\textbf{A B S T R A C T}

Mycothiol (MSH) functions as major low molecular weight (LMW) thiol in the industrially important Corynebacterium glutamicum. In this study, we genomically integrated an Mrx1-roGFP2 biosensor in C. glutamicum to measure dynamic changes of the MSH redox potential \((E _ {\text{MSH}})\) during the growth and under oxidative stress. \(C.\ glutamicum\) maintains a highly reducing intrabacterial \(E _ {\text{MSH}}\) throughout the growth curve with basal \(E _ {\text{MSH}}\) levels of \(-296\) mV. Consistent with its \(H_2O_2\) resistant phenotype, \(C.\ glutamicum\) responds only weakly to \(40\) mM \(H_2O_2\), but is rapidly oxidized by low doses of NaOCl. We further monitored basal \(E _ {\text{MSH}}\) changes and the \(H_2O_2\) response in various mutants which are compromised in redox-signaling of ROS (OxyR, SigH) and in the antioxidant defense (MSH, Mtr, KatA, Mpx, Tpx). While the probe was constitutively oxidized in the \(mshC\) and \(mtr\) mutants, a smaller oxidative shift in basal \(E _ {\text{MSH}}\) was observed in the \(sigH\) mutant. The catalase KatA was confirmed as major \(H_2O_2\) detoxification enzyme required for fast biosensor re-equilibration upon return to non-stress conditions. In contrast, the peroxiredoxins Mpx and Tpx had only little impact on \(E _ {\text{MSH}}\) and \(H_2O_2\) detoxification. Further live imaging experiments using confocal laser scanning microscopy revealed the stable biosensor expression and fluorescence at the single cell level. In conclusion, the stably expressed Mrx1-roGFP2 biosensor was successfully applied to monitor dynamic \(E _ {\text{MSH}}\) changes in \(C.\ glutamicum\) during the growth, under oxidative stress and in different mutants revealing the impact of Mtr and SigH for the basal level \(E _ {\text{MSH}}\) and the role of OxyR and KatA for efficient \(H_2O_2\) detoxification under oxidative stress.

\section{1. Introduction}

The Gram-positive soil bacterium Corynebacterium glutamicum is the most important industrial platform bacterium that produces millions of tons of L-glutamate and L-lysine every year as well as other value-added products\textsuperscript{[1–4]}. In addition, \(C.\ glutamicum\) serves as model bacterium for the related pathogens \(Corynebacterium\ diphtheriae\) and \(Corynebacterium\ jeikeium\)\textsuperscript{[5]}. In its natural soil habitat and during industrial production, \(C.\ glutamicum\) is exposed to reactive oxygen species (ROS), such as hydrogen peroxide (\(H_2O_2\)) which is generated as consequence of the aerobic lifestyle\textsuperscript{[6–8]}. The low molecular weight (LMW) thiol mycothiol (MSH) functions as glutathione surrogate in detoxification of ROS and other thiol-reactive compounds in all actinomycetes, including \(C.\ glutamicum\) and mycobacteria to maintain the reduced state of the cytoplasm\textsuperscript{[9–11]}. Thus, MSH-deficient mutants are sensitive to various thiol-reactive compounds, although the secreted histidine-derivative ergothioneine (EGT) also functions as alternative LMW thiol\textsuperscript{[12–16]}.

MSH is a thiol-cofactor for many redox enzymes and is oxidized to mycothiol disulfide (MSSM) under oxidative stress. The NADPH-dependent mycothiol disulfide reductase (Mtr) catalyzes the reduction of MSSM back to MSH to maintain the highly reducing MSH redox potential \((E_{\text{MSH}})\) [17,18]. Overexpression of Mtr has been shown to increase the fitness, stress tolerance and MSH/MSSM ratio during exposure to ROS, antibiotics and alkylating agents in \(C. glutamicum\) [19].

Under hypochloric acid (HOCl) stress, MSH functions in protein S-mycothiolations as discovered in \(C. glutamicum, C. diphtheriae\) and \(Mycobacterium smegmatis\) [15,16,20]. In \(C. glutamicum\), 25 S-mycothiolated proteins were identified under HOCl stress that include the peroxiredoxins (Tpx, Mpx, AhpE) and methionine sulfoxide reductases (MsrA, MsrB) as antioxidant enzymes that were inhibited by S-mycothiolation [16,21–26]. The regeneration of their antioxidant activities required the mycoredoxin-1 (Mrx1)/MSH/Mtr redox pathway, but could also be coupled to the thioferredoxin/thioredoxin reductase (Trx/TrxR) pathway which both operate in de-mycothiolation [9,10,27]. Detailed biochemical studies on the redox-regulation of antioxidant and metabolic enzymes (Tpx, Mpx, MsrA, GapDH) showed that both, the Mrx1 and Trx pathways function in de-mycothiolation at different kinetics. Mrx1 was much faster in regeneration of GapDH and Mpx activities during recovery from oxidative stress compared to the Trx pathway [20,21,23–26].

The enzymes for MSH biosynthesis and the Trx/TrxR systems are under control of the alternative extracytoplasmic function (ECF) sigma factor SigH which is sequestered by its cognate redox-sensitive anti sigma factor RshA in non-stressed cells [28–30]. RshA is oxidized under disulfide stress leading to structural changes and relief of SigH to initiate transcription of the large SigH disulfide stress regulon [16,31–33]. In addition, the LysR-type transcriptional regulator OxyR plays a major role in the peroxide response in \(C. glutamicum\) which controls genes encoding antioxidant enzymes for \(H_2O_2\) detoxification and iron homeostasis, such as the catalase (katA), two miniferriptins (dps, fmaA), the Suf machinery and ferrochelatase (hemS) [30,34]. Thus, SigH and OxyR can be regarded as main regulatory systems for the defense under disulfide and oxidative stress to maintain the redox balance in actinomycetes.

