Wnt-5a-CKIα Signaling Promotes β-Catenin/E-Cadherin Complex Formation and Intercellular Adhesion in Human Breast Epithelial Cells

Received for publication, June 27, 2008, and in revised form, February 24, 2009. Published, JBC Papers in Press, February 25, 2009, DOI 10.1074/jbc.M804923200

Wnt-5a is a non-transforming Wnt protein that is implicated in cell polarity, adhesion, and motility. We have previously shown that low expression of Wnt-5a is a predictor of shorter disease-free survival in human breast cancer. Here, we investigated whether β-catenin/E-cadherin-mediated cell-cell adhesion was affected by loss of Wnt-5a in breast carcinomas, thereby promoting a metastatic behavior of the tumor. We show that Wnt-5a stimulation of human breast epithelial cells leads to an increased Ca²⁺-dependent cell-cell adhesion. Furthermore, Wnt-5a/casein kinase Iα (CKIα)-specific Ser-45 phosphorylation of β-catenin is associated with an increased complex formation of β-catenin/E-cadherin. Mutation of Ser-45 decreases the β-catenin/E-cadherin association. Also, the inhibitory effect of Wnt-5a on breast epithelial cell invasion is reduced upon mutation of β-catenin-Ser-45. The Wnt-5a-CKIα-induced Ser-45 phosphorylation does not lead to degradation of β-catenin. Finally we show that human breast cancers lacking Wnt-5a protein have a significantly lower level of membrane-associated β-catenin. Down-regulation of Wnt-5a expression and subsequent reduction of membrane-associated β-catenin in invasive breast cancer, can therefore contribute to a decreased cell-cell adhesion and increased motility resulting in a higher probability for metastatic disease.

In a normal mammary gland the ducts are lined with epithelial cells that are both interconnected and connected to the basement membrane. Mutations in genes encoding adhesion molecules have been implicated in the progression of breast cancer (1). E-cadherin is a transmembrane, calcium (Ca²⁺)-dependent adhesion molecule that connects adjacent epithelial cells. The loss of cell-cell adhesion at the original tumor site has been suggested to be related to the loss of E-cadherin expression or function in many epithelial cancers (2). The E-cadherins are dynamically linked to the cytoskeleton via β-catenin, plakoglobin, p120, and α-catenin (3, 4). Mutations in the E-cadherin gene are frequent in invasive lobular breast cancers, whereas they are absent or might occur at a low frequency in the more common invasive ductal breast carcinomas (5). Despite this, a low membrane expression of β-catenin was recently shown to be associated with a poor outcome in human breast cancer patients (6). The question as to whether Wnt β-catenin signaling can affect E-cadherin-dependent cellular adhesion, or vice versa, has long been debated (7).

β-Catenin plays a role both in the β-catenin/E-cadherin complex and as a transcriptional regulator in the nucleus upon canonical Wnt signaling (reviewed in Ref. 8). There are therefore three different pools of β-catenin; a membrane bound, a cytoplasmic that is constantly being phosphorylated and targeted for ubiquitination and degradation, and a nuclear unphosphorylated form. It has previously been suggested that β-catenin targeted to adhesive or transcriptional complexes have distinct molecular forms that would allow it to coordinate the two processes (9). However, the mechanisms that target β-catenin to adhesive complexes have not yet been described. It is known that the association between β-catenin/E-cadherin is increased when E-cadherin is phosphorylated on serine residues 834, 836, and 842 (8). GSK-3β and CK2 have been implicated as potential kinases. In contrast, phosphorylation of serine 846 by CKI and tyrosine phosphorylation of both β-catenin and E-cadherin association (10, 11), although conflicting data are present (12). Still, there is little evidence concerning β-catenin phosphorylation and E-cadherin association. In a recent review (8) it was suggested that the interaction might be affected by Wnt signals because the CK1, CK2, and GSK-3β kinases are part of this pathway.

Members of the Wnt family are signaling proteins that are involved in many differentiation events (13). They can be divided into three different classes based on experiments performed in C57MG mammary myoepithelial cells (14), the transforming (Wnt-1, Wnt-2, Wnt-3, and Wnt-3a), the weakly transforming (Wnt-6 and Wnt-7a), and the non-transforming group (Wnt-4, Wnt-5a, Wnt-5b, and Wnt-7b). The transforming Wnt proteins signal via the canonical β-catenin pathway and activate TCF/LEF-dependent transcription. In the absence

2 The abbreviations used are: GSK-3β, glycogen synthase kinase-3β; CK, casein kinase; APC, adenomatous polyposis coli; DMEM, Dulbecco’s modified Eagle’s medium; rWnt-5a, recombinant Wnt-5a.
of a Wnt signal, β-catenin is targeted for ubiquitination and degradation by a complex consisting of CKIα, GSK-3β, APC, and Axin (APC-Axin-destruction complex) (15). Upon Wnt signaling this complex is inactivated and β-catenin is accumulated in the cytosol, thereby leading to nuclear redistribution (7). In the present study we will focus on the role of the non-transforming Wnt-5a. Wnt-5a primarily activates distinct non-canonical pathways, including the Wnt/Ca²⁺ signaling pathway (16). The Wnt-5a protein has been shown to be involved in cell adhesion, motility, and polarity (17, 18), processes that are known to relate to the β-catenin/E-cadherin complex.

