Numerical models are increasingly used for non-invasive diagnosis and treatment planning in coronary artery disease, where service-based technologies have proven successful in identifying hemodynamically significant and hence potentially dangerous vascular anomalies. Despite recent progress towards clinical adoption, many results in the field are still based on a deterministic characterization of blood flow, with no quantitative assessment of the variability of simulation outputs due to uncertainty from multiple sources. In this study, we focus on parameters that are essential to construct accurate patient-specific representations of the coronary circulation, such as aortic pressure waveform, intramyocardial pressure and quantify how their uncertainty affects clinically relevant model outputs. We construct a deformable model of the left coronary artery subject to a prescribed inlet pressure and with open-loop outlet boundary conditions, treating fluid-structure interaction through an Arbitrary-Lagrangian-Eulerian frame of reference. Random input uncertainty is estimated directly from repeated clinical measurements from intra-coronary catheterization and complemented by literature data. We also achieve significant computational cost reductions in uncertainty propagation thanks to multifidelity Monte Carlo estimators of the outputs of interest, leveraging the ability to generate, at practically no cost, one- and zero-dimensional low-fidelity representations of left coronary artery flow, with appropriate boundary conditions. The results demonstrate how the use of multi-fidelity control variate estimators leads to significant reductions in variance and accuracy improvements with respect to traditional Monte-Carlo. In particular, the combination of three-dimensional hemodynamics simulations and zero-dimensional lumped parameter network models produces the best results, with only a negligible (less than one percent) computational overhead.

KEY WORDS: Cardiovascular simulation, Multi-fidelity framework, Coronary artery hemodynamics, Uncertainty quantification.

1. INTRODUCTION

Cardiovascular disease poses significant burden on the lives of millions of people worldwide, with projected total costs estimated by the American Heart Association of over 1 trillion dollars by 2035. As the standard of care improves through continued research and innovation, virtual hemodynamic representations have been proposed as a...
non-invasive, image-based approach to complement clinical diagnostics, assess patient risk, aid in clinical decision-making and facilitate treatment planning. Use of numerical models in clinical diagnosis for specific pathologies has also been extensively tested and supported by clinical studies (see, e.g., [2–4]). The complexity of these models has substantially increased in recent years, transitioning from idealized and patient-agnostic concepts to patient-specific models constructed through a complex pipeline which includes image acquisition and segmentation, application of physiologically sound boundary conditions, specification of heterogeneous wall material properties and accurate solution of the governing equations on high-performance computing platforms [5,6]. In this context, numerous studies in the literature report applications, for example, to non-invasive assessment of fractional flow reserve (FFR) [7], new surgical designs for congenital heart disease [8], risk assessment in coronary artery bypass surgery [9], thrombotic risk stratification in Kawasaki disease [10], design of ventricular assist devices [11], study of cerebral and aortic aneurysms [12], stent design and placement [13,14] and many others.

Although the realism of simulation tools has improved in recent years, the predictions provided through these tools are essentially deterministic in most of the literature. Most cardiovascular simulations ignore impact of variability due to uncertainty in input parameters on simulation outcomes. In our view, this shortcoming can be overcome through the establishment of strict guidelines and effective methods to assess the impact of uncertainty on simulation predictions, particularly for model-as-a-device technologies used in the clinic. In particular, there is a need for methods that can increase efficiency of uncertainty quantification to make it tractable for full-scale patient-specific problems. Common sources of uncertainty relate to basic hemodynamic metrics (e.g., heart rate or blood pressure), echocardiography measures (stroke volume, ejection fraction, cardiac output, acceleration times) and invasive cardiac catheterization data (cardiac pressures or intravascular ultrasound velocities). Inter-patient variability from population studies as well as intra-patient variability from repeated measurements, can also be useful in complementing information on uncertainty.

After characterizing the input variability, output statistics are determined by propagation through a computationally expensive three-dimensional cardiovascular model. This step can easily become prohibitive, particularly for models with large discretizations, models that account for fluid-structure interaction [15] or include physiologic boundary conditions [16], possibly assimilated from available clinical data under uncertainty [17,18]. Several studies in the literature have investigated the effects of parametric uncertainty in the context of coronary artery disease, for example considering one-dimensional hemodynamic models and the effect of variability in constitutive model parameters [19], arterial wall stiffness, inlet velocity [20], combined boundary conditions and material properties [21], physiologic and anatomic parameters that impact the predictions of FFR [22], resistance and pressure [23], and assessment of global sensitivity. In most of these studies, uncertainty propagation is performed using spectral stochastic approaches based on generalized polynomial chaos expansion [24], multi-element [25] or multi-resolution [26–28] approaches, probabilistic tessellations [29], compressive sampling and lasso [30,31] and others. While offering significant computational savings when the problem at hand has a smooth stochastic response under a moderate dimensionality, these methods suffer significantly from the increase in computational complexity of handling tensor product basis in high dimensions.