The standard thiol-redox potential of MSH was previously determined with biophysical methods as \(E^0\) (MSM/MSH) of \(-230\text{ mV}\) which is close to that of glutathione (GSH) [35]. However, Mrx1 was also recently fused to redox-sensitive green fluorescent protein (roGFP2) to construct a genetically encoded Mrx1-roGFP2 redox sensor for dynamic measurement of \(E_{\text{MSH}}\) changes inside mycobacterial cells. \(E_{\text{MSH}}\) values of \(-300\text{ mV}\) were calculated using the Mrx1-roGFP2 biosensor in mycobacteria that were much lower compared to values obtained with biophysical methods [35,36]. This Mrx1-roGFP2 biosensor was successfully applied for dynamic \(E_{\text{MSH}}\) measurements in the pathogen \(Mycobacterium tuberculosis\) (\(Mtb\)). Using Mrx1-roGFP2, \(E_{\text{MSH}}\) changes were studied in drug-resistant \(Mtb\) isolates, during intracellular replication and persistence in the acidic phagosomes of macrophages [36–38]. Mrx1-roGFP2 was also applied as tool in drug research to screen for ROS-generating anti-tuberculosis drug sorts to reveal the mode of action of combination therapies based on roGFP2 [36,39,40]. The \(Mtb\) population exhibited redox heterogeneity of \(E_{\text{MSH}}\) during infection inside macrophages which was dependent on sub-vacuolar compartments and the cytoplasmic acidification controlled by WhiB3 [36,38]. Thus, application of the Mrx1-roGFP2 biosensor provided novel insights into redox changes of \(Mtb\). However, Mrx1-roGFP2 has not been applied in the industrial platform bacterium \(C. glutamicum\).

In this work, we designed a genetically encoded Mrx1-roGFP2 biosensor that was genomically integrated and expressed in \(C. glutamicum\). The biosensor was successfully applied to measure dynamic \(E_{\text{MSH}}\) changes during the growth, under oxidative stress and in various mutant backgrounds to study the impact of antioxidant systems (MSH, KatA, Mpx, Tpx) and their major regulators (OxyR, SigH) under basal and oxidative stress conditions. Our results revealed a highly reducing basal \(E_{\text{MSH}}\) of \(-296\text{ mV}\) that is maintained throughout the growth of \(C. glutamicum\). \(H_2O_2\) stress had only little effect on \(E_{\text{MSH}}\) changes in the wild type due to its \(H_2O_2\) resistance, which was dependent on the catalase KatA supporting its major role for \(H_2O_2\) detoxification. Confocal imaging further confirmed equal Mrx1-roGFP2 fluorescence in all cells indicating that the biosensor strain is well suited for industrial application to quantify \(E_{\text{MSH}}\) changes in \(C. glutamicum\) at the single cell level.

2. Materials and methods

2.1. Bacterial strains and growth conditions

Bacterial strains, plasmids and primers are listed in Tables S1 and S2. For cloning and genetic manipulation, \(Escherichia coli\) was cultured in Luria Bertani (LB) medium at 37°C. The \(C. glutamicum\) ATCC13032 wild type as well as the \(\Delta mshC\), \(\Delta mtr\), \(\Delta oxyR\), \(\Delta sigH\), \(\Delta katA\), \(\Delta mpx\), \(\Delta pxH\) and \(\Delta mpx\) \(\Delta pxH\) mutant strains were used in this study for expression of the Mrx1-roGFP2 biosensor which are described in Table S1.

All \(C. glutamicum\) strains were cultivated in heart infusion medium (HI; Difco) at 30°C overnight under vigorous agitation. The overnight culture was inoculated in CGC minimal medium supplemented with 1% glucose to an optical density at 500 nm (\(OD_{500}\)) of 3.0 and grown until \(OD_{600}\) of 8.0 for stress exposure as described [16]. \(C. glutamicum\) mutants were cultivated in the presence of the antibiotics nalidixic acid (50 \(\mu\)g/ml) and kanamycin (25 \(\mu\)g/ml).

2.2. Construction, expression and purification of His-tagged Mrx1-roGFP2 protein in \(E. coli\)

The \(mrx1\) gene (cg0964) was amplified from chromosomal DNA of \(C. glutamicum\) ATCC13032 by PCR using the primer pair Cgmxr1-roGFP2-NdeI-FOR and pQE60-Cgmxr1-roGFP2-Spel-REV. The PCR product was digested with NdeI and SpeI and cloned into plasmid pET11b-brx-roGFP2 [42] to exchange the brx sequence by \(mrx1\) with generation of plasmid pET11b-mrx1-roGFP2 (Table S2). The correct sequence was confirmed by PCR and DNA sequencing.

The \(E. coli\) BL21 (DE3) plyS expression strain containing the plasmid pET11b-mrx1-roGFP2 was grown in 11 LB medium until \(OD_{600}\) of 0.6 at 37°C, followed by induction with 1 mM IPTG (isopropyl-\(\beta\)-D-thiogalactopyranoside) for 16 hours at 25°C. Recombinant His6-tagged Mrx1-roGFP2 protein was purified using His TrapTM HP Ni-NTA columns (5 ml; GE Healthcare, Chalfont St Giles, UK) and the ÄKTApurifier liquid chromatography system (GE Healthcare) according to the instructions of the manufacturer (USB). The purified protein was dialyzed against 10 mM Tris-HCl (pH 8.0), 100 mM NaCl and 30% glycerol and stored at \(-80\text{ °C}\). Purity of the protein was analyzed after sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Coomasie brilliant blue (CBB) staining.

2.3. Construction of katA, mtr, mpx and pxH deletion mutants in \(C. glutamicum\)

The vector pK18mobsacsB was used to create marker-free deletions in \(C. glutamicum\) (1). The gene-SOEing method of Horton (2) was used to construct pK18mobsacsB derivatives to perform allelic exchange of the \(katA\) and \(mtr\) genes in the chromosome of \(C. glutamicum\) ATCC13032 using the primers listed in Table S2. The constructs include the \(katA\) and \(mtr\) genes with flanking regions and internal deletions (\(\Delta katA\) (1555 bp) and \(\Delta mtr\) (1382 bp)). The pK18mobsacsB derivatives were sub-cloned in the 
\(e. coli\) JM109 (Table S1) and transformed into \(C. glutamicum\) ATCC13032. The pK18mobsacsB: \(\Delta pxH\) plasmid containing the \(pxH\) flanking regions was constructed previously (3) and transformed into the \(C. glutamicum\) \(\Delta pxH\) mutant (3). The gene replacement in the chromosome of \(C. glutamicum\) ATCC13032 resulted in \(\Delta katA\) and \(\Delta mtr\) single deletion mutants and the gene replacement of \(pxH\) in the
chromosome of *C. glutamicum* Δmpx resulted in the *C. glutamicum* Δmpx Δpx double deletion mutant. The deletions were confirmed by PCR using the primers in Table S2.