We have previously shown that expression of Wnt-5a is a prognostic factor for longer disease-free survival in human breast cancer (19, 20). It was further shown that a low Wnt-5a expression led to a decreased adherence of the cells to collagen and increased motility of ductal breast epithelial cells (21). Together, these data indicate that loss of Wnt-5a protein expression might be involved in the initial de-adhesion events of metastasis in invasive breast carcinomas. The role for Wnt-5a as a prognostic marker has now been confirmed in several other cancers (22–24). However, the present available data concerning how Wnt-5a affects Ca²⁺-dependent intercellular adhesion (E-cadherin) (25), does not match the clinical findings. In this study we show that in contrast to previous data, but in line with clinical findings, the non-transforming Wnt-5a protein actually increases the Ca²⁺-dependent intercellular adhesion in human breast epithelial cells by affecting the cellular distribution and function of β-catenin.

**EXPERIMENTAL PROCEDURES**

**Cell Culture**—We used the human breast cancer cell line MCF-7 and the non-cancerous mammary epithelial cell line HB2, which is a subclone of the MTSV-7 cell line originating from the laboratory of Dr. J. Taylor-Papadimitriou (ICRF, UK) and 4T1 mouse mammary cancer cells (from ATCC). The following clones, which had previously been produced in our laboratory (21) were used: Wnt-5a, overexpressing cells stably transfected with a pLNCX Wnt-5a-HA vector (Wnt-5ahigh HB2 or MCF-7 cells), Wnt-5a-antisense cells obtained by transfecting with a pLNCX vector containing the Wnt-5a cDNA in the antisense direction (3′–5′; Wnt-5alow HB2 cells).

**Chemicals and Reagents**—Antibodies directed against Ser(P)-45 and Ser(P)-33/37/41 β-catenin were from Cell Signaling (Beverly, MA), anti-β-catenin and E-cadherin from BD Transduction Laboratories (Franklin Lakes, NJ), the anti-E-cadherin antibody for immunoprecipitations and immunofluorescence was clone SHE 78-7 from Axxora (Takara, Shiga, Japan), anti-FLAG (Sigma), anti-pan phospho-Ser/Thr (BD Chemicals and Reagents), anti-pan phospho-Ser/Thr (BD Chemicals and Reagents), and anti-pan phospho-Ser/Thr (BD Chemicals and Reagents) from R&D Systems (Minneapolis, MN) and was used at a concentration of 10 μM for 5 h prior to cell lysis, and the protease inhibitor N-ethylmaleimide (Sigma) was used at a concentration of 10 mM in the lysis buffer.

**Tumor Samples**—Samples were collected from primary tumors that had been removed from 94 consecutive patients with invasive breast carcinoma. Of the 94 tumors, 85 were ductal, four mucinous, two medullar, and three lobular. According to the classification system of the International Union against Cancer, 23 patients had stage I, 56 patients stage II, one patient stage III, and six patients stage IV breast carcinomas. In eight patients, the stage of the disease was not known due to a lack of data on tumor size or axillary node status. None of the patients had received radiation treatment or chemotherapy before surgery. Tissue samples were fixed in formalin, embedded in paraffin, and used for routine morphological examination (grading and immunostaining) and construction of tumor tissue arrays. To ensure that clearly defined areas of malignant tissue were used in the arrays, for each tumor sample, a slide with a fresh tissue section was prepared from the paraffin block and stained with hematoxylin. Areas including representative tumor cells were identified and marked, and two biopsies (Ø 0.6 mm (diameter)) corresponding to the marked areas on the slide were taken from each paraffin block. These biopsies were remounted in a new paraffin block in a tissue array machine according to the manufacturer’s instructions (Becher Instruments, MD). At the time of analysis of membrane-associated β-catenin, 24 random tumors were lost from the paraffin block and thus 70 tumors were left to analyze.

**Immunohistochemistry**—Immunohistochemistry was performed as previously described (20). The antibodies were Wnt-5a (19) and β-catenin (Sigma). Two independent observers (G. L. and C. M.), with no knowledge of the clinical outcome, evaluated the stained slides. The tumors were graded based on the intensity of the staining: for Wnt-5a (0, 1, 2, and 3) immunoreactivity equivalent to that seen in: 3, normal epithelial cells; 2, immunoreactivity moderately decreased; 1, weak immunoreactivity; 0, no immunoreactivity; and for membrane-associated β-catenin (0, 1, 2, and 3); 3, high immunoreactivity in the membrane; 2, normal immunoreactivity; 1, immunoreactivity moderately decreased; 0, weak immunoreactivity (Table 1 and Fig. 1A). In the histogram (Fig. 1A) the gradings (0 and 1) were viewed as β-cateninlow tumors and gradings (2 and 3) as β-cateninhigh tumors. For statistical analysis a Chi-square test was used and the linear to linear association between Wnt-5a and membrane-bound β-catenin was assessed.

**Membrane Fractionation**—Adherent cells were lysed and incubated for 30 min in 350 μl of lysis buffer A containing 20 mM Hapes, pH 8, 2 mM MgCl₂, 1 mM EDTA, 5 mM Na₃VO₄, 0.6 mM pefabloc, and 4 μg/ml leupeptin. The cells were further lysed with a homogenizer 25 times and centrifuged for 10 min at 500 × g. The supernatants were collected, centrifuged for 10 min at 10,000 × g, and collected again and centrifuged for 5 min at 10,000 × g, before ultracentrifuged for 1 h at 200,000 × g. The pellets (plasma membrane) were suspended in lysis buffer A and the protein concentrations were measured.