Acceleration, more precisely variance reduction, in Monte Carlo sampling has been widely discussed in the literature but, more recently, new multifidelity Monte Carlo estimators are increasingly appearing in applications (see, e.g., a recent review in [32]). In this study, we focus on approximate control variate estimators [33]. The basic idea is to shift the computational cost from the solution of an expensive high-fidelity model to that of a family of inexpensive low-fidelity surrogates, with the only requirement for high- and low-fidelity models being that they are sufficiently correlated. In other words, the low-fidelity models do not necessarily need to be an exact approximation of higher fidelity models, as long as they are correlated. Our group has recently demonstrated the efficiency of such estimators on fully pulsatile simulations using healthy and diseased cardiovascular geometries [34], but further applications of multi-fidelity approach research remains to be conducted in cardiovascular simulations. In this study, we focus on a vascular submodel with boundary conditions that are specifically designed to capture coronary physiology [35,36]. We aim to quantify the variability of clinically relevant model outputs, based on uncertainty in input parameters that are often subjectively chosen by the analyst. The following original contributions are discussed in this paper:

- Random input uncertainty is informed directly through repeated measurements from intra-coronary catheterization. To the authors knowledge, this is one of the few studies where clinical data collection is designed to
provide sufficient data so that uncertain random inputs could be statistically characterized.

- We focus on the most important parameters, whose characterization is essential for accurately simulating the coronary arterial circulation in specific patients. For example, the intra-myocardial pressure and its time derivative are difficult to determine in practice, and often assumed equal to the left ventricular pressure.
- Coronary boundary conditions have been implemented for all model fidelities, in particular for one- and zero-dimensional flow solvers.
- We demonstrate the effectiveness of multi-fidelity approaches in models incorporating wall deformation with ALE.

The paper is organized as follows. Section 2 presents the formulation for the three-, one- and zero-dimensional hemodynamic solvers used to analyze the coronary circulation and discusses the boundary conditions used to mimic the coronary physiology. This is followed by a discussion of approximate control variate estimators and their variance in Section 3. Section 4 focuses on the random inputs and their representation in terms of a random combination of time-varying modes. We also identify the quantities of interest, the computational cost needed for their determination and the correlations across different model fidelities. Variance reduction and accuracy for the selected Monte Carlo estimators are analyzed in Section 5 and finally, in Section 6 we summarize our findings, discuss limitations and briefly outline future work.

2. MULTI-DIMENSIONAL MODELS FOR THE CORONARY CIRCULATION

![FIG. 1: Computational cost versus fidelity for the three hemodynamic models used throughout this study.](image)

2.1 Three-dimensional left coronary model

A three-dimensional anatomic model of the left coronary artery was constructed from CT clinical images using SimVascular [37]. Outlet boundary conditions are specified through a lumped parameter network (LPN) representation of the downstream circulation whose parameters are tuned to match multiple clinical targets (stroke volume, ejection fraction, pressure etc.) and found to reproduce physiologically admissible responses [17,38]. Interaction between
FIG. 2: Numerical models with coronary boundary conditions at the outlets. Three-dimensional model with deformable walls (left), one-dimensional model (center) and zero-dimensional lumped parameter network model (right).

fluid and structure is simulated through Arbitrary Lagrangian-Eulerian (ALE) coupling provided through the SimVascular svFSI solver, which implements a variational multi-scale finite element method with second order implicit generalized-α time integration [39,40]. The incompressible Navier-Stokes equations in ALE form are

\[
\begin{align*}
    \rho \frac{\partial \mathbf{u}}{\partial t} + \rho \mathbf{v} \cdot \nabla \mathbf{u} &= \rho \mathbf{f} + \nabla \cdot \mathbf{\sigma}_f \\
    \nabla \cdot \mathbf{u} &= 0
\end{align*}
\]

in \( \Omega_f \),

where \( \rho, \mathbf{u} = \mathbf{u}(x, t) \), and \( \mathbf{f} \) are fluid density, velocity vector, and body force in the fluid domain \( \Omega_f \). Blood is assumed as a Newtonian fluid, for which \( \mathbf{\sigma}_f = -p \mathbf{I} + \mu \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) = -p \mathbf{I} + \mu \nabla \mathbf{s} u \), with kinematic viscosity \( \mu \), pressure \( p = p(x, t) \), and \( \mathbf{v} = \mathbf{u} - \hat{\mathbf{u}} \) is the fluid velocity relative to the mesh. Additionally, in the solid domain \( \Omega_s \), we solve the equilibrium equations