2.4. Construction of *C. glutamicum* Mrx1-roGFP2 biosensor strains

For construction of the genomically integrated Mrx1-roGFP2 biosensor, a 237 bp fragment of *mrx1* (cg0964) was fused to roGFP2 containing a 30-amino acid linker (GGSGG) under control of the strong *P_{mpx}* promoter of the *C. glutamicum* *tuf* gene encoding the translation elongation factor EF-Tu. The *P_{mpx}*-roGFP2 fusion was codon-optimized, synthesized with flanking *Mun*I and *Xho*I restriction sites and sub-cloned into PUC-SP by Bio Basic resulting in PUC-SP::*P_{mpx}-mrx1-roGFP2*. For genomic integration of the biosensor into the cg1121-cg1122 intergenic region of *C. glutamicum* (Table S1), the vector pK18mobSacB-cg1121-cg1122 was used [43], kindly provided by Julia Frunzke, Forschungszentrum Jülich. The vector was PCR amplified with primers pK18_MunI and pK18_XhoI to swap the restriction sites. After digestion of the pK18mobSacB-cg1121-cg1122 PCR product and the PUC-SP::*P_{mpx}-mrx1-roGFP2* plasmid with *Mun*I and *Xho*I, both digestion products were ligated to obtain pK18mobSacB-cg1121-cg1122-*P_{mpx}-mrx1-roGFP2*. The resulting plasmid was sequenced with biosensor_seq_primer_1 and biosensor_seq_rev_primer_2. Transfer of the plasmid into *C. glutamicum* strains (Table S1) was performed by electroporation and screening for double homologous recombination events using the conditions described previously [42,44] based to the following Eq. (1).

$$
\text{OxD} = \frac{1400_{\text{sample}} \times 1488_{\text{red}} - 1400_{\text{red}} \times 1488_{\text{sample}}}{1400_{\text{sample}} \times 1488_{\text{red}} - 1400_{\text{red}} \times 1488_{\text{sample}}} - 1400_{\text{red}} \times 1488_{\text{sample}}
$$

The values of 1400_{sample} and 1488_{sample} are the observed fluorescence excitation intensities at 400 and 488 nm, respectively. The values of 1400_{red}, 1488_{red}, 1400_{ox} and 1488_{ox} represent the fluorescence intensities of fully reduced and oxidized controls, respectively.

Based on the OxD and $E_{\text{GFP2}}^{\text{red}} = -280 \text{ mV}$ [45], the MSH redox potential was calculated according to the Nernst Eq. (2) as follows:

$$
E_{\text{MSH}} = \frac{RT}{2F} \ln \left( \frac{1 - \text{OxD}}{\text{OxD}} \right)
$$

2.5. Characterisation of recombinant Mrx1-roGFP2 biosensor in vitro

The purified Mrx1-roGFP2 protein was reduced with 10 mM dithiothreitol (DTT) for 20 min, desalted with Micro-Bio spin columns (Bio-Rad), and diluted to a final concentration of 1 μM in 100 mM potassium phosphate buffer, pH 7.0. The oxidation degree (OxD) of the biosensor was determined by calibration to fully reduced and oxidized probes which were generated by treatment of the probes with 10 mM DTT and 5 mM diamide for 5 min, respectively [42]. The thiol disulfides and oxidants were injected into the microplate wells (BD Falcon 353219) 60 s after the start of measurements. Emission was measured at 510 nm after excitation at 400 and 488 nm using the CLARIOstar microplate reader (BMG Labtech) with the Control software version 5.20 R5. Gain setting was adjusted for each excitation maximum. The data were analyzed using the MARS software version 3.10 and exported to Excel. Each in vitro measurement was performed in triplicate.

2.6. Measurements of Mrx1-roGFP2 biosensor oxidation in *C. glutamicum* in vivo

*C. glutamicum* wild type and mutant strains expressing stably integrated Mrx1-roGFP2 were grown overnight in HI medium and inoculated into CGC medium with 1% glucose to a starting OD_{500} of 3.0. For stress experiments, the strains were cultivated for 8 h until they have reached an OD_{500} of 14–16. Cells were harvested by centrifugation, washed twice with CGC minimal medium, adjusted to an OD_{500} of 40 in CGC medium and transferred to the microplate reader. Aliquots were treated for 15 min with 10 mM DTT and 20 mM cumene hydroperoxide (CHP) for fully reduced and oxidized controls, respectively. Injection of the oxidants was performed 5 min after the start of microplate reader measurements.

For the OxD measurements along the growth curves, cells were harvested by centrifugation at different time points and washed in 100 mM potassium phosphate buffer, pH 7.0. Aliquots were treated with 20 mM CHP and 10 mM DTT for fully reduced and oxidized controls, respectively. Samples and controls were incubated with 10 mM N-ethylmaleimide (NEM) to block free thiols and transferred to microplate wells. The Mrx1-roGFP2 biosensor fluorescence emission was measured at 510 nm after excitation at 400 and 488 nm using the CLARIOstar microplate reader (BMG Labtech). The OxD of biosensor was calculated for each sample and normalized to fully reduced and oxidized controls as described previously [42,44] based to the following Eq. (1).
3. Results

3.1. The Mrx1-roGFP2 biosensor of C. glutamicum responds most specifically to MSSM in vitro

Previous studies have revealed a specific response of the Mrx1-roGFP2 biosensor to MSSM in vitro, which was based on a fusion of mycobacterial Mrx1 toroGFP2 [36]. Here we aimed to engineer a related Mrx1-roGFP2 biosensor for the MSH-producing industrially important bacterium C. glutamicum. Mrx1 (Cg0964) of C. glutamicum exhibits a similar redox-active CxxC motif and shares 46.8% and 42.1% sequence identity with Mrx1 homologs of M. tuberculosis H37Rv (Rv3198A) and M. smegmatis mc2155 (MSMEG_1947), respectively (Fig. 1AB) [27]. The principle of the Mrx1-roGFP2 biosensor oxidation is shown. Under ROS stress, MSH is oxidized to MSSM which reacts with Mrx1 to S-mycothiolated Mrx1. MSH is transferred from Mrx1 to the roGFP2 moiety leading to S-mycothiolated roGFP2 which is rearranged to the roGFP2 disulfide. The roGFP2 disulfide leads to a structural change resulting in ratiometric changes of the 400 and 488 nm excitation maxima of Mrx1-roGFP2. (D, E) The ratiometric response of the Mrx1-roGFP2 biosensor in the reduced and oxidized state in vitro (D) and after expression in C. glutamicum in vivo (E). For fully reduced and oxidized Mrx1-roGFP2, 10 mM DTT and 5 mM diamide were used in vitro as well as 10 mM DTT and 20 mM CHP in vivo (n = 5). The fluorescence excitation spectra were monitored using the microplate reader. (F) The purified Mrx1-roGFP2 biosensor (1 µM) responds most strongly to 100 µM of MSSM, but only weakly to BSSB and GSSG in vitro (n = 3). The thiol disulfides were injected into the microplate wells 60 s after the start of the measurements of the Mrx1-roGFP2 biosensor response. The control (Co) indicates the measurement of the Mrx1-roGFP2 biosensor response without thiol-disulfides. The OxD was calculated based on the 400/488 nm excitation ratio with emission measured at 510 nm. Mean values and standard error of the mean (SEM) are shown in all graphs.