**Immunoprecipitation and Western Blotting**—Adherent cells were lysed in lysis buffer containing 50 mM Tris, pH 7.4, 1%
Wnt-5a Affects β-Catenin/E-Cadherin

Nonidet P-40, 5 mM EDTA, 5 mM EGTA, 50 mM NaCl, 5 mM sodium fluoride, 1 mM Na3VO4, 20 μg/ml aprotinin, 1 μg/ml leupeptin, 2.5 mM benzamidine, and 2 mM pefabloc. For immunoprecipitations, Protein A-Sepharose beads (Amersham Biosciences) were added and the lysates were precleared for 30 min. Thereafter specific antibodies were added for 5 min prior to addition of new Protein A-Sepharose beads with incubation at 4 °C for 1 h. The beads were washed six times in Heps pH 7.5, wash buffer with 1 mM Na3VO4.

Transient Transfections—Wnt-5a(low) and Wnt-5a(high) HB2 or MCF-7 cells were transfected with Oligofectamine or Lipofectamine streptomycin, 4 mM L-glutamine, 10 mM Hepes, and 20% serum-free medium and then washed and incubated in methionine-stabilized aqueous solution, Easy tag precipitation experiments wild type β-catenin, Ser-45Δβ-catenin, and Ser-33Δβ-catenin, kindly provided by Professor David Rimm, were used. At the end of the transfection the cells were either left untreated or stimulated with rWnt-5a (20 nM; R&D Systems) as indicated, and subsequently immunoprecipitated with an anti-FLAG antibody. The coprecipitated proteins were analyzed by Western blots using E-cadherin and β-catenin-specific antibodies. The kinase-deficient CK1α mutants pCS2-CK1α 2-K46A, pCS2-CK1α 2-D136N, and pCS2-CK1α 2-D136N-K138E were kind gifts from Professor Jiandong Chen (26).

Pulse-Chase—Wnt-5a(low) HB2 cells were starved overnight in serum-free medium and then washed and incubated in methionine-free DMEM (Invitrogen) supplemented with heat-inactivated fetal bovine serum, 100 units/ml penicillin, 100 units/ml streptomycin, 4 mM L-glutamine, 10 mM Hepes, and 20 μCi/ml L-[35S]methionine-stabilized aqueous solution, Easy tag (PerkinElmer Life Sciences) for 2 h. Thereafter cold DMEM plus 2 mM methionine were added. Cells were stimulated with rWnt-5a, LiCl, and harvested after 0 and 2 h. Lysates were subjected to immunoprecipitation using an antibody against β-catenin. Radiolabeled β-catenin was visualized and quantified using a Fuji LAS3000 phosphorimager and Multigauge software (Fujifilm, Tokyo, Japan).

Immunofluorescence—Wnt-5a(high) or Wnt-5a(low) cells were seeded on glass coverslips. The cells were fixed in freshly prepared 4% paraformaldehyde for 15 min, permeabilized in phosphate-buffered saline, 0.5% Triton X-100 for 15 min, and then blocked in 3% bovine serum albumin, phosphate-buffered saline for 1 h at room temperature. Staining was done with anti-E-cadherin (SHE 78-7), anti-β-catenin or isotype control antibodies in 1% bovine serum albumin, phosphate-buffered saline and with secondary anti-rabbit Alexa Fluor 488. The coverslips were mounted in fluorescent mounting medium (DAKO A/S), and examined and photographed in a Nikon Eclipse 800 microscope, using a ×60 objective. Images were recorded with a scientific-grade, charge-coupled device (CCD) camera (Hamamatsu, Japan) and analyzed with HazeBuster deconvolution software (VayTek, Inc., Fairland, CT).

Cell Aggregation—Wnt-5a(high) or Wnt-5a(low) HB2 cells were detached by treatment with Versene. The cells were washed in phosphate-buffered saline and then resuspended in Ca2+ low (10 μM CaCl2; DMEM, 10% fetal calf serum, 4 mM EGTA, 1 mM MgCl2) or Ca2+ high (1.8 mM CaCl2; DMEM, 10% fetal calf serum) medium. Approximately 5 × 105 cells/ml and sample were rocked gently in an Eppendorf tube for 1 h in a normal cell incubator. The cells were then poured into a 12-well plate and viewed under a light microscope. Approximately 1500 cells were counted from each well and the number of aggregates was estimated. 200 μl was taken from each sample and propidium iodide was added for 20 min prior to analysis using a FACS Calibur flow cytometer (n = 6, standard bars = S.E.).

Ca2+-induced Cell-Cell Adhesion—Confluent Wnt-5a(low) HB2 cells were quickly washed with Versene and subsequently with Ca2+ low medium (10 μM CaCl2; DMEM, 10% fetal calf serum, 4 mM EGTA, 1 mM MgCl2). The cells were viewed under a microscope to assure that the cell-cell contacts were disrupted (~1 min). Thereafter Ca2+ high (1.8 mM CaCl2; DMEM, 10% fetal calf serum) medium was added to the cells in the presence or absence of rWnt-5a and incubated for 1 h prior to lysis. In the wells containing Ca2+ high medium the cell-cell contacts had clearly been re-established during this time, whereas in the control wells with Ca2+ low medium no cell-cell contacts were present.

Matrigel Invasion Assays—Invasion assays were carried out using Matrigel invasion chambers (BD) with 8.0-μm pore size membranes in 24-well plates. Transiently transfected (48 h) Wnt-5a(low) HB2 cells were harvested, washed, and resuspended at a concentration of 5 × 105 cells/ml in serum-free culture media. Serum containing medium (10% fetal calf serum) was added to the lower well and 0.5 ml (2.5 × 105 cells) of the cell suspension, containing recombinant Wnt-5a (0.8 μg/ml) where indicated, was added to the invasion chamber, and the cells were allowed to invade for 72 h. Cells that had invaded through the Matrigel were fixed (4% paraformaldehyde), stained with crystal violet (Sigma), and counted. The lower wells were always checked for cells to ensure that the experiments were stopped at the appropriate time. Transfection procedures were as described above, and the transfection efficiency (FLAG-β-catenin) and endogenous levels of β-catenin were evaluated using Western blot of β-catenin on 6% SDS gels.

