \sum_k (-1)^k z^k \cdot \partial_1^k(1). \]

Thus, \( \mathbf{v} \) is determined by the Frobenius manifold, and in particular \( \mathbf{v} \equiv 1 \) if the identity is flat. Conversely, if \( \mathbf{v}(z) \equiv 1 \) at some point \( u \), then \( \partial_1 / \partial v = 0 \) at \( u \) for all \( \nu \), by Prop. \( \text{7.13} \) and induction shows the vanishing of all higher derivatives of \( 1 \).

\( \text{(7.15) Homogeneity and the Euler vector field.} \) Assume that we are given a vector field \( \xi \) on our Frobenius manifold \( U \subset A \), whose Lie derivative action on \( T_u U \) we denote by \( \mathcal{L} \). We call \( U \) \emph{homogeneous} (or \emph{conformal}) of weight \( d \) with \emph{Euler vector field} \( \xi \) if the \( (u\text{-dependent}) \) multiplication operator on \( T_u U \) and the quadratic form \( \beta \) are homogeneous with weights \( 1 \) and \( 2 - d \), respectively.

Since flat coordinates remain flat under the \( \xi \)-flow, it follows that \( \xi \) must be affine-linear in any flat coordinates \( x^i \) on \( A \):

\[ \xi = \xi_0 + \mu^i \cdot x^i \partial_i + (1 - d/2)x^i \partial_j. \]

The matrix \( \mu^i \) contributes an infinitesimal rotation about 0 in \( A \), and the last term is the conformal scaling. The action of \( \mathcal{L} \) on the flat frame of vector fields, commonly denoted \( \text{ad}_\xi \), is given by \( \mu + \left( \frac{d}{2} - 1 \right) \text{Id} \).

Following Dubrovin, we can reformulate homogeneity by viewing the space of sections \( \Gamma(U; TU) \) as a Frobenius algebra over the ring \( \mathbb{C}[U] \) of functions on \( U \). Differentiation by \( \xi \) gives a derivation of \( \mathbb{C}[U] \), and the shifted operator \( \mathcal{L}^+ := \mathcal{L} + \text{Id} \) defines a compatible derivation of the algebra \( \Gamma(U; TU) \). The metric has \( \mathcal{L}^+ \)-weight \( (-d) \), and in general the \( \mathcal{L}^+ \)-weights of the basic objects in \( A \) are eminently more reasonable than their \( \mathcal{L} \)-weights, cf. Table \( \text{III} \).

View now the CohFT data \( \mu \sum^n_z : \mathbb{C} \to \nu \ast (M^n_{\mathbb{C}}) \) as a collection of \( n \)-ary tensor fields on \( U \), with values in \( H^\bullet(M^n_{\mathbb{C}}) \). Using the Lie action \( \mathcal{L}^+ \) and weighting the cohomology of \( M \) by half the degree, we can extend the notion of homogeneity to the entire CohFT:

\[ \text{7.16 Definition.} \quad \text{The CohFT} \ \nu \sum_z \text{ is homogeneous of weight } d \text{ under the vector field } \xi \text{ if each tensor field } \sum^n_z : (TU)^n \to H^\bullet(M^n_{\mathbb{C}}) \text{ is } \mathcal{L}^+ \text{-homogeneous with weight } (g - 1)d. \]

By considering \( g = 0 \) and the values \( n = 3 \) and \( 4 \), we recover the Frobenius manifold homogeneity condition. Conversely, Manin’s genus-zero reconstruction theorem shows that the latter implies the seemingly stronger property \( \text{(7.16)} \), in genus \( g = 0 \), for all \( n \).
Table 1: Some basic weights

| object | $\mathcal{L}$-weight | $\mathcal{L}^+$-weight | reason |
|--------|----------------------|----------------------|--------|
| product | 1                    | 0                    | definition |
| $\beta$ | $2-d$                | $-d$                 | definition |
| $1 \in A$ | $-1$                | 0                    | $1 \cdot x = x$ |
| projector $P$ | $-1$                | 0                    | $P \cdot P = P$ |
| $\theta_i$ | $-d$                | $-d$                 | $\beta(P,P)$ |
| $\theta : A \to C$ | $1-d$               | $-d$                 | $\beta(1,\cdot)$ |
| $a_{u,\cdot}$ | $\bar{d}-1$          | $\bar{d}$            | $\theta(x \cdot \alpha) = \text{Tr}_A(x \cdot \alpha)$ |
| $(a_{u,\cdot})$ | $\bar{d}$            | $\bar{d}$            | |}