Fig. 1. Structure and alignment of Mrx1 homologs, principle and specific response of the Mrx1-roGFP2 biosensor to MSSM. (A) The Mrx1 structure of C. glutamicum was modelled using SWISS-MODEL (https://swissmodel.expasy.org/) and visualized with PyMol using the template of M. tuberculosis Rv3198A (PDB code: 2LQO). The Cys12 active site and Cys15 resolving site of the CXXC motif of Mrx1 are labelled with arrows. (B) The Mrx1 homologs Cg0964 of C. glutamicum, Rv3198A of M. tuberculosis and MSMEG_1947 of M. smegmatis were aligned with ClustalW2 and presented in Jalview. Intensity of the blue color gradient is based on 50% identity. Conserved Cys residues are marked with asterisks. (C) The principle of the Mrx1-roGFP2 biosensor oxidation is shown. Under ROS stress, MSH is oxidized to MSSM which reacts with Mrx1 to S-mycothiolated Mrx1. MSH is transferred from Mrx1 to the roGFP2 moiety leading to S-mycothiolated roGFP2 which is rearranged to the roGFP2 disulfide. The roGFP2 disulfide leads to a structural change resulting in ratiometric changes of the 400 and 488 nm excitation maxima of Mrx1-roGFP2. (D, E) The ratiometric response of the Mrx1-roGFP2 biosensor in the reduced and oxidized state in vitro (D) and after expression in C. glutamicum in vivo (E).

Integrated into the genome of C. glutamicum wild type in the intergenic region between cg1121-cg1122 and placed under control of the strong P_tuf promoter using the pK18mobsacB-int plasmid as constructed previously [43]. First, the Mrx1-roGFP2 biosensor response of the purified biosensor and of the stably integrated Mrx1-roGFP2 fusion were compared under fully reduced (DTT) and fully oxidized (diamide) conditions. The Mrx1-roGFP2 biosensor fluorescence excitation spectra were similar under in vitro and in vivo conditions exhibiting the same excitation maxima at 400 and 488 nm for fully reduced and oxidized probes (Fig. 1DE). Thus, the Mrx1-roGFP2 probe is well suited to monitor dynamic E_MS changes during the growth and under oxidative stress in C. glutamicum. In addition, it was verified that purified Mrx1-roGFP2 reacts very fast and most strongly to 100 µM MSSM, although weaker responses were also observed with bacillithiol disulfide (BSSB) and glutathione disulfide (GSSG) which are, however, not physiologically relevant for C. glutamicum (Fig. 1F).

Furthermore, we assessed the direct response of Mrx1-roGFP2 and unfused roGFP2 to the oxidants H2O2 and NaOCl to compare the sensitivities of the probes for direct oxidation (Fig. 2). This was important since a previous study showed a high sensitivity of fused Grx-roGFP2 and roGFP2-Orp1 to 10-fold molar excess of 2 µM NaOCl [47]. In our in vitro experiments, the Mrx1-roGFP2 and roGFP2 probes did not respond...
to 100 µM H₂O₂ as in previous studies. Only 1–5 mM H₂O₂ lead to a direct oxidation of both probes with a faster response of the Mrx1-roGFP2 fusion. Both probes were rapidly oxidized by 10–40 µM NaOCl in vitro, and again Mrx1-roGFP2 was more sensitive to thiol-oxidation by NaOCl compared to unfused roGFP2 (Fig. 2). The rapid oxidation of roGFP2 and fused roGFP2 biosensors to low levels of HOCl is in agreement with previous studies [47] and was also observed using the Brx-roGFP2 biosensor in S. aureus [42]. The higher sensitivity of fused roGFP2 biosensors (Brx-roGFP2, Mrx1-roGFP2) to NaOCl indicates that the redox active Cys residues of Brx or Mrx1 are more susceptible for thiol-oxidation compared to the thios of roGFP2. In conclusion, our Mrx1-roGFP2 probe is highly specific to low levels of MSSM. The response of Mrx1-roGFP2 to higher levels of 1 mM H₂O₂ in vitro are not expected to occur inside C. glutamicum cells due to its known H₂O₂ resistance mediated by the highly efficient catalase.

3.2. The intracellular redox balance was affected in mutants with defects of MSH, Mtr and SigH

Next, we applied the genomically expressed Mrx1-roGFP2 biosensor to monitor the perturbations of basal level E_MSSH along the growth curve in various C. glutamicum mutant backgrounds, which had deletions of major antioxidant systems (MSH, Mtr, KatA, Tpx, Mpx) and redox-sensing regulators (OxyR, SigH) (Figs. 3 and 4). The oxidation degree was calculated in C. glutamicum wild type and mutants during the 5–12 h time points representing the log phase and transition to stationary phase in defined CGC medium. The biosensor oxidation of each C. glutamicum sample was normalized between 0 and 1 based on the fully reduced (DTT) and oxidized (CHP) controls. It is interesting to note, that C. glutamicum wildtype cells maintained a highly reducing and stable E_MSSH of ~−296 mV with little fluctuations during the log and stationary phase (Table S3). Thus, this basal level E_MSSH of C. glutamicum is very similar to that measured in M. smegmatis previously (E_MSSH of ~−300) [36].