RESULTS

Wnt-5a Increases the Intercellular Adhesion in Human Breast Epithelial Cells—To experimentally investigate the effects of Wnt-5a on Ca2+-dependent intercellular adhesion in human ductal breast epithelial cells, we initially investigated whether Wnt-5a signaling affected intercellular adhesion of a non-cancerous ductal breast epithelial cell line (HB2, see “Experimental Procedures”) that was either stably transfected with antisense Wnt-5a (HB2 Wnt-5a(low)) or with Wnt-5a (HB2 Wnt-5a(high)) (21). To this end, we analyzed the fraction of large cell aggregates formed upon slow rocking of single cell suspensions in Ca2+-depleted and Ca2+-containing medium for 1 h (Fig. 1A, Ca2+low and Ca2+high). We found that Wnt-5a(high) HB2 cells formed more aggregates as compared with Wnt-5a(low) HB2 cells in the presence of extracellular Ca2+ (Fig. 1A) without affecting the amount of dead cells (data not shown).
Wnt-5a Affects β-Catenin/E-Cadherin

Wnt-5a Induces β-Catenin Membrane Association—To investigate whether the Wnt-5a-induced increase in intercellular adhesion was mediated by the β-catenin/E-cadherin complex we analyzed the membrane association of β-catenin in human breast epithelial cells using immunofluorescence with β-catenin-specific antibodies. We used two cell lines, the noncancerous human ductal breast epithelial cell line (HB2) and the MCF-7 ductal breast cancer cell line, that again were either stably transfected with antisense Wnt-5a (HB2 Wnt-5a(low)) or with Wnt-5a (HB2 Wnt-5a(high) and MCF-7(high)) (21). All experiments were confirmed by using recombinant Wnt-5a (rWnt-5a). The advantage of using both Wnt-5a overexpressing cells (HB2 Wnt-5a(high) and MCF-7(high)) and stimulating HB2 Wnt-5a(low) cells with rWnt-5a is that the overexpressing cells have a continuous release of Wnt-5a, whereas a prompt rWnt-5a treatment gives us a better opportunity to directly analyze Wnt-5a-specific cell signaling cascades. Interestingly, in HB2 Wnt-5a(low) cells and in HB2 Wnt-5a(high) cells that were treated with rWnt-5a (2.5 h), the increase in membrane-associated β-catenin was substantial (Fig. 1B). Wnt-5a treatment also led to an altered morphology of the cells with membrane protrusions, suggesting initiation of intercellular contacts (Figs. 1B and 2A). We did not detect significant differences in nuclear β-catenin (Fig. 1B). Also in the breast cancer cell line MCF-7, an increased membrane association of β-catenin was found upon Wnt-5a expression (MCF-7(high)) or treatment with rWnt-5a (Fig. 1B, lower panel).

The same results were obtained using immunofluorescence with E-cadherin-specific antibodies (Fig. 2A). We next performed membrane fractionations using α-tubulin as a control for the cytosolic fractions and caveolin as control for the membrane fractions (Fig. 2B). As shown in Fig. 2B, the levels of β-catenin in the cell membrane were significantly elevated in HB2 Wnt-5a(high) cells compared with HB2 Wnt-5a(low) cells. When the membrane fractions were analyzed for E-cadherin we found a profound increase in the levels of membrane-associated E-cadherin (Fig. 2B). Neither the protein nor mRNA levels of β-catenin or E-cadherin were affected by a short (2.5 h) stimulation with rWnt-5a in human breast epithelial cells. This indicates that the increased membrane level of β-catenin was not caused by a general increase in β-catenin expression. In line with this, TCF/LEF reporter assays using the TOPflash/FOPflash reporters in human breast epithelial cells indicated that Wnt-5a signaling did not induce canonical β-catenin signaling (supplemental materials Fig. S1A and Ref. 16).

Wnt-5a Induces an Increased β-Catenin/E-Cadherin Complex Formation—To investigate the underlying mechanism responsible for the Wnt-5a-induced membrane association of β-catenin, we performed co-immunoprecipitations of β-catenin and E-cadherin. We found an increased association of E-cadherin to β-catenin both in HB2 Wnt-5a(high) cells and in HB2 Wnt-5a(low) cells treated with rWnt-5a for 2.5 h (Fig. 3, A and B, left panel). The Wnt-5a-induced association occurred already after 1 h of treatment with rWnt-5a (Fig. 3A). This was

also seen in the breast cancer cell line MCF-7 either treated with rWnt-5a for 2.5 h, or constitutively overexpressing Wnt-5a (MCF-7 Wnt-5a\textsubscript{high}; Fig. 3B, right panel).

Wnt-5a Does Not Affect Tyrosine Phosphorylation of β-Catenin—β-Catenin can be tyrosine phosphorylated at two residues, Tyr(P)-142 and Tyr(P)-691. Previous studies suggest that one of the phosphorylated tyrosines leads to dissociation from α-catenin, whereas the other leads to dissociation from the E-cadherin complex (27). To explore whether Wnt-5a signaling can affect the association of β-catenin to E-cadherin by affecting the tyrosine phosphorylations of β-catenin, we performed immunoprecipitation studies of total β-catenin from HB2 Wnt-5a\textsubscript{low} and Wnt-5a\textsubscript{high} cells treated with rWnt-5a (Fig. 3C). However, we did not see a reduced tyrosine phosphorylation of β-catenin. The experiment was also performed comparing HB2 Wnt-5a\textsubscript{low} and HB2 Wnt-5a\textsubscript{high} cells with the same result (data not shown).