7.17 Example. In the Gromov-Witten theories of §3.16, the series

$$GW_{g,u}^n := \sum_{\delta \in H^2(X;\mathbb{Z})} e^{\langle u|\delta \rangle} \cdot GW_{g,\delta}$$

(7.18)

gives a (possibly formal) function on the group $H^2(X;\mathbb{C}^\times)$, expressed in the Fourier modes $e^u$. This group is a disjoint union of tori, each labelled by a character of the torsion subgroup of $H_2(X;\mathbb{Z})$. The divisor equation (see for instance [1P] [G2])

$$\int GW_{\delta}^{n+1}(\ldots,u) = -\langle u|\delta \rangle \cdot GW_{\delta}^n(\ldots), \quad \text{for} \quad u \in H^2(X),$$

where we integrate along the last forgetful map, ensures that the family $u\mathbb{Z} := GW_u$ is its own $u$-variation along the $H^2$ torus directions, in the sense of Definition 7.1. Near any chosen base-point, $H^2(X;\mathbb{C}^\times)$ can be identified with $U \cap H^2(X;\mathbb{C}) \subset A$ by means of a translated exponential map. Subject to convergence, we can extend the family $GW_u$ to an open set $U$ of $A = H^{ev}(X)$, starting from our base point. If convergence fails, we treat $H^2(X;\mathbb{C}^\times) \times H^{ev,\neq 2}(X)$ as a formal Frobenius manifold. The dimension formula (1.7) for the spaces of stable maps ensures that the family $GW_u$ obtained from (7.18) is homogeneous of weight $d = \dim_{\mathbb{C}} X$ with respect to the Euler field

$$\xi_{\text{GW}} = c_1(X) + \sum_j \left(1 - \frac{\deg(x^j)}{2}\right) \frac{\partial}{\partial x_j}$$

in a homogeneous basis $x^j$ of $H^*(X)$. Thus, $u = (\deg - d)/2$.

We conclude by describing the homogeneity condition in terms of the data $E_u, \mathbb{Z}_u$.

7.19 Proposition. In a homogeneous semi-simple CohFT, $E_u(z), \mathbb{Z}_u^+$ and $v_u(z)$ are invariant under the shifted Lie action $\mathcal{L}^+$ of the Euler field $\xi$.

Recall that $z$ has weight 1, so we are saying that the $z^j$th Taylor coefficient in $E_u$ has weight $(-j)$. The same applies to the coefficient $a_j$ of $\kappa_j$ in $\log \mathbb{Z}^+$. It is not difficult to show that, for a vector field $\xi$ of the form in (7.15) these conditions are also sufficient for homogeneity of $\mathbb{Z}$, but we will not use that fact.

Proof. The operator $^{1}_uZ_{g}^{1}$ for smooth surfaces must have weight $gd = (g-1)d + 2 + (d-2)$, the last term being the added weight of replacing an input by an output. In particular, $^{1}\mathbb{Z}_{g}^{1} = (a^g \mathbb{Z}^+)$ has weight $gd$, whereas $(a \cdot)$ has weight $d$; this settles $(\mathbb{Z}_u^+)$.