In agreement with previous studies of bacillithiol (BSH-) and GSH-deficient mutants, the absence of MSH resulted in constitutive oxidation of the Mrx1-roGFP2 biosensor in the mshC mutant (Fig. 3A). This indicates an impaired redox state in the mshC mutant and the importance of MSH as major LMW thiol to maintain the redox balance in C. glutamicum (Fig. 3A). We hypothesize that increased levels of ROS may lead to constitutive biosensor oxidation in the MSH-deficient mutant since the mshC mutant had a H₂O₂-sensitive phenotype in previous studies [48]. The high MSH/MSSM redox balance is maintained by the NADPH-dependent mycothiol disulfide reductase Mtr which reduces MSSM back to MSH [9]. The importance of Mtr to maintain a reduced E_MSSH was also supported by our biosensor measurements which

Fig. 2. The response of the purified Mrx1-roGFP2 and roGFP2 biosensors to H₂O₂ and NaOCl in vitro. Purified Mrx1-roGFP2 and roGFP2 probes (1 µM) were treated with increasing concentrations of 0.1–5 mM H₂O₂ (A, B) and 10–40 µM NaOCl (C, D), respectively. The oxidants were injected into the microplate wells 60 s after the start of the measurements of the Mrx1-roGFP2 biosensor response as indicated by arrows. The control (Co) indicates the measurement of the Mrx1-roGFP2 and roGFP2 response without oxidants. The OxD was calculated based on the 400/488 nm excitation ratios with emission at 510 nm and related to the fully oxidized (5 mM diamide) and reduced controls (10 mM DTT). Mean values of 5 independent experiments are shown and error bars represent the SEM.
revealed an oxidative shift in \( E_{\text{MSH}} \) to \(-280.2\text{mV}\) in the \( \text{mtr} \) mutant during all growth phases (Fig. 3B, Table S3). The alternative ECF sigma factor SigH controls a large disulfide stress regulon mainly involved in the redox homeostasis, including genes for thioredoxins and thioredoxin reductases (TrxAB), mycorodoxin-1 (Mrx1) and genes for MSH biosynthesis and recycling (MshA, Mca, Mtr) [9,28,29,32]. The \( C.\) glutamicum \( \text{sigH} \) mutant showed an increased sensitivity to ROS and NaOCl stress [16,28,29]. Mrx1-roGFP2 biosensor measurements confirmed a slightly more oxidized \( E_{\text{MSH}} \) of \(-286\text{mV}\) in the \( \text{sigH} \) mutant supporting the regulatory role of SigH for the redox balance (Fig. 3C, Table S3). However, the oxidative \( E_{\text{MSH}} \) shift was lower in the \( \text{sigH} \) mutant compared to the \( \text{mtr} \) mutant. In conclusion, our Mrx1-roGFP2 biosensor results document the important role of MSH, Mtr and SigH to maintain the redox homeostasis in \( C.\) glutamicum during the growth.

In addition to MSH, \( C.\) glutamicum encodes many antioxidant enzymes that are involved in \( \text{H}_2\text{O}_2 \) detoxification and confer strong resistance of \( C.\) glutamicum to millimolar levels of \( \text{H}_2\text{O}_2 \). The \( \text{H}_2\text{O}_2 \) scavenging systems in \( C.\) glutamicum are the major vegetative catalase (KatA) and the peroxiredoxins (Tpx, Mpx). The catalase is highly efficient for detoxification at high \( \text{H}_2\text{O}_2 \) levels while Tpx and Mpx are more involved in reduction of physiological low levels of \( \text{H}_2\text{O}_2 \) generated during the aerobic growth [49]. In \( C.\) glutamicum, expression of katA is induced by \( \text{H}_2\text{O}_2 \) and controlled by the redox-sensing OxyR repressor which is inactivated under \( \text{H}_2\text{O}_2 \) stress [34]. Thus, the \( \text{oxyR} \) mutant exhibits increased \( \text{H}_2\text{O}_2 \) resistance due to constitutive derepression of katA [34]. Here, we were interested in the contribution of OxyR, and the antioxidant enzymes KatA, Tpx and Mpx to maintain the reduced basal level \( E_{\text{MSH}} \) in \( C.\) glutamicum. In all mutants with deletions of \( \text{oxyR} \), \( \text{katA} \), \( \text{tpx} \) and \( \text{mpx} \), the basal level of \( E_{\text{MSH}} \) was still highly reducing and comparable to the wild type during different growth phases (Fig. 3D, Fig. 4A–D, Table S3). Thus, we can conclude that the major antioxidant enzymes for \( \text{H}_2\text{O}_2 \) detoxification (KatA, Mpx and Tpx) do not contribute to the reduced basal \( E_{\text{MSH}} \) level in \( C.\) glutamicum during aerobic growth. These results further point to the main roles of these \( \text{H}_2\text{O}_2 \) scavenging systems under conditions of oxidative stress to recover the reduced state of \( E_{\text{MSH}} \) which was investigated in the next section.

3.3. \( \text{katA} \)-roGFP2 biosensor responses in \( C.\) glutamicum under oxidative stress in vivo

Next, we were interested to determine the kinetics of \( \text{Mrx1-roGFP2} \) biosensor oxidation in \( C.\) glutamicum under \( \text{H}_2\text{O}_2 \) and NaOCl stress and the recovery of reduced \( E_{\text{MSH}} \). \( C.\) glutamicum can survive even 100 mM \( \text{H}_2\text{O}_2 \) without killing effect which depends on the very efficient catalase KatA [34]. In accordance with the \( \text{H}_2\text{O}_2 \) resistant phenotype, the \( \text{Mrx1-roGFP2} \) biosensor did not respond to 10 mM \( \text{H}_2\text{O}_2 \) in \( C.\) glutamicum wild type cells and was only weakly oxidized by 40 mM \( \text{H}_2\text{O}_2 \) (Fig. 5A). \( C.\) glutamicum cells were able to recover the reduced \( E_{\text{MSH}} \) within 40–60 min after \( \text{H}_2\text{O}_2 \) treatment. Importantly, even 100 mM \( \text{H}_2\text{O}_2 \) did not further enhance the biosensor oxidation degree, indicating highly efficient antioxidant systems (data not shown).