Wnt-5a-induced Serine Phosphorylation of β-Catenin Leads to an Increased E-Cadherin Complex Formation—It has been suggested that phosphorylation of specific Ser/Thr residues on β-catenin can increase the binding of β-catenin to E-cadherin (7, 8). To investigate whether β-catenin is serine/threonine phosphorylated upon Wnt-5a treatment we performed new immunoprecipitations of β-catenin and analyzed the phosphoserine/threonine levels (Fig. 3D). We could detect an increased phosphorylation of serine/threonine both in HB2 Wnt-5a\textsubscript{high} cells and Wnt-5a\textsubscript{low} cells treated with rWnt-5a.

The serine/threonine kinase CKI has previously been shown to phosphorylate β-catenin-Ser-45 in the absence of canonical Wnt signaling (28), but also to phosphorylate E-cadherin on Ser-846, hence leading to a decreased association to β-catenin (11). However, there are conflicting data as to whether CKI activity actually is negative for the β-catenin/E-cadherin interaction (11, 12). We have previously shown that Wnt-5a activates CKIα in human breast epithelial cells (16). Interestingly, upon addition of the selective CKIα/e inhibitor (IC261), we saw a small reduction in phosphoserine/threonine levels of β-catenin (Fig. 3D). More importantly, this only occurred in cells stimulated with Wnt-5a.

The Wnt-5a-induced β-catenin/E-Cadherin complex formation was also inhibited upon addition of the CKI inhibitor (Fig. 4A). Again, this was Wnt-5a specific because the HB2 Wnt-5a\textsubscript{low} cells treated with the CKI inhibitor did not show a decreased complex formation (see below). The complex formation was inhibited after a 1-h treatment with CKI inhibitor and had virtually disappeared after 2.5 h. Interestingly, and in line with a recent study mentioned above (11), treatment with the CKI inhibitor in cells lacking Wnt-5a signaling rather led to an increased complex formation of E-cadherin to β-catenin (Fig. 4, A and C, left). In rWnt-5a-stimulated cells where CKI had only been inhibited for 0.5 h (Fig. 4B) we still have an increased β-catenin association to E-cadherin, indicating that the induced β-catenin/E-cadherin complex formation indeed is Wnt-5a specific, and due to its activation of CKI. As seen in supplemental materials Fig. S1B, the overall β-catenin and E-cadherin levels were not reduced upon treatment with the CKI inhibitor at the time points used in the experiments, although at 12 h a reduction of E-cadherin levels could be observed. Finally, we could also show that the Wnt-5a/CKI-induced β-catenin/E-cadherin complex formation was induced in breast cancer cell lines treated with rWnt-5a (Fig. 4C, left, MCF-7; and right, 4T1 mouse mammary cancer cells lacking endogenous Wnt-5a; for statistics see supplemental materials Fig. S2A).
**Wnt-5a Affects β-Catenin/E-Cadherin**

![Graphs and data](image)

Wnt-5a/Cki-induced β-Catenin Ser-45 Phosphorylation Correlates with an Increased β-Catenin/E-Cadherin Complex Formation—It is well established that Ckiα induces phosphorylation of Ser-45 on β-catenin (28, 29). However, it has to our knowledge not been shown that a non-canonical Wnt can induce this Ser-45 phosphorylation. We have previously shown that Wnt-5a activates Ckiα in human breast epithelial cells (16), an observation that was recently confirmed in dopaminergic neurons (30). Upon stimulation with Wnt-5a we observed a distinct increase in Ser-45 phosphorylation in Wnt-5alow cells treated with rWnt-5a and a higher level of Ser-45 phosphorylation in HB2 Wnt-5ahigh cells (Fig. 5A). The elevated levels were abolished upon addition of the Cki inhibitor. More importantly, the levels of co-precipitated E-cadherin correlated well with Ser-45 phosphorylation of β-catenin (Fig. 5A). We also performed reverse co-immunoprecipitations with an antibody toward E-cadherin (supplemental materials Fig. S1C) but the levels of coprecipitated β-catenin were constant. However, the level of Ser-45 phosphorylation varied in accordance with previous results. We do not know the reason for this observation, but we suspect that the only antibody available for immunoprecipitation of E-cadherin (SHE 78-7, recognizing its ectodomain) only detects E-cadherin bound to β-catenin, because unbound E-cadherin is degraded (31). To confirm that the Wnt-5a-induced Ser-45 phosphorylation of β-catenin was caused by Ckiα we transfected Wnt-5ahigh cells with three different kinase-deficient mutants of Ckiα (pCS2-Ckiα2-K46A, pCS2-Ckiα2-D136N, and pCS2-Ckiα2-D136N-K138E). These behave differently as it was previously shown that Ckiα2-K46A had lost the ability to not only phosphorylate but also to bind its target protein (26). As shown in Fig. 5B, only overexpression of the kinase-deficient pCS2-Ckiα2-K46A plasmid inhibited Ser-45 phosphorylation of β-catenin by Wnt-5a. In support of this, the Wnt-5a-induced increase in β-catenin/E-cadherin complex formation also was inhibited upon expression of pCS2-Ckiα2-K46A (Fig. 5C).