\[
\rho_s \frac{\partial \mathbf{u}}{\partial t} = \rho_s \mathbf{f} + \nabla \cdot \mathbf{\sigma}_s \quad \text{in} \ \Omega_s,
\]

where \( \rho_s \) and \( \mathbf{\sigma}_s \) denote the density and stress tensor in the solid, respectively. The spatial discretization is based on the variational multi-scale finite element method (see, e.g., [38,40]) and P1-P1 (linear and continuous) elements with co-located nodal velocity and pressure unknowns, while a Saint Venant-Kirchhoff hyper-elastic constitutive model is used for the solid wall. For a complete formulation of the above equations in weak form and the resulting algebraic system, the interested reader is referred to [38,40]. Linear system solutions are computed using the Trilinos library [41], developed at Sandia National Laboratory and coupled with the SimVascular svFSI solver. We use either the Bi-Conjugate Gradient iterative linear solver with incomplete LU preconditioner or the Generalized Minimum Residual with a diagonal preconditioner. These combinations were shown to be optimal for cardiovascular simulations with deformable walls in our prior work [38]. The computational mesh for the coronary artery lumen was informed by a preliminary convergence study [42] and contains 567,373 tetrahedral elements. The wall mesh consists of 373,435 tetrahedral elements, with three elements through the thickness, which is regarded as appropriate due to the prevalent membrane deformations.

2.2 One-dimensional left coronary model

The formulation of the one-dimensional hemodynamics solver used in this study, and available through the SimVascular project, is adapted from Hughes and Lubliner [43], with details discussed in [44,46]. Blood is assumed Newtonian, flowing in the axial direction (\( z \)) of an ideal cylindrical branch, the pressure is assumed constant over the entire vessel cross section, and a no-slip boundary conditions is applied at the lumen.

International Journal for Uncertainty Quantification
Conservation of mass and momentum are formulated by integrating the incompressible Navier-Stokes equations over the cross section of a deformable cylindrical domain as

\[
\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial z} = 0, \quad \frac{\partial Q}{\partial t} + \frac{\partial}{\partial z} \left[ (1 + \delta) \frac{\partial Q^2}{\partial A} \right] + \frac{A}{\rho} \frac{\partial \rho}{\partial z} = Af + N \frac{Q}{A} + \nu \frac{\partial^2 Q}{\partial z^2}.
\]

(3)

Here the solution variables are the vessel cross-sectional area \( A \) and blood flow rate \( Q \); other parameters are the density \( \rho \), external force \( f \), viscosity \( \nu \), and velocity profile parameters \( \delta \) and \( N \) defined as

\[
\delta = \frac{1}{A} \int_A (\phi^2 - 1) ds, \quad N = \nu \int_{\partial A} \frac{\partial \phi}{\partial m} dl.
\]

(4)

A linear constitutive equation is given by

\[
\bar{p}(A, z) = p_0(z) + \left( \frac{E h_0}{r_0(z)} \right) \left( \sqrt{\frac{A(z, t)}{A_0(z)}} - 1 \right),
\]

(5)

where \( E \) is the Young’s modulus of the vascular tissue, \( h_0 \) the wall thickness, \( r_0(z) \) and \( A_0(z) \) the undeformed inner radius and area, respectively. Our in-house 1D solver combines a stabilized finite element discretization in space and a discontinuous Galerkin approach in time; the non-linear algebraic system is solved using modified Newton iterations, while pressure and cross-sectional area continuity at the joints between two segments is enforced through Lagrange multipliers. Location and properties of joints, segments, boundary conditions, data tables, initial conditions and solver parameters are specified through a text input file. Input flow and pressure waveforms are prescribed through time/frequency data tables, while supported boundary conditions include pressure, area, flow, resistance (steady or time-varying), pressure wave, RCR, coronary, impedance and admittance. Further details can be found in [44].