Next, since $^{1}_uE_{s,1} = E(-\psi_0) \circ ^{1}\mathbb{Z}_{g}^{1}$,

$$\mathcal{L}(^{1}_uZ_{g,1}) = \mathcal{L}(E(-\psi_0)) \circ ^{1}\mathbb{Z}_{g}^{1} + E(-\psi_0) \circ \mathcal{L}(^{1}\mathbb{Z}_{g}^{1}),$$

38
showing that the first term vanishes, so \( L(E(\psi_0)) = 0 \). The final statement follows from the relation
\[
E(z)^{-1}(\psi(z)) = (\tilde{Z}^+)^{-1}\big|_{\kappa_j = z'}.
\]

8. Reconstruction

I now explain the reconstruction of semi-simple cohomological field theories from genus zero data, confirming a conjecture of Givental’s for Gromov-Witten theory [G1]. In the case of homogeneous theories with flat vacuum, I also give a concrete variant which uses less input: the Euler vector field plus the Frobenius algebra at a single semi-simple point of the Frobenius manifold (Theorem 1). This more economical recipe is implicit in Dubrovin’s paper [D]. The present section is largely a review and adaptation of Givental’s relevant work.

(8.1) Reconstruction from the Frobenius manifold: Givental’s conjecture. Let \( u \) be the vector of canonical coordinates, for which the associated vector fields \( \partial / \partial u_i \) are the projectors \( P_i \) in the multiplication at the respective point. As shown in [D], the existence of such coordinates follows from the integrability conditions of \( \S 7.3 \). Clearly, the \( u_i \) are unique up to constant shifts. In the case of homogeneous Frobenius manifolds, a preferred choice of canonical coordinates is given by the eigenvalues of the operator \( (\xi \cdot u) \) of multiplication by the Euler vector field \( \xi \).

8.2 Proposition. (i) The linear map \( d\mathbf{u} : T_u \mathcal{U} \to \mathbb{C}^N \) is given by \( \Pi^{-1}u \circ (\mathbf{v} \cdot u) - \frac{1}{z} \).
(ii) The system of ODE’s in \( \mathbb{Z}^N \mathbf{u} \) is equivalent to
\[
\frac{dF}{dv} = -(v \cdot u) \circ F, \quad \text{with} \quad F(z) = E_u(z) \circ \Pi_u \circ \exp \left( -\frac{\mathbf{u} \cdot \xi}{z} \right).
\]

Proof. The first part merely rewrites the defining property of \( u \): \( d\mathbf{u} \) takes the projector frame to the standard frame of \( \mathbb{C}^N \). For the second claim, use the chain rule and the relation \( \Pi \circ (\partial \Pi / \partial v^*) = (v \cdot u) \circ \Pi \), which in turn is a consequence of part (i) and of formula (7.5).

8.3 Remark. (i) Letting \( \xi = \sum u_i \partial / \partial u_i \) in canonical coordinates, an alternative expression for \( F \) is
\[
F(z) = E_u(z) \circ \exp \left( -\frac{(\xi \cdot u)}{z} \right) \circ \Pi_u.
\]

In the homogeneous case, \( \xi \) is the Euler vector field.
(ii) Usually, \( E(z) \) does not converge; so \( F(z) \) may not belong to any symplectic loop group, but only to a thickened version of it (analogous to the space of Laurent series infinite in both directions). One such thickening can be constructed as a moduli of (twisted) principal GL(\( A \))-bundles over \( \mathbb{P}^1 \), with formal sections at 0 and at \( \infty \). This variety has no group structure, but is a homogeneous space for a (left and a right) loop group action, and this suffices to make the ODE meaningful.

The system of ODE’s in Proposition 8.2.ii is that of [G1, pp.1269–1270], with the change of notation \( \Psi = \Pi, R(z) = \Pi^{-1}E(z)\Pi \). Recall:

8.4 Proposition ([D, G1]). The system of Proposition 8.2.ii has solutions in which \( R \equiv \text{Id (mod z)} \) satisfies the symplectic condition \( R_u(z)R_u^\dagger(-z) = \text{Id} \). These solutions are unique up to right multiplication by a matrix series \( H(z) = \exp \left( H_1z + H_3z^3 + \ldots \right) \) with constant diagonal matrices \( H_{2i+1} \). In the homogeneous case, there is a unique solution with \( R \) invariant under the Euler field.
The proof of the proposition, for which we refer to Givental \cite{givental1996cohomological}, is closely related to the reconstruction procedure we will give below, in the homogeneous case. The ambiguity in $R$ reflects the possibility of a $z$-dependent shift in the canonical coordinates; the parity constraint comes from the symplectic condition. In terms of $E$, this ambiguity is the right composition with the operator of multiplication by a “symplectic” unit in $A[z]$. Note that Euler invariance of $R$ and $E$ are equivalent because of the relation $L(II) = (d/2 - 1)II$.