An Increased Intercellular Adhesion Does Not Induce β-Catenin Ser-45 Phosphorylation per se—Because it is known that Wnt-5a increases cell-extracellular adhesion by various mechanisms it was important to analyze whether an increased cell-cell adhesion per se could induce β-catenin Ser-45 phosphorylation on its own. We therefore performed Ca²⁺-switch experiments to experimentally induce Ca²⁺-dependent E-cadherin phosphorylation...

**FIGURE 4. A**, the Wnt-5α-induced β-catenin/E-cadherin complex formation is specifically inhibited by the CKI inhibitor only in cells treated with, or expressing, Wnt-5α. The blot shown is representative of several separate experiments and OD measurements of the band intensities were performed to quantify the differences (lower panel, histograms). Error bars indicate S.E., n = 8; *, p < 0.05; **, p < 0.01. B, time kinetics of treatment with the CKI inhibitor indicates that Wnt-5α is upstream of CKI in induction of β-catenin/E-cadherin complex formation (n = 3). C, the Wnt-5α/CKI induced β-catenin/E-cadherin complex formation is also seen in two different breast cancer cell lines: MCF-7 (left) and 4T1 (right). The blot shown is representative of several separate experiments and OD measurements of the band intensities were performed to quantify the differences (supplemental Fig. S2A). WB, Western blot; IP, immunoprecipitate.

herin/E-cadherin interactions and analyzed the grade of β-catenin Ser-45 phosphorylation in the absence or presence of rWnt-5α (1 h). Interestingly, Ca²⁺-deprived cells that just recently (5 min) lost cell-cell contacts show a clear phosphorylation of β-catenin Ser-45 (Fig. 5D). However, reintroduction of Ca²⁺-dependent cell-cell contacts led to a decreased β-catenin Ser-45 phosphorylation (1 h) in the absence of rWnt-5α (Fig. 5D). Importantly, the addition of Wnt-5α still led to a clear β-catenin Ser-45 phosphorylation indicating that Wnt-5α indeed phosphorylates β-catenin on Ser-45 (Fig. 5D). In an attempt to understand why β-catenin became Ser-45 phosphorylated upon Ca²⁺ deprivation, we next performed co-immunoprecipitations of E-cadherin in Ca²⁺-deprived cells, or cells where Ca²⁺-dependent cell-cell contacts had been reintroduced, with or without rWnt-5α stimulation. As seen in Fig. 5E, the β-catenin that associated with E-cadherin was not Ser-45 phosphorylated after Ca²⁺ deprivation, indicating that the Ser-45-phosphorylated β-catenin in Ca²⁺-deprived cells was cytosolic. In contrast, in cells where Ca²⁺-dependent cell-cell contacts had been reintroduced the E-cadherin-associated β-catenin was Ser-45 phosphorylated. As previously mentioned, it is not possible to compare the levels of coprecipitated β-catenin using the (SHE 78-7) E-cadherin ectodomain antibody. Nevertheless, we conclude that the Ser-45-phosphorylated β-catenin in Ca²⁺-deprived cells is most likely due to an increased level of cytosolic, degrading β-catenin as a result of disruption of Ca²⁺-dependent cell-cell contacts. Thus, the increase in β-catenin Ser-45 phosphorylation seen in Fig. 5D is indeed induced by Wnt-5α.

**Wnt-5α Signaling Does Not Lead to β-Catenin Degradation in Human Breast Epithelial Cells**—Because we found that β-catenin is phosphorylated on Ser-45 by Wnt-5α/CKIα signaling in human mammary epithelial cells and that it is known since before that Wnt-5α could inhibit canonical Wnt-β-catenin signaling through β-catenin degradation (32), it was important to control whether β-catenin is targeted for degradation upon Wnt-5α signaling. Initially, we performed Western blots using Ser(P)-33/Ser(P)-37/Thr(P)-41 β-catenin-specific antibodies of cell lysates from Wnt-5α-low cells stimulated or not with rWnt-5α for 2.5 h and Wnt-5α-high HB2 cells. We did not see an increased phosphorylation of β-catenin Ser-33/Ser-37/Thr-41 (Fig. 6A). We next performed co-immunoprecipitations of Axin to investigate whether the Wnt-5α/CKIα-induced β-catenin Ser-45 phosphorylation could occur in the classical Wnt destruction complex (supplemental materials Fig. S1D). The association of both CKIα and β-catenin with Axin were slightly induced upon Wnt-5α signaling supporting that the Wnt-5α-induced Ser-45 phosphorylation of β-catenin occurs in the conventional APC-Axin-destruction complex in the cytosol. We next analyzed the effects of Wnt-5α on β-catenin ubiquitination, using protease inhibitors (Fig. 6B, upper panel, loading control). In line with the previous results we could not detect an increased level of ubiquitinated β-catenin upon Wnt-5α treatment (lower panel). Finally we performed pulse-chase experiments to verify whether Wnt-5α affects degradation of β-catenin in human breast epithelial cells or not. As shown in Fig. 6C degradation of β-catenin in human breast epithelial cells was similar in untreated and Wnt-5α-treated cells at the time points used in this study (2.5 h). The experiment was also performed using longer chase periods with similar results (data not shown). This is in agreement with the finding that we observed similar levels of β-catenin protein in resting compared with Wnt-5α-stimulated cells. Together this indicates that Wnt-5α induces Ser-45 phosphorylation of β-catenin in human breast epithelial cells, but neither induces a GSK-3β nor Siah-2-specific degradation of β-catenin (32–34).