2.3 Zero-dimensional left coronary model

Our simplest low-fidelity representation consists of a lumped parameter network, i.e., an equivalent circuit layout formulated by hydrodynamic analogy, with flow rate and pressure as the main unknowns. Each circuit element is associated with an algebraic or differential equation, so that

\[
\text{resistor } \Delta P = R Q, \quad \text{capacitor } Q = C \frac{dP}{dt}, \quad \text{inductor } \Delta P = L \frac{dQ}{dt}.
\]

(6)

Resistors, capacitors and inductors are used to represent viscous dissipation in vessels through friction at the endothelium, vascular tissue compliance and blood inertia, respectively. A Poiseuille flow assumption is used to determine the model parameters for these circuit elements [47], i.e.

\[
R = \frac{8 \mu l}{\pi r^4}, \quad C = \frac{3 \mu r^3}{2 Eh}, \quad L = \frac{l \rho}{\pi r^2},
\]

(7)

where \( \mu \) is the dynamic viscosity, \( l \) is the vessel length, \( r \) is the vessel radius, \( E \) is the elastic modulus, \( h \) is the wall thickness and \( \rho \) is the blood density. An in-house automated 0-D solver is used in this study, designed to formulate arbitrary circuit layouts from the integration of simple templates, such as capacitors, inductors, resistors, junctions, pressure sources, flow sources, and diodes. Each template is connected via edges and junctions with user-specified connectivity among the templates. The equations are then automatically assembled in a system of differential-algebraic equations,

\[
E(y, t) \dot{y} + F(y, t) + C(t) = 0,
\]

(8)

which is solved numerically. The above equation is discretized in time and integrated in time using an implicit, generalized-\( \alpha \) scheme.
2.4 LPN boundary conditions at the coronary arteries

Specialized boundary conditions are applied in this study to three-, one- and zero-dimensional model fidelities, to better capture the physiology of coronary blood flow [48]. In this context, it is well known how the contraction of the cardiac muscle during systole impedes the flow in the coronaries, which instead reaches its maximum following diastolic relaxation. In other words, a typical coronary flow waveform is out-of-phase with the aortic pressure (Figure 2). To mimic this behavior, a special coronary boundary condition has been proposed in the literature [48], consisting of an RCRCR circuit connected to an intramyocardial pressure generator. Coronary boundary conditions [48,49] are applied to the \( n_o = 6 \) left coronary artery (LCA) outlets, formulated through the ordinary differential equations

\[
\frac{dP_{p,i}}{dt} = \frac{1}{C_{a,i}} \left( Q_i - \frac{P_{p,i} - P_{d,i}}{R_{am,i}} \right), \quad i = 1, 2, ..., n_o.
\]

\[
\frac{dP_{d,i}}{dt} = \frac{1}{C_{im,i}} \left( \frac{P_{p,i} - P_{d,i}}{R_{am,i}} - \frac{P_{d,i} - P_{im}}{R_{vi,i}} \right) + \frac{dP_{im}}{dt}, \quad i = 1, 2, ..., n_o.
\]

where \( P_{p,i} \) and \( P_{d,i} \) are the proximal and distal pressures, \( C_{a,i} \) and \( C_{im,i} \) are the proximal and distal capacitances and \( R_{am,i} \) and \( R_{vi,i} \) are the resistances, respectively (Figure 2). Note that the same rate of intramyocardial pressure \( dP_{im}/dt \) is used for all \( n_o \) outlets. In the 3D model, the above equations are integrated in time using a fourth-order Runge-Kutta explicit scheme, while the pressure at the 3D model outlet \( P_{o,i} \) is computed as \( P_{o,i} = P_{p,i} + R_{a,i} Q_i \), and coupled to the three-dimensional model solution at each time step (50). In the 1D model, algebraic equations of the coronary circuit are instead implemented as discussed in [48], whereas the compartment containing the coronary boundary conditions simply extends the 0D circuit network and these two are solved in a monolithic fashion.

The total coronary resistance was computed by assigning 4% of the cardiac output to the coronary arteries [51] and vessel resistances were distributed among outlets following a morphometric relation associating flow rates with vessel diameters, i.e., \( Q \propto (d/2)^m \). An empirically derived morphometry exponent \( m = 2.6 \) has been suggested in [52,53]; for the coronary circulation, a previous uncertainty quantification study found only negligible difference in the simulation results with \( m \) ranging between 2.4 and 2.8 [42]. Approximating the diameter with the square root of the area \( \sqrt{A_i} \), the resistance of a distal branch, \( R_i \) is computed as

\[
R_i = \frac{\sum_j \sqrt{A_{ij}^{2.6}}}{\sqrt{A_{ij}^{2.6}}} \cdot R_{total}, \quad i, j = 1, 2, ..., n_o,
\]

while the capacitances are instead distributed proportional to the outlet area [49].