8.5 Corollary. A semi-simple homogeneous CohFT is determined from its Frobenius manifold, by the unique Euler-invariant solution $E$ of the ODE \((7.7)\) and the vacuum \((7.14)\).

(8.6) Ambiguity for inhomogeneous theories. The inhomogeneous theories corresponding to a given semi-simple Frobenius manifold are related geometrically by Hodge bundle twists. More precisely, let $\mu_j = ch_j \Lambda$ be the Chern components of the Hodge bundle $\Lambda$, whose fibres are the spaces of global differentials along the universal curve, with simple poles allowed at the marked sections $\sigma_i$. Recall that the classes $\mu_j$ vanish for even $j$. Euler invariance of the Hodge bundle $\Lambda$ under forgetful pull-back by the addition of a trivial line. Note, in addition, that $n^j \tilde{Z}_j[h]$ is the trivial genus-zero theory on $A$, because the Hodge bundle $\Lambda$ is trivial there. Givental’s calculation in \cite{givental1996cohomological} \S 2.3, summarised in Part (i) of the next proposition (and re-derived below), identifies the theory for us.

8.7 Proposition. (i) The theory $\tilde{Z}[h]$ is the transform $T_{z}^{-1} \circ \exp h(z) \circ T_{z}(I_A)$ of the trivial $A$-theory.

(ii) All cohomological Field theories with flat vacuum based on a fixed semi-simple, pointed Frobenius manifold are classified by matrices $E \circ \exp h(z) \in Sp_L^+$, with arbitrary $h$ but the same $E$. That is, they have the form $T_{z}^{-1} E(z) \exp h(z) T_{z}(I_A)$, with a fixed $E$.

Let us revisit the flat vacuum condition \((4.13)\) in light of statement (i). Over $M_g$, we find

$$\sum_j h_{2j-1} \frac{(2j)!}{B_{2j}} \cdot \mu_{2j-1} = \sum_j h_{2j-1} \kappa_{2j-1},$$

recovering the Riemann-Roch identities $\mu_{2j-1} = \frac{B_{2j}}{(2j)!} \cdot \kappa_{2j-1}$ over $M_g$. These identities, in turn, prove statement (i), because $\tilde{Z}$ determines $E$ when the latter is a multiplication operator in the Frobenius algebra and $\nu \equiv 1$.

(8.8) Rank one theories: a conjecture of Manin and Zograf. When $A$ has rank 1, we can give a closed formula for all possible CohFT’s (which are necessarily semi-simple).

Taking logarithms converts the FTFT factorisation axiom for the classes $\tilde{Z}_g^n$ into the primitivity condition. Manin and Zograf conjectured in \cite{manin1990higher} that the $\kappa_j$ ($j \geq 0$) and the $\mu_j$ ($j > 0$, odd) were the only primitive classes on the $\overline{M}_g^0$; consequently, they proposed that any rank 1 theory should have the form

$$\tilde{Z}_g = \exp \left\{ \sum_{j \geq 0} a_j \kappa_j + \sum_{j > 0} b_{2j-1} \mu_{2j-1} \right\} \cdot \exp(a_0)^{\otimes n},$$

for freely chosen constants $a_j, b_j \in \mathbb{C}$. (Note that $\exp(a_0)$ is the normalised canonical vector.)

\footnote{When there are no marked points, we must normalise the bundle by virtually subtracting a trivial line.}
8.10 Proposition. Formula (8.9) describes all possible rank one CohFT’s. Flat vacuum theories are those with \( a_j = 0 \) for \( j > 0 \).

Proof. The symplectic condition forces the element \( E(z) \) in our classification to have the form \( \exp h(z) \). A general translation vector \( \zeta \) in our classification inserts unrestricted \( \kappa \)-class combinations in (8.9), but the flat vacuum condition fixes the \( a_j \) to be zero.