**Mutation of β-Catenin Ser-45 Leads to a Decreased β-Catenin/E-Cadherin Association**—To verify that Ser-45 phosphorylation of β-catenin affects the association between β-catenin and E-cadherin we performed co-immunoprecipitations of transfected FLAG-tagged β-catenin mutants (wild type or Ser-45A and Ser-33A mutants (35)) and blotted for endogenous E-cadherin from cells stimulated or not with Wnt-5α. The amounts of immunoprecipitated FLAG β-catenin in each sample added to the gel were set to equal levels, and OD measurements of co-immunoprecipitated E-cadherin versus immuno-
precipitated FLAG-β-catenin were performed (ratio E-cadherin/FLAG β-catenin). In line with our previous observations, a mutation at Ser-45 led to a significantly decreased association between β-catenin and E-cadherin as compared with wild type β-catenin, both under non-stimulating (white bars) and Wnt-5a stimulating (gray bars) conditions.

A Ser-33Δ mutated form of β-catenin where Ser-45 still is phosphorylated did not have this profound effect on the association between E-cadherin and β-catenin (Fig. 7A), especially not under Wnt-5a stimulating conditions. This supports the fact that a Wnt-5a-induced Ser-45 phosphorylation of β-catenin is essential for an increased association between β-catenin and E-cadherin.

The Wnt-5a-specific Inhibition of Human Breast Epithelial Cell Matrigel Invasion Is Reduced upon Mutation of β-Catenin Ser-45—We also tested whether the Wnt-5a-specific inhibition of human breast epithelial cell Matrigel invasion (16) would be affected by mutation of β-catenin Ser-45. To assure that the mutation-induced accumulation of β-catenin was equal in all samples, and therefore not a parameter that would affect the outcome of the assay, we transfected HB2 Wnt-5a-low cells with either β-catenin Ser-33Δ (control samples) or β-catenin Ser-45Δ (Fig. 7, B and C). After a 48-h transfection period we transferred the cells to Matrigel invasion chambers (see “Experimental Procedures”) and either left the cells untreated, or treated them with rWnt-5a. As shown in Fig. 7, B and C, we could still see the Wnt-5a specific reduction of invasive capacity in β-catenin Ser-33Δ expressing cells, whereas cells expressing β-catenin Ser-45Δ, where the β-catenin/E-cadherin complexes are unresponsive to Wnt-5a stimulation, invaded the Matrigel also after addition of Wnt-5a. The levels of transfected FLAG β-catenin were similar in each experiment and the FLAG β-catenin protein levels exceeded the endogenous β-catenin levels (Fig. 7D). Interestingly, and for unknown reasons, as shown in Fig. 7B, the basic invasive capacity of FLAG β-catenin Ser-45Δ-transfected cells was lower than that for FLAG β-catenin Ser-33Δ-transfected cells.

Wnt-5a Expression Correlates with β-Catenin Membrane Expression in Human Breast Tumors—We have previously shown that human breast cancers with a low Wnt-5a protein expression are more prone to metastasize and hence Wnt-5a
expression is a predictor of longer disease-free survival (19, 20). Furthermore, it was previously shown that a low membrane expression of β-catenin correlated with a poor outcome in human breast cancer patients (6). To further investigate this, and to compare the findings in this study to clinical parameters, we analyzed changes in Wnt-5a protein expression in human breast tumors relates to an altered membrane distribution of β-catenin. We analyzed the membrane expression levels of β-catenin and the expression levels of Wnt-5a in a human breast tumor tissue microarray consisting of 70 primary breast tumors. The breast tissue tumor arrays were stained with antibodies against β-catenin and Wnt-5a and were categorized according to the expression levels of membrane-bound β-catenin (0, 1, 2, 3) and total Wnt-5a (0, 1, 2, 3), see “Experimental Procedures”). Interestingly, as shown in Table 1 and Fig. 8, A and B, we found a significant correlation between low membrane expression of β-catenin and low levels of Wnt-5a protein expression (linear by linear association, p = 0.004). In line with the experiments in this study, we did not see a significant difference in cytoplasmic or nuclear β-catenin protein levels in Wnt-5a expressing or non-expressing tumors (data not shown).
DISCUSSION

In this study we show that Wnt-5a can increase the Ca\(^{2+}\)-dependent intercellular adhesion in human epithelial breast cells. This is in line with previous clinical observations where loss of Wnt-5a has been associated with an increased risk of metastasis and a worse prognosis (19, 22–24). We explain this fact by the ability of Wnt-5a to specifically induce \(\beta\)-catenin membrane localization through association with the adhesion molecule E-cadherin and an increased E-cadherin-specific intercellular adhesion. We also show that the mechanism behind it is an active process where Wnt-5a-induced activation of CKI\(\alpha\) leads to Ser-45 phosphorylation of \(\beta\)-catenin and thereby an increased complex formation of \(\beta\)-catenin/E-cadherin and subsequently increased membrane localization. Finally, we present a clinical correlation where low expression of Wnt-5a in human breast tumors strongly correlates with a reduced membrane association of \(\beta\)-catenin and an increased potential to metastasize.