In contrast, \( C.\) glutamicum was more sensitive to sub-lethal doses of NaOCl stress and showed a moderate biosensor oxidation by 0.5–1 mM NaOCl, while 1.5 mM NaOCl resulted in the fully oxidation of the probe. Moreover, cells were unable to regenerate the reduced basal level of \( E_{\text{MSH}} \) within 80 min after NaOCl exposure, which could be only restored with 10 mM DTT (Fig. 5B).
Since H₂O₂ is the more physiological oxidant in *C. glutamicum*, we studied the biosensor response under 40 mM H₂O₂ stress in the various mutants deficient for MSH and Mtr, antioxidant enzymes (KatA, Mpx, Tpx) and redox regulators (SigH, OxyR). The sigH mutant showed an increased basal level of E₅₃₈₅ of ~286 mV as noted earlier (Fig. 3C), but a similar oxidation increase with 40 mM H₂O₂ and recovery of the reduced state after 40 min compared to the wild type (Fig. 6A). The similar kinetics of biosensor oxidation and regeneration in wild type and

---

**Fig. 4.** The absence of the antioxidant enzymes KatA, Tpx and Mpx has no influence on the basal level E₅₃₈₅ during the growth of *C. glutamicum*. The basal level of E₅₃₈₅ was measured using the Mrx1-roGFP2 along the growth curve in *C. glutamicum* wild-type and ∆katA (A), ∆tpx (B), ∆mpx (C) and ∆tpxmpx (D) mutants, but was not affected compared to the wild type. OxD was calculated based on the 400/488 nm excitation ratios with emission at 510 nm and related to the fully oxidized and reduced controls. Mean values and SEM of four independent experiments are shown and p-values were calculated by the Student’s unpaired two-tailed t-test by the graph prism software (ns > 0.05; *p < 0.05; **p < 0.01; ***p < 0.001; and ****p < 0.0001).

---

**Fig. 5.** The Mrx1-roGFP2 biosensor responds weakly to H₂O₂ and strongly to NaOCl in *C. glutamicum* wild-type cells. The Mrx1-roGFP2 biosensor was weakly oxidized by 10–40 mM H₂O₂ in *C. glutamicum* wild-type (p = 0.0002 at 20 mM H₂O₂; p < 0.0001 at 40 mM H₂O₂) (A), but rapidly and fully by low doses of 0.5–1.5 mM NaOCl (p = 0.007 at 0.5 mM NaOCl; p = 0.0004 at 1.0 mM NaOCl; p < 0.0001 at 1.5 mM NaOCl) (B). While cells could recover the reduced state after 50 min of H₂O₂ exposure (A), regeneration of Mrx1-roGFP2 was not possible in NaOCl-stressed cells (B). To analyze the reversibility of Mrx1-roGFP2 oxidation in NaOCl-treated cells, 10 mM DTT was added 45 min after NaOCl exposure resulting in recovery of reduced E₅₃₈₅ (B). Mean values and SEM of three independent experiments are shown in all graphs and p-values are calculated by a Student’s unpaired two-tailed t-test by the graph prism software. The addition of oxidants to *C. glutamicum* cells was performed 5 min after the start of the measurements and is indicated by arrows. The control (Co) denotes the response of the Mrx1-roGFP2 probe inside *C. glutamicum* wild-type cells in the absence of oxidants.
**Fig. 6.** Kinetics of H$_2$O$_2$ detoxification in *C. glutamicum* mutants deficient for redox-regulators (OxyR, SigH) or antioxidant enzymes (KatA, Mpx, Tpx). The Mrx1-roGFP2 biosensor response and kinetics of recovery was analyzed under 40 mM H$_2$O$_2$ stress in *C. glutamicum* wild type and mutants deficient for the disulfide stress regulatory sigma factor SigH (A), the peroxide-sensitive repressor OxyR (B) and the catalases and peroxiredoxins for H$_2$O$_2$ detoxification (KatA, Mpx, Tpx) (C-F). The sigH mutant showed a higher E$_{S_{ox}}$ basal level of E$_{S_{red}}$, but the response and recovery under H$_2$O$_2$ stress was similar to the wild type (A). The constitutive derepression of katA in the oxyR mutant resulted in a lower Mrx1-roGFP2 biosensor response under H$_2$O$_2$ stress (p = 0.006 WT versus oxyR H$_2$O$_2$) (B). The catalase KatA is essential for H$_2$O$_2$ detoxification as revealed by the strong oxidation increase of the katA mutant and the lack of regeneration of reduced E$_{S_{ox}}$ (p < 0.0001 WT versus katA H$_2$O$_2$) (C). The Mrx1-roGFP2 biosensor response of the tpx mutant was only slightly increased under H$_2$O$_2$ stress (p = 0.0017 WT versus tpx H$_2$O$_2$) (B), but not in mpx and mpx tpx mutants (p = 0.7981 or p = 0.9489 WT versus tpx or mpx tpx H$_2$O$_2$) (D, F). Mean values and SEM of three independent experiments are shown in all graphs and p-values are obtained by a Student’s unpaired two-tailed t-test by the graph prism software. The addition of oxidants to *C. glutamicum* wild type and mutant cells was performed 5 min after the start of the measurements and is indicated by arrows. The control (Co) shows the response of the Mrx1-roGFP2 probe inside *C. glutamicum* wild type and mutant cells without H$_2$O$_2$ treatment.

sigH mutant cells may indicate that MSH is not directly involved in H$_2$O$_2$ detoxification. In contrast, the oxyR mutant showed a lower H$_2$O$_2$ response than the wild type, but required the same time of 40 min for recovery of the reduced state of E$_{S_{ox}}$ (Fig. 6B). The derepression of katA in the oxyR mutant is most likely responsible for the lower biosensor oxidation under H$_2$O$_2$ stress [34,50]. This hypothesis was supported by the very fast response of katA mutant cells to 40 mM H$_2$O$_2$ stress, resulting in full oxidation of the biosensor due to the lack of H$_2$O$_2$ detoxification in the absence of KatA (Fig. 6C). Exposure of katA mutant cells to 40 mM H$_2$O$_2$ might cause enhanced oxidation of MSH to MSSM leading to full biosensor oxidation with no recovery of the reduced state. In contrast, kinetic biosensor measurements under H$_2$O$_2$ stress revealed only slightly increased oxidation in the tpx mutant while the mpx mutant showed the same oxidation increase like the wild type (Fig. 6DE). However, the H$_2$O$_2$ response of the mpx tpx mutant was similar compared to the wild type, indicating that Tpx and Mpx do not contribute significantly to H$_2$O$_2$ detoxification during exposure to high levels of 40 mM H$_2$O$_2$ stress, while KatA plays the major role (Fig. 6F). The small oxidation increase in the tpx mutant might indicate additional roles of Tpx for detoxification of low levels of H$_2$O$_2$ as found in previous studies [51]. Altogether, our studies on the kinetics of the Mrx1-roGFP2 biosensor response under H$_2$O$_2$ stress support that KatA plays the most important role in H$_2$O$_2$ detoxification in *C. glutamicum*.