2.5 Agreement between low- and high-fidelity model outputs

Low fidelity one-dimensional models were extracted from the three-dimensional segmentation using a newly developed plugin in SimVascular [54] that automatically creates one-dimensional solver input files, containing the appropriate inlet and outlet boundary conditions. Similarly, low-fidelity zero-dimensional models were generated through a separate set of conversion tools from one-dimensional model segments. The agreement between low fidelity and three-dimensional model outputs was found to be excellent under both RCR and coronary outlet boundary conditions as shown in Figure 3 for selected flow and pressure quantities of interest.

3. MULTI-FIDELITY MONTE CARLO UNCERTAINTY PROPAGATION

Consider a complete probability space \( (\Omega, F, P) \) where \( \Omega \) is a set of elementary events, \( F \) is a Borel \( \sigma \)-algebra of \( 2^\Omega \), and \( P \) a probability measure assuming values in [0,1] over events in \( F \). Model inputs are represented though the random vector \( \tilde{\xi} = (\xi_1, \xi_2, ..., \xi_d) \), with components \( \xi_i : \Omega \rightarrow \Sigma, i = 1, ..., d \), having marginals \( \xi_i \sim \rho_i(\xi_i) \) and joint probability density \( \rho(\tilde{\xi}) \). Space and time are denoted by \( \bar{x} \in \mathbb{R}^n \) and \( t \in \mathbb{R}_+ \), respectively. In this study, we focus on the forward problem in uncertainty quantification, i.e, the statistical characterization of the quantity of

International Journal for Uncertainty Quantification
FIG. 3: Three-, one- and zero-dimensional model results with pulsatile inlet pressure and coronary outlet boundary condition.

interest $Q = Q(\vec{x}, \vec{\xi}, t)$, (through its mean $\mathbb{E}[Q]$ or variance $\mathcal{V}[Q]$), where, for a given realization $\vec{\xi}^{(i)}$ of the random inputs, $Q^{(i)} = Q(\vec{\xi}^{(i)})$ is determined through the numerical solution of a high-fidelity model. For simplicity, in what follows we assume space $\vec{x}$ and time $t$ to be fixed, leading to $Q = Q(\vec{\xi})$.

The Monte Carlo estimator $\hat{Q}^{MC}_N$ of the expected value of $Q$ based on $N$ realizations is defined as

$$\mathbb{E}[Q] = \int_{\Sigma} Q(\vec{\xi})\rho(\vec{\xi})d\vec{\xi} \simeq \frac{1}{N} \sum_{i=1}^{N} Q^{(i)},$$

with variance $\mathcal{V}[\hat{Q}^{MC}_N] = \frac{\mathcal{V}[Q]}{N}$. (12)

The variance $\mathcal{V}[\hat{Q}^{MC}_N]$ can be reduced by either increasing its denominator or reducing its numerator. The former can be achieved through stratified or low-discrepancy sampling sequences, such as Latin Hypercube or Quasi Monte Carlo sampling (QMC), which offer a more uniform coverage of the random input range $\Sigma$, and have been shown to improve the convergence rate of MC estimators up to $O(N^2)$. In this study, we use Sobol’ QMC sequences, as shown in Figure 4.

Alternatively, reduction in the numerator $\mathcal{V}[Q]$ can be achieved by introducing approximate control variate Monte Carlo estimators, which combine contributions from two different model fidelities (low-fidelity LF and high-fidelity HF, respectively). The Monte Carlo estimator for the high-fidelity model $\hat{Q}^{HF}$ is replaced by $\hat{Q}^{CV, HF}$ which embeds a correction based on the LF model [56,57]

$$\hat{Q}^{HF,CV}_N(r) = \hat{Q}^{HF}_N + \alpha \left( \hat{Q}^{LF}_N - \mathbb{E}[Q^{LF}] \right) \approx \hat{Q}^{HF}_N + \alpha \left( \hat{Q}^{LF}_N - \hat{Q}^{LF}_N \right),$$

(13)

where $N_{LF} = N_{HF} + \Delta_{LF} = N_{HF} (1 + r)$, and the additional LF realizations $\Delta_{LF} = r N_{HF}$ are used to estimate $\mathbb{E}[Q^{LF}]$ as $\hat{Q}^{LF}_N$. Similarly to the MC estimator, $\hat{Q}^{HF,CV}$ is unbiased with variance

$$\mathcal{V}[\hat{Q}^{HF,CV}_N] = \mathcal{V}[\hat{Q}^{HF}_N] + \alpha^2 \mathcal{V}[\hat{Q}^{LF}_N] + 2 \alpha \mathcal{C}[\hat{Q}^{HF}_N, \hat{Q}^{LF}_N].$$