It is known that the association between \(\beta\)-catenin and E-cadherin is regulated through phosphorylation of a serine-rich stretch of E-cadherin that comprises the \(\beta\)-catenin binding domain (36). Only recently was the specific serine residues that regulates this interaction identified (8). It has also become evident that it is not only phosphorylation of E-cadherin that regulates the \(\beta\)-catenin/E-cadherin interaction. In fact, phosphorylation of \(\beta\)-catenin itself can regulate the binding to E-cadherin (Tyr\(\text{P}\)-654) (8, 37). It is interesting to note that most \(\beta\)-catenin binding partners (cadherins, Axin/APC, and TCF/LEF) bind to the same positively charged groove of the central part of \(\beta\)-catenin. Just as for Axin/APC and TCF/LEF it would be logical that phosphorylation at the NH\(_2\)-terminal end (Ser-45) of \(\beta\)-catenin could affect the binding of E-cadherin, perhaps indirectly. Indeed, it has been shown that the NH\(_2\)-terminal end of \(\beta\)-catenin is a prerequisite for binding to E-cadherin (9). In this study we show that Wnt-5a/CKI\(\alpha\) signaling can increase the complex formation between \(\beta\)-catenin/E-cadherin. We also show that a Ser-45\(\Delta\) mutated form of \(\beta\)-catenin binds significantly less E-cadherin.

It has previously been suggested that the \(\beta\)-catenin/E-cadherin association is formed in the endoplasmic reticulum and that E-cadherin is brought up to the surface by \(\beta\)-catenin (38). Whether \(\alpha\)-catenin associates with \(\beta\)-catenin before or after joining E-cadherin is not fully understood (9, 39, 40). However,
it is known that the binding of α-catenin to β-catenin facilitates
the association of β-catenin to E-cadherin (9, 39). Indeed, we
were able to show that Wnt-5a signaling increased the amount of
both β-catenin and E-cadherin in α-catenin co-immunoprecipitates (supplemental materials Fig. S1E). Also, through its
association with either β-catenin/E-cadherin or actin fila-
ments, α-catenin acts as a molecular switch, regulating actin
filament assembly at cell-cell contacts (3, 4). We do not know
whether α-catenin promotes the β-catenin/E-cadherin assembly,
or if the increased binding of α-catenin to β-catenin is a result of increased β-catenin/E-cadherin complex formation at
cell-cell contacts. It is interesting to note that Wnt-5a induces
actin stress fiber formation in mammary epithelial cells (41)
and, as shown in this study, that Wnt-5a treatment leads to cell
protrusions resembling a nascent cell-cell contact with lamelli-
podia formations indicating that the increased binding of α-catenin to β-catenin could lead to a local re-modulation of
the actin network (3). However, the half-life of E-cadherin at
cell contacts is short (42). Because the membrane protein levels
of both β-catenin and E-cadherin are increased upon short time
Wnt-5a signaling (<2.5 h), without affecting the total protein
levels of the respective proteins at this time point, we propose
that Wnt-5a indeed promotes the formation of the β-catenin/
E-cadherin complex in the endoplasmic reticulum as a conse-
quence of β-catenin Ser-45 phosphorylation, perhaps facili-
tated by α-catenin. Indeed, E-cadherin-associated β-catenin
Ser-45 phosphorylation was not a secondary effect caused by an
increased intercellular adhesion per se, but was clearly induced
by Wnt-5a/CKIα signaling.

The Wnt-5a/CKIα-induced Ser-45 phosphorylation of
β-catenin does not lead to an increased degradation of β-
catenin, ruling out a possible role for both GSK-3β and Siah-2 (32–
34). This again points out the differences between varying cell
types concerning Wnt induced effects. Our data clearly indi-
cates that Wnt-5a can affect β-catenin in a novel fashion medi-
ating membrane localization without affecting the nuclear dis-
tribution or degradation of β-catenin. A study suggested that
β-catenin targeted to adhesive or transcriptional complexes
have distinct molecular forms that would allow it to coordinate
the two processes (9). Indeed, we found that upon mutation of
β-catenin-Ser-45, the Wnt-5a-induced β-catenin/E-cadherin
association was decreased. In line with these results, expression
of the mutated β-catenin-Ser-45 in invasion assays with breast
epithelial cells lead to a non-responsiveness to Wnt-5a in con-
trast to expression of the mutated β-catenin-Ser-33. It is an
interesting observation that the NH2-terminal of β-catenin is
phosphorylated in the β-catenin/E-cadherin complex in our
system, in contrast to what was previously suggested (9). How-
ever, it is in agreement with the observation that β-catenin with
a truncated NH2-terminus cannot bind E-cadherin (9). Further-
more, it is interesting to note that we see an association of
α-catenin with β-catenin under Wnt-5a stimulating condi-
tions, indicating that β-catenin does not preferentially partici-
pate in transcriptional activation (9), as supported by our luci-
erase TCF/LEF transcription experiments (16). Last, the data
from the breast tumor tissue array also supports the fact that
neither an increased nor a lowered level of membrane-associa-
ated β-catenin per se induced a nuclear accumulation of
β-catenin.

The observation that cancers lacking E-cadherin mutations,
such as ductal breast cancer, might still have an altered E-cad-
herin intercellular adhesion property due to a secondary me-
chanism such as loss of Wnt-5a protein expression and signaling
is interesting. The effect of Wnt-5a on β-catenin membrane
localization presented in this study is a novel mechanism ascribed to Wnt proteins that is of importance for the analysis
of metastatic cancers lacking E-cadherin mutations. It also
strengthens the role of Wnt-5a as a tumor suppressor in breast
cancer, now pointing to a role not only in cell-extracellular
adhesion (20, 21, 43) but also in Ca2+-dependent intercellular
adhesion.

Acknowledgments—We thank Professor D. Rimm for the FLAG
β-catenin plasmids and Professor J. Chen for the kinase-deficient
CKIα plasmids. We also thank Elise Nilsson for histological stainings,
Lena Axelson for technical assistance, Dr. R. Massoumi for scientific
advice regarding the ubiquitination protocol, Professor L. Rönnstrand
for professional advice concerning the pulse-chase assays, and Prof. T
Leanderson for critical reading of the manuscript.