(8.11) Classification of homogeneous CohFT’s. Since the family \( \mu \mathcal{Z} \) of theories is constructed from its special value at \( u = 0 \), we can describe the homogeneity condition in terms of the Euler field \( \xi = \xi_0 - \mu_i x^i \partial_i + (1 - d/2) x^i \partial_i \) and the classification datum \( E \); as always, \( (\xi_0 \cdot) \) denotes the operator of multiplication by the (constant vector) \( \xi_0 \) in \( A \). We focus on the important special case of flat vacuum theories, and show that they are completely determined by the Frobenius algebra structure and the Euler field.

8.12 Proposition. The CohFT \( \mathcal{Z} \) with flat vacuum defined by \( E \) is homogeneous of weight \( d \) for \( \xi \) iff

\[
\mu(\mathbf{1}) = -\frac{d}{2} \cdot \mathbf{1} \quad \text{and} \quad [ (\xi_0 \cdot, E_{k+1} ] + (\mu + k) E_k = 0.
\]

8.13 Remark. (i) Without the flat vacuum assumption, the first equation must be replaced by the differential equation

\[
\frac{d v(z)}{dz} + \frac{\mu + d/2}{z} (v(z)) = \frac{\xi_0}{z^2} \cdot (v(z) - \mathbf{1}).
\]

The calculation follows the same steps as the proof of the proposition. At a generic point where \( \xi_0 \) is invertible in the algebra (that is, away from the canonical coordinate axes), the Taylor coefficients of \( v \) are recursively determined by this equation.

(ii) The second recursion is equivalent to an ODE for the expression \( F(z) \) of Remark 8.3 ii,

\[
\frac{d F}{dz} + \frac{\mu}{z} \circ F = \frac{(\xi \cdot)}{z^2} \circ F.
\]

(iii) For \( k = 0 \), we find \( \mu = [ E_1, (\xi \cdot) ] \). When \( (\xi \cdot) \) has repeated eigenvalues (on the big diagonal in canonical coordinates), solvability of this equation places constraints on \( \mu \). In a general Frobenius manifold, one can expect semi-simplicity to fail on the big diagonal. However, the requisite constraint on \( \mu \) must hold at all semi-simple diagonal points, because the solution \( E_u \) exists there.

Proof. First, \( \mathbf{1} = -\mathcal{L}(\mathbf{1}) = -\partial(\mathbf{1})/\partial \xi - \mu(\mathbf{1}) = (1 - d/2) \cdot \mathbf{1} \); flatness of \( \mathbf{1} \), \( \partial(\mathbf{1})/\partial \xi = 0 \), gives the first relation. Next, \( \mathcal{L}(E_k) = -kE_k \) from Proposition 7.19. But

\[
\mathcal{L}(E_k) = \frac{\partial E_k}{\partial \xi} + \mu \circ E_k - E_k \circ \mu,
\]

whereas according to equation (7.2 a),

\[
\frac{\partial E_k}{\partial \xi} = [ E_{k+1}, (\xi \cdot) ] - E_k \circ \frac{\partial \Pi}{\partial \xi} \circ \Pi^{-1}.
\]

The normal canonical frame \( \Pi \) scales with weight \( (d/2 - 1) \) under the Euler flow; since

\[
\mathcal{L}(\Pi) = \frac{\partial \Pi}{\partial \xi} + \mu \circ \Pi + (d/2 - 1) \Pi,
\]

41
we have $\partial_x \Pi \circ \Pi^{-1} = -\mu$ and combining the equations proves necessity of the conditions:

$$-kE_k = [E_{k+1}, (\xi)] - E_k \circ \partial_x (\Pi) \circ \Pi^{-1} + \mu \circ E_k - E_k \circ \mu = [E_{k+1}, (\xi)] + \mu \circ E_k.$$ 