(14)

Thus, the regression coefficient $\alpha$ that minimize (14) can be determined as

$$\alpha = -\rho \sqrt{\frac{\mathcal{V}[\hat{Q}^{HF}_N]}{\mathcal{V}[\hat{Q}^{LF}_N]}}.$$
where \( \rho \) is Pearson’s correlation coefficient between the LF and HF estimators. Substituting the optimal \( \alpha \) from (15) into (14), leads to

\[
\sqrt[\text{HF,CV}]{\text{Var}} = \sqrt[\text{HF}]{ \text{Var}} \left( 1 - \frac{\rho^2}{1 + \rho^2} \right).
\]

Expression (16) suggests how a sufficiently large correlation between HF and LF models is the main determinant of variance reduction and, since \( \rho^2 \in (0,1) \) approximate control variate estimators are always superior to their \textit{vanilla} Monte Carlo counterpart.

4. INPUT AND OUTPUT UNCERTAINTIES

In an effort to focus our attention on relevant uncertain inputs, essential for the physiological admissibility of the coronary outputs of interest, we consider the left coronary artery inlet pressure waveform, whose intra-patient variability is determined from repeated clinical data acquired \textit{in-vivo} through cardiac catheterization [32], and the intramyocardial pressure whose variability is instead assumed.

4.1 Karhunen-Loève representation of the random inputs

We approximate the left coronary pressure waveform with a wide-sense stationary Gaussian process in time with exponential covariance, i.e., \( K(t,t') = \sigma^2 \exp(-|t - t'|/l_c) \), where \( t \) and \( t' \) are two arbitrary time points, \( l_c \) is the correlation length, and \( \sigma^2 \) the process variance (58). Under these circumstances, for a sufficiently large truncation level \( N \), such a process admits the representation

\[
P(t, \omega) \approx \tilde{P}(t) + \sum_{i=1}^{N} \sqrt{\lambda_i} \psi_i(t) \xi_i(\omega),
\]

where \( \tilde{\xi}(\omega) = (\xi_1(\omega), \xi_2(\omega), \ldots, \xi_N(\omega)) \), \( \omega \in \Omega \) is a collection of independent standard Gaussian random variables and \( \lambda_i, \psi_i(t) \) are the eigenvalues and eigenvectors of the covariance kernel \( K(t,t') = \sum_{i=1}^{N} \lambda_i \psi_i(t) \psi_i(t') \), respectively (59). For an estimated correlation length equal to \( l_c = T/2 = 0.5 \) s, a satisfactory approximation of \( P(t, \omega) \) can be obtained using only the eigenmodes associated with the four largest eigenvalues. Moreover, the process standard deviation is set equal to 7% of the mean, as per repeated pressure measurements from cardiac catheterization in six patients [42]. Samples from \( \xi_i(\omega), i = 1, \ldots, 4 \) are obtained by projecting the four-dimensional Sobol’ sequence in Figure 4(a) through the inverse cumulative distribution function of a multivariate Gaussian. Results are illustrated in Figure 4. A collection of eigenfunctions \( \psi_i(t), i = 1, \ldots, 6 \) from the selected covariance kernel is shown in Figure 4(b), while Figure 4(c) contains an ensemble of inlet pressure realizations from (17). Due to the significant challenge of measuring the intramyocardial pressure \textit{in-vivo}, the left ventricular pressure and its time-derivative are often used as a viable replacement (see, e.g., [9,17,21,49]). This is clearly an approximation, whose effect on the simulation results is rarely discussed in the literature, despite the key importance of intramyocardial pressure in defining the diastolic character of coronary flow. This may relate to the use of open loop boundary conditions with prescribed coronary flow in many studies. Here, rather than a flow, we prescribe an inlet pressure and additionally model the uncertain intramyocardial pressure time-derivative \( P_{\text{im},t} \) as a stochastic process in time. To do so, we perturbed a baseline intramyocardial pressure time derivative (17) using a zero-mean Gaussian process having standard deviation equal to \( 0.1 \cdot \max_{t \in [0,T]} P_{\text{im},t} \) with \( T \) the heart cycle duration (Figure 4(d)).