To correlate increased biosensor responses under H$_2$O$_2$ stress to peroxide sensitive phenotypes, we compared the growth of the wild type and mutants after exposure to 80 mM H$_2$O$_2$ (Fig. 7). Exposure of the wild type to 80 mM H$_2$O$_2$ did not significantly affect the growth rate indicating the high level of H$_2$O$_2$ resistance in *C. glutamicum*. Of all mutants, only the katA mutant was significantly impaired in growth under non-stress conditions and lysed after exposure to 80 mM H$_2$O$_2$ (Fig. 7C). In contrast, deletions of sigH, oxyR, tpx and mpx did not significantly affect the growth under control and H$_2$O$_2$ stress conditions (Fig. 7AB, DE). However, we observed a slightly decreased growth rate of the mpx tpx mutant in response to 80 mM H$_2$O$_2$ stress supporting the residual contribution of thiol-dependent peroxiredoxins in the peroxide stress response (Fig. 7F). Overall, the growth curves are in agreement with the biosensor measurements indicating the major role of KatA for detoxification of high levels of H$_2$O$_2$ and the recovery of cells from oxidative stress.

### 3.4. Single cell measurements of E$_{S_{ox}}$ changes under H$_2$O$_2$ stress using confocal imaging

To verify the biosensor response under H$_2$O$_2$ stress in *C. glutamicum* at the single cell level, we quantified the 405/488 nm fluorescence excitation ratio in *C. glutamicum* cells expressing stably integrated Mrx1-roGFP2 using confocal laser scanning microscopy (CLSM) (Fig. 8A). For control, we used fully reduced and oxidized *C. glutamicum* cells treated with DTT and diamide, respectively. In the confocal microscope, most cells exhibited similar fluorescence intensities at the 405 and 488 nm excitation maxima, respectively, indicating that the Mrx1-roGFP2 biosensor was equally expressed in 99% of cells. Fully reduced and untreated *C. glutamicum* control cells exhibited a bright fluorescence intensity at the 488 nm excitation maximum which was false-
colored in green, while the 405 nm excitation maximum was low and false-colored in red (Fig. 8A). In agreement with the microplate reader results, the basal $E_{\text{MSS}}$ was highly reducing and calculated as $-307$ mV for the single cell population (Fig. 8B, Table S4). Treatment of cells with 80 mM $\text{H}_2\text{O}_2$ for 20 min resulted in a decreased fluorescence intensity at the 488 nm excitation maximum and a slightly increased signal at the 405 nm excitation maximum, causing an oxidative shift of $E_{\text{MSS}}$. Specifically, the $E_{\text{MSS}}$ of control cells was increased to $-263$ mV after 20 min H$_2$O$_2$ treatment. The recovery phase could be also monitored at the single cell level after 40 and 60 min of H$_2$O$_2$ stress, as revealed by the regeneration of reduced $E_{\text{MSS}}$ of $-271$ mV and $-293$ mV, respectively (Fig. 8B, Table S4). The oxidative $E_{\text{MSS}}$ shift after H$_2$O$_2$ treatment and the recovery of reduced $E_{\text{MSS}}$ were comparable between the microplate reader measurements and confocal imaging (Fig. 8B). This confirms the reliability of biosensor measurements at both single cell level and for a greater cell population using the microplate reader.

4. Discussion

Here, we have successfully designed the first genome-integrated Mrx1-roGFP2 biosensor that was applied in the industrial platform bacterium $C.\text{ glutamicum}$ which is of high biotechnological importance. During aerobic respiration and under industrial production processes, $C.\text{ glutamicum}$ is frequently exposed to ROS, such as H$_2$O$_2$. Thus, $C.\text{ glutamicum}$ is equipped with several antioxidant systems, including $\text{MSH}$ and the enzymatic ROS-scavengers KatA, Mpx and Tpx. Moreover, Mpx and Tpx are dependent on the MSH cofactor required for recycling during recovery from oxidative stress [16,21,22]. The kinetics of H$_2$O$_2$ detoxification has been studied for catalases and peroxiredoxins in many different bacteria. However, the roles of many H$_2$O$_2$ detoxification enzymes are unknown and many seem to be redundant and not essential [49]. There is also a knowledge gap to which extent the H$_2$O$_2$ detoxification enzymes contribute to the reduced redox balance under aerobic growth conditions and under oxidative stress.

Thus, we applied this stably integrated Mrx1-roGFP2 biosensor to measure dynamic $E_{\text{MSS}}$ changes to study the impact of antioxidant systems (MSH, KatA, Mpx, Tpx) and their major regulators (OxyR, SigH) under basal conditions and ROS exposure. The basal $E_{\text{MSS}}$ was highly reducing with $-296$ mV during the exponential growth and stationary phase in $C.\text{ glutamicum}$ wild type, but maintained reduced also in the $\text{katA}$, $\text{mpx}$ and $\text{tpx}$ mutants. In contrast, the probe was strongly oxidized in $\text{mshC}$ and $\text{mtr}$ mutants indicating the major role of MSH for the overall redox homeostasis under aerobic growth conditions. While the enzymatic ROS scavengers KatA, Mpx and Tpx did not contribute to the reduced basal level of $E_{\text{MSS}}$ during the growth, the catalase KatA was essential for efficient H$_2$O$_2$ detoxification and the recovery of the reduced $E_{\text{MSS}}$ under H$_2$O$_2$ stress. In contrast, both MSH-dependent peroxiredoxins Tpx and Mpx did not play a significant role in the H$_2$O$_2$ defense and recovery from stress, which was evident in the $\text{mpx}$ $\text{tpx}$ double mutant. These results were supported by growth phenotype analyses, revealing the strongest H$_2$O$_2$-sensitive growth phenotype for the $\text{katA}$ mutant, while the growth of the $\text{mpx}$ $\text{tpx}$ double mutant was only slightly affected under H$_2$O$_2$ stress. These biosensor and phenotype results clearly support the major role of the catalase KatA for H$_2$O$_2$ detoxification.

Since expression of $\text{katA}$ is controlled by the OxyR repressor, we observed even a lower H$_2$O$_2$ response of the oxyR mutant, due to the constitutive derepression of $\text{katA}$ as determined previously [34]. In contrast, the sigH mutant showed an enhanced basal $E_{\text{MSS}}$ during...
aerobic growth, since SigH controls enzymes for MSH biosynthesis and recycling (MshA, Mca, Mtr) which contribute to reduced $E_{\text{MSH}}$ [29,32]. However, the sigH mutant was not impaired in its H$_2$O$_2$ response of Mrx1-roGFP2, since H$_2$O$_2$ detoxification is the role of KatA. Thus, we have identified unique roles of SigH and Mtr to control the basal $E_{\text{MSH}}$ level, while OxyR and KatA play the major role in the recovery of reduced $E_{\text{MSH}}$ under oxidative stress.