Conversely, the same calculations show that the two conditions imply the $L$-homogeneity of $\partial_x \mathbb{Z}_n^g$ to first order at $u = 0$,

$$L(\mathbb{Z}_n^g) \big|_{u=0} = (gd - d + n)\mathbb{Z}_n^g.$$

We now check that Euler homogeneity at any other point is a formal consequence. Recall from Definition 7.15 the action $\text{ad}_E$ of $L$ on the flat frame of $TU$ and its multi-linear extension to tensors. Also, denote by $\Delta$ half the degree operator on $H^\bullet(\mathbb{M})$; it was implicit in Definition 7.16. At a point $u$, $\xi$ has the value $\xi_u = \xi_0 - \text{ad}_E(u)$ and

$$(L - \Delta)(\mathbb{Z}_n^g) = \partial_\xi (\mathbb{Z}_n^g) - \mathbb{Z}_n^g \circ \text{ad}_E = \int_{\mathcal{M}_g^{2n}} \int_{\mathcal{M}_g^{2n+1}} i(\xi_0 - \text{ad}_E(u)) \mathbb{Z}_n^{g+1} - \mathbb{Z}_n^g \circ \text{ad}_E.$$

Substitute now formula (7.1) for $\mathbb{Z}$, this becomes

$$-\sum_m \frac{(-1)^m}{m!} \int_{\mathcal{M}_g^{2n+m}} \int_{\mathcal{M}_g^{2n+m+1}} \left( i(u)^m i(\xi_0) \mathbb{Z}_n^{g+m+1} - i(u)^m i(\text{ad}_E(u)) \mathbb{Z}_n^{g+m+1} \right) - \mathbb{Z}_n^g \circ \text{ad}_E,$$

and shifting the summation index $m \mapsto m+1$ in the second term of the sum converts this into

$$\sum_m \frac{(-1)^m}{m!} \int_{\mathcal{M}_g^{2n+m}} \int_{\mathcal{M}_g^{2n+m+1}} i(u)^m \left( \partial_\xi \mathbb{Z}_n^{g+m} - \mathbb{Z}_n^{g+m} \circ \text{ad}_E \right)$$

By homogeneity at $u = 0$, the integrand is $i(u)^m (L - \Delta)\mathbb{Z}_n^{g+m} = i(u)^m (gd - d + n + m - \Delta)\mathbb{Z}_n^{g+m}$. Pulling $\Delta$ through the integral gives $(gd - d + n - \Delta)u \mathbb{Z}_n^g$, proving homogeneity at $u$. \hfill $\Box$

(8.14) GW invariants from quantum cohomology. As we now explain, Proposition 8.12 determines $E$ from $A$, $\xi_0$ and $\mu$. In Gromov-Witten theory, we have:

**8.15 Theorem.** The Gromov-Witten classes $GW^g_{n,d} \in H^\bullet(\mathcal{M}_g^{2n})$ of a compact symplectic manifold are uniquely determined by its first Chern class and by the quantum multiplication law at any single semi-simple point.

**Proof.** Assume first that the quantum multiplication operator $(\xi^*)$ at our chosen semi-simple point has distinct eigenvalues. Working in the normal canonical basis, the second equation in Proposition 8.12 supplies the off-diagonal entries of $E_k$, once $E_k$ is known. Next, since $(\xi^*)$ is a diagonal matrix, the diagonal entries of the commutator $[E_k, E_{k+1}] = (\mu + k)E_k$ must vanish; since those of the skew matrix $\mu$ vanish as well, this fact determines the diagonal part of $E_k$ from its off-diagonal part. Finally, $E_0 = \text{Id}$.

In the general case, consider the block-decompositions of $\mu$ and of the $E_k$ corresponding to the eigenspaces of $(\xi^*)$. The first equation $[[\xi^*], E_1] = \mu$ implies the vanishing of the diagonal blocks of $\mu$. This is a constraint which must hold if $A$ is semi-simple. Given that, the off-diagonal blocks of $E_1$ are determined from those of $\mu$. The diagonal blocks are determined from the vanishing of those of $(\mu + \text{Id})E_1$ — which must equal $[[\xi^*], E_2]$ — and in this way, the recursive determination of the $E_k$ proceeds as before. \hfill $\Box$