4.2 Quantities of interests

We focused on three hemodynamic quantities of interests (QoIs), i.e., flow rate and pressure at each outlet \( (Q_i, P_i, i = 1, \ldots, n_d) \), and branch wall shear stress (WSS). In more detail, the shear stress \( \tau(x,t) \) was averaged over one heart cycle in time and over the vessel circumference in space so that

\[
\text{WSS}_i(z) = \int_{C} \frac{1}{T} \left| \int_{0}^{T} \tau(x,t) \ dt \right| \ ds
\]

\[ (18) \]
where \( z \) is the spatial distance along the vessel branch centerline, and \( C \) is the lumen circumference at the branch cross section. Finally we averaged \( \text{WSS}_i(z) \) along the centerlines of each vessel branch to obtain a single averaged value for WSS. For zero-dimensional models, the wall shear stress is determined based on Poiseuille flow conditions on an ideal vessel with circular cross section of radius \( r \)

\[
|\tau| = \frac{4 \mu Q}{\pi r^3},
\]

where \( Q \) is the instantaneous flow rate, \( \mu \) the dynamic viscosity and the vessel radii are based on a one-dimensional model anatomy.

### 4.3 Computational cost

Outputs for each model fidelity were computed using a fixed number of input parameter realizations. Specifically, we solved 400 high-fidelity cardiovascular model instances in parallel using 48 cores, either through the Comet cluster available through a XSEDE allocation, or using resources from the Center for Research Computing at the University of Notre Dame. All simulations were performed over four cardiac cycles, the first half consisting of QMC realizations of the inlet pressure \( P_{in} \), while the remaining 200 with stochastic intramyocardial pressure \( P_{im} \). One- and zero-dimensional models were solved 1,000 and 10,000 times, respectively for each random input. Relative and cumulative simulation costs are reported in Tables 1 and 2 respectively.

### 4.4 Correlations of high- and low-fidelity models

Following the discussion on approximate control variate Monte Carlo estimators in Section 3, it should be clear how the correlations among high- and low-fidelity model outputs are the main determinant of variance reduction. We observe very large average Pearson correlations (i.e., \( \rho > 0.9 \)) across all QoIs and all coronary branches, as reported...
### TABLE 1: Absolute and relative simulation costs for all three model fidelities.

| Solver | Cost (1 Simulation) | Effective Cost (1 Simulation) |
|--------|---------------------|-----------------------------|
| 3D     | 1775 hrs            | 1                           |
| 1D     | 8.5 mins            | $7.98 \times 10^{-5}$       |
| 0D     | 5 secs              | $7.82 \times 10^{-7}$       |

### TABLE 2: Effective cost and associated number of model evaluations for high-fidelity Monte Carlo and multi-fidelity estimators.

| Method | Effective Cost (Percentage to QMC) | No. 3D simulations | No. 1D simulations | No. 0D simulations |

5. UNCERTAINTY PROPAGATION RESULTS

5.1 Uncertainty in the Inlet pressure waveform

To provide a preliminary idea of how the variability in inlet pressure waveform affects the model outputs, we first performed 200 realizations from the zero-dimensional model in Figure 6, and observed similar results as in previous studies from our research group [42]. Next, we compared the variance reduction obtained for QoIs in six left coronary artery branches resulting from vanilla Monte Carlo sampling and approximate control variate estimators with one-
FIG. 5: Low- versus high-fidelity model outputs at LCX branch and Pearson correlations under intramyocardial pressure uncertainty.

FIG. 6: Schematic workflow showing how the uncertainty in the inlet pressure waveform is propagated through a zero-dimensional left coronary artery model, specifically for outlet pressure and flow QoIs.

(CV-1D) and zero-dimensional (CV-0D) low-fidelity models, respectively (Figure 7). From a pilot run consisting of 200,1,000, and 10,000 model evaluations, the CV-1D estimator reduces the variance by a factor of three to four, while an order of magnitude reduction is achievable using the CV-0D estimator. We now define the accuracy of a generic estimator \( \hat{Q} \) as six times the coefficient of variation, or, in other words, the amplitude of ±3\( \sigma \) (i.e. three standard deviations) confidence interval normalized by the mean,

\[
\text{Acc}[\hat{Q}] = \frac{6\sqrt{\text{Var}[\hat{Q}]} }{\text{E}[\hat{Q}]} = \frac{(\mu + 3\sigma) - (\mu - 3\sigma)}{\mu} = \frac{6\sigma}{\mu},
\]

FIG. 7: Variance reduction for QMC and approximate control variate estimators.
with smaller values of $\text{Acc}[\hat{Q}]$ indicating a higher level of confidence in the estimates from $\hat{Q}$. The accuracy of QMC, CV-1D and CV-0D estimators is shown in Figure 8 for all relevant QoIs. Similar to previous results, reductions in accuracy of one order of magnitude result from the CV-0D estimator. Finally, we note that the discussion above is equally valid for global pressure/flow and for local wall shear stress QoIs.