In previous work, the kinetics for H$_2$O$_2$ detoxification by catalases and peroxiredoxins was been measured using the unfused roGFP2 biosensor in the Gram-negative bacterium Salmonella Typhimurium [52]. The deletion of catalases affected the detoxification efficiency of H$_2$O$_2$ strongly, while mutations in peroxidases (ahpCF, tsaA) had only a minor effect on the H$_2$O$_2$ detoxifying power. These results are consistent with our data and previous results in E. coli, which showed that catalases are the main H$_2$O$_2$ scavenging enzymes at higher H$_2$O$_2$ concentrations, while peroxidases are more efficient at lower H$_2$O$_2$ doses [53]. The reason for the lower efficiency of H$_2$O$_2$ detoxification by peroxidases might be due to low NAD(P)H levels under oxidative stress that are not sufficient for recycling of oxidized peroxidases under high H$_2$O$_2$ levels [53]. Overall, these data are in agreement with our Mrx1-roGFP2 measurements in the katA, tpx and mpx mutants in C. glutamicum.
However, *C. glutamicum* differs from *E. coli* by its strong level of H$_2$O$_2$ resistance since *C. glutamicum* is able to grow with 100 mM H$_2$O$_2$ and the biosensor did not respond to 10 mM H$_2$O$_2$. In contrast, 1–5 mM H$_2$O$_2$ resulted in a maximal roGFP$^2$ biosensor response with different detoxification kinetics in *E. coli* [52]. Since the high H$_2$O$_2$ resistance and detoxification power was attributed to the catalases, it will be interesting to analyze the differences between activities and structures of the catalases of *C. glutamicum* and *E. coli*. Of note, due to its remarkable high catalase activity, KatA of *C. glutamicum* is even commercially applied at Merck (CAS Number 9001-05-2). However, the structural features of KatA that are responsible for its high catalase activity are unknown.

While our biosensor results confirmed the strong H$_2$O$_2$ detoxification power of the catalase KatA [51], the roles of the peroxiredoxins Mpx and Tpx for H$_2$O$_2$ detoxification are less clear in *C. glutamicum*. Both Tpx and Mpx were previously identified as S-mycytothiolated proteins in the proteome of NaOCl-exposed *C. glutamicum* cells [16]. S-mycytothiolation inhibited Tpx and Mpx activities during H$_2$O$_2$ detoxification *in vitro*, which could be restored by the Trx and Mrx1 pathways [16,21,22]. Moreover, Tpx displayed a gradual response to increasing H$_2$O$_2$ levels and was active as Trx-dependent peroxiredoxin to detoxify low doses H$_2$O$_2$, while high levels H$_2$O$_2$ resulted in overoxidation of Tpx [51]. Overoxidation of Tpx caused oligomerization to activate the chaperone function of Tpx. Since mpx and katA are both induced under H$_2$O$_2$ stress, they were suggested to compensate for the inactivation of Tpx for detoxification of high doses of H$_2$O$_2$. Previous analyses showed that the katA and mpx mutants are more sensitive to 100–150 mM H$_2$O$_2$ [21,22]. In our analyses, the mpx mutant was not more sensitive to 80 mM H$_2$O$_2$ and displayed the same H$_2$O$_2$ response like the wild type, while the katA mutant showed a strong H$_2$O$_2$ sensitivity and responded strongly to H$_2$O$_2$ in the biosensor measurements. Thus, our biosensor and phenotype results clearly support the major role of KatA in detoxification of high doses H$_2$O$_2$ in vivo.

Finally, we confirmed using confocal imaging further that the genomically expressed Mrx1-roGFP$^2$ biosensor shows equal fluorescence in the majority of cells indicating that the biosensor is suited for industrial application to quantify $E_{MSH}$ changes in *C. glutamicum* at the single cell level or under production processes. Previous Mrx1-roGFP$^2$ biosensor applications involved plasmid-based systems which can result in different fluorescence intensities within the cellular population due to different copy numbers. Moreover, plasmids can be lost under long term experiments when the selection pressure is decreased due to degradation or inactivation of the antibiotics.

We also compared the fluorescence intensities of the plasmid-based expression of Mrx1-roGFP$^2$ using the IPTG-inducible pEKEx2 plasmid with the stably integrated Mrx1-roGFP$^2$ strain in this work (Fig. S1). Using confocal imaging, the plasmid-based Mrx1-roGFP$^2$ biosensor strain showed only roGFP$^2$ fluorescence in < 20% of cells, while the genomically expressed biosensor was equally expressed and fluorescent in 99% of cells. The integration of the Mrx1-roGFP$^2$ biosensor was performed into the cg1121–1122 intergenic region and the biosensor was expressed from the strong P$_{pef}$ promoter using the plK18mobsacB construct designed previously for an Lrp-biosensor to measure L-valine production [54]. Previous live cell imaging using microfluidic chips revealed that only 1% of cells with the Lrp-biosensor were non-fluorescent due to cell lysis or dormancy [54]. Thus, expression of roGFP$^2$ fusions from strong constitutive promoters should circumvent the problem of low roGFP$^2$ fluorescence intensity after genomic integration. The advantage and utility of a stably integrated Grxl-roGFP$^2$ biosensor has been also recently demonstrated in the malaria parasite *Plasmodium falciparum* which can circumvent low transfection frequency of plasmid-based roGFP$^2$ fusions [55]. Moreover, quantifications using the microplate reader are more reliable, less time-consuming and reproducible with strains expressing genomic biosensors compared to measurements using confocal microscopy [55]. Thus, stably integrated roGFP$^2$ biosensors should be the method of the choice for future applications of roGFP$^2$ fusions to monitor redox changes in a greater cellular population.

In conclusion, in this study we designed a novel Mrx1-roGFP$^2$ biosensor to monitor dynamic $E_{MSH}$ changes in *C. glutamicum* during the growth, under oxidative stress and in mutants with defects in redox-signaling and H$_2$O$_2$ detoxification. This probe revealed the impact of Mrx and SigH to maintain highly reducing $E_{MSH}$ throughout the growth and the main role of KatA and OxyR for efficient H$_2$O$_2$ detoxification and the regeneration of the redox balance. This probe is now available for application in engineered production strains to monitor the impact of industrial production of amino acids on the cellular redox state. In addition, the effect of genome-wide mutations on $E_{MSH}$ changes can be followed in *C. glutamicum* in real-time during the growth, under oxidative stress and at the single cell level.