![FIG. 8: Estimator accuracy improvements from approximate control variate Monte Carlo.](image)

5.2 Uncertainty in the intramyocardial pressure time-derivative

Variability in the intramyocardial pressure time-derivative significantly affects outlet flow and time-averaged wall shear stress uniformly across all branches (≈30% variation [42]), leaving the pressure almost unaltered, as shown in Figure 9. Variance reduction for QMC and multifidelity estimators is quantified in Figure 10 while their accuracy is shown in Figure 11.

![FIG. 9: Ensemble of model outputs for the zero-dimensional model of the left coronary circulation under intramyocardial pressure uncertainty.](image)

Similarly to the findings in the previous section, both variance reduction and accuracy are greatly improved by the multifidelity estimators with superior performance of CV-0D. This is due to the Pearson correlations being very high over all the QoIs for this latter estimator and the larger number of zero-dimensional simulations (10,000 for each input uncertainty) included in the pilot run. This suggests zero-dimensional models to be particularly well suited for low-fidelity or reduced-order representations of the coronary sub-circulation due to their almost negligible computational demand.

International Journal for Uncertainty Quantification
cost and highly correlated QoIs. Finally, we observe how outlet pressure variability due to intramyocardial pressure uncertainty is limited if compared to flow or wall shear stress QoIs. This justifies the clustering of accuracy results in Figure 11.

6. DISCUSSION

Recent advances in model-based diagnostics of coronary artery disease have demonstrated how models can be successfully integrated in clinical routines, but have raised questions related to their robustness, in light of possible uncertainty or ignorance associated with their input parameters. In this study, we focused on two clinically relevant parameters, the inlet pressure for coronary circulation sub-networks, and the intramyocardial pressure time-derivative. Stochastic processes in time are used to inject uncertainty in these parameters, leading to a representation by a finite volume.
collection of independent random variables following Karhunen-Loève expansion. Inlet pressure waveform uncertainty is directly estimated from repeated measurements obtained during cardiac catheterization in six patients [42], while variability in intramyocardial pressure is assumed equal to 10% of its maximum systolic rate.

We have quantified the variance in model outputs expectations for a three-dimensional multi-scale cardiovascular model with deformable walls, arbitrary Lagrangian Eulerian (ALE) fluid-structure interaction and conforming fluid and wall mesh interfaces. We also generated computationally inexpensive one- and zero-dimensional low-fidelity representations from three-dimensional segmentation, using a recently developed pipeline in SimVascular. Coronary boundary conditions were also implemented for all low-fidelity formulations and thoroughly validated against three-dimensional simulation results. Despite a common misconception that UQ analysis can easily become computationally intractable for large cardiovascular models containing millions of degrees of freedom, we were able to characterize confidence in expectations of clinically relevant quantities of interest under a fixed computational budget of approximately 200 high-fidelity model runs.

This is possible thanks to the high correlations between high- and low-fidelity outputs, even if these outputs are not necessarily in perfect agreement with each other, or in other words low-fidelity QoIs do not need in general to be close to their high-fidelity counterpart. Our results highlight how CV-1D estimators of mean pressure, flow and wall shear stress have variance which is reduced by a factor of 3 to 4 with respect to QMC estimators, with accuracy improvements of the same order. CV-0D estimators show superior performance with improvements up to one order of magnitude and total simulation cost equal to less than 1 percent with respect to high-fidelity three-dimensional models. The computational cost savings using extrapolation of the current results shows that one can save one or two orders of magnitude compared to high-fidelity model evaluations alone to achieve a targeted accuracy by using the multi-fidelity framework.

Estimator variance and accuracy are computed, in this study, from a pilot run consisting of a fixed number of simulations selected a-priori. A better approach would be to adaptively refine the number of simulations needed to achieve a certain variance reduction or to satisfy a certain computational budget from an small initial pilot run. This will be easily achieved through a software interface between SimVascular and the Dakota UQ software platform (developed at Sandia National Laboratory), currently under development [34].

Future work will extend the present results for high-dimensional, arbitrary distributed and correlated random inputs. There are multiple sources of uncertainty in cardiovascular simulations, including boundary conditions, material properties and geometry that should be combined in future studies to offer a complete picture of uncertainty in predictions. The effects of these uncertainty sources used to be studied independently. In more realistic cases these uncertainty sources may be correlated. By reducing the computational cost, the multi-fidelity framework will be exploited to study the effect of multiple sources.
