Type III secretion system (T3SS) is a protein translocator complex family including pathogenic injectisome or bacterial flagellum. The injectisomal T3SS serves to deliver virulence proteins into host cell and the flagellar T3SS constructs the flagellar axial structure. Although earlier studies have provided many findings on the molecular mechanism of the Type III protein export, they were not sufficient to reveal energy transduction mechanism due to difficulties in controlling measurement conditions in vivo. Recently, we developed an in vitro flagellar Type III protein transport assay system using inverted membrane vesicles (IMVs), and analyzed protein export by using the in vitro method. We reproduced protein export of the flagellar T3SS, hook assembly and substrate specificity switch in IMV to a similar extent to what is seen in living cell. Furthermore, we demonstrated that ATP-hydrolysis energy can drive protein transport even in the absence of proton-motive force (PMF). In this mini-review, we will summarize our new in vitro Type III transport assay method and our findings on the molecular mechanism of Type III protein export.

Key words: In vitro reconstitution, Inverted membrane vesicle, Type III secretion system, injectisome, bacterial flagellum

Type III secretion system (T3SS) is one of the bacterial protein translocators and its family contains two types of supramolecular complexes, the injectisome (or the needle complex) and the bacterial flagellum [1,2]. The bacterial flagellum is a filamentous organelle with a rotary motor in the cell envelope and responsible for motility in aqueous environments or on wet surfaces. The flagellum is composed of a basal body ring structure consisting of the MS-ring and the C-ring, and a filamentous axial structure consisting of the rod, the hook, and the filament (Fig. 1). The axial structure is assembled from more than 20,000 protein subunits of 9 different proteins with the help of 3 different scaffold proteins. The axial proteins and their scaffold proteins are translocated through the flagellar T3SS, called the export apparatus, into the central tubular space across the cell membrane. The exported proteins diffuse through the central tube toward the growing end of the flagellum [3,4]. The export apparatus consists of the transmembrane export gate complex formed by FlhA, FlhB, FliP, FliQ and FliR and the cytoplasmic ATPase complex formed by FliH, FliI and FliJ [1,5,6]. The export gate is located inside of the trans-
membrane MS ring of the basal body and exports the proteins by proton-motive force [7,8]. The ATPase complex interacts with the export gate and the cytoplasmic C ring of the basal body [9]. FliI is a Walker-type ATPase and forms a homo-hexameric ring [10,11]. FliH is a negative regulator of FliI ATPase and interacts with the N-terminal region of FliI [12–14]. FliJ interacts with FlhA and a C ring component, FlIN, to anchor the ATPase complex to the basal body [15]. FliJ fits into a central hole of the hexameric FliI ring [16]. The ATPase complex is structurally similar to the F1- and V1-ATPase, suggesting that it hydrolyzes ATP in a similar manner as F1- and V1-ATPase [11,12,16]. While FliH, FliI and FliJ form the ATPase complex in the export apparatus, FliHI and FliI form the FliH/FliI hetero-trimeric complex in cytoplasm and interacts with the filament-type proteins in complex with their specific cognate chaperones, which allow the filament-type proteins to somehow come close to the export gate [17–19]. Two different energy sources, proton-motive force (PMF) and ATP-hydrolysis energy, are utilized to export the substrate proteins through the export gate [7,8,15,20]. Since addition of CCCP, which is a proton ionophore to disrupt PMF, inhibits the export of the substrate proteins, PMF is a primary driving energy for protein export. The export gate acts as a proton/protein antiporter to couple the proton translocation to the protein export [21,22]. The proton is thought to be translocated through an export gate component, FlhA. On the other hand, the role of ATP-hydrolysis energy remains controversial. The ATP hydrolysis by FliI ATPase is not an essential event for exporting the substrate proteins across the cell membrane because fliH-fliI double null mutant cells formed the flagella [7,8]. PMF is defined as the sum of $\Delta \Psi$ and $\Delta \mathrm{pH}$. The wild-type cells can export the proteins by only $\Delta \Psi$, whereas the fliH-fliI double null mutant cells require both $\Delta \Psi$ and $\Delta \mathrm{pH}$ for protein export [7,8,20]. In frequent ATP hydrolyzing mutant, FliI E211D still transported enough proteins to construct the axial structure, hence ATP hydrolysis energy may be used for activation of the export gate and switching of the export gate into a highly efficient $\Delta \Psi$-driven engine [23]. In the injection, however, the ATP-hydrolysis energy is suggested to be utilized for unfolding substrate proteins for export [24]. Although genetic and biochemical in vivo experiments have revealed many aspects of the molecular mechanism of the T3SS, they are not enough to reveal the energy transduction mechanism for protein export due to difficulties in controlling measurement conditions in vivo. Therefore, an in vitro transport assay system is required for further understanding of the Type III protein transport. Here we summarize the new in vitro method to analyze the Type III protein transport and the energy utilization mechanism found by using our method [25].

Construction of an in vitro protein transport assay system based on inverted membrane vesicles

When people plan to construct a biochemical in vitro experiment, they often have to purify protein molecules or complexes of interest. The export apparatus, however, has never been purified as an active complex so far because the export apparatus with the base structure is a huge transmembrane protein complex with molecular mass of over 7 MDa. Therefore, an inverted membrane vesicle (IMV)-based protein transport assay system seems to be a possible in vitro method. Since the IMV is a membrane vesicle with inside-out orientation derived from the cytoplasmic membrane, we can precisely control measurement conditions for protein transport. To prepare the IMVs, we introduced the following mutations into Salmonella cells: fliT null mutation and exogenous FlhD/FlhC expression to increase the number of ATP-hydrolysis energy utilization mechanism found by using our method [25].

![Diagram of the Salmonella flagellum](image-url)
The IMV-based assay system preserved protein transport ability as well as that seen in cells

First of all, we confirmed the protein transport ability of the IMV using purified FlgD, FlgE and FliK. FlgE is a hook protein and FlgD is a scaffolding protein for hook formation [28]. FlgE is incorporated into the growing hook beneath the FlgD cap complex that is attached on the tip of the hook [29]. FliK is a molecular ruler protein which regulates the hook length at c.a. 55 (±6) nm [30]. FlgD was transported into the IMVs in the presence of ATP-Mg²⁺ but not in the absence of ATP-Mg²⁺. Addition of CCCP, a proton ionophore, hindered the protein transport, indicating that protein...
Analysis of energy transduction mechanism by using the \textit{in vitro} protein transport assay system

Protein export by T3SS is thought to be primarily driven by PMF and facilitated by ATP hydrolysis energy \cite{7,8,15,20}, but the roles of these energies are still not clear. To clarify the role of ATP hydrolysis energy produced by the T3SS ATPase complex, we tried to examine the protein transport without PMF. Since our IMV includes endogenous $F_0F_1$-ATP synthase, we genetically disrupted both $fliH$-$fliI$ genes and $F_0F_1$-ATP synthase locus (subunit α, β, γ, δ, ε, A, B, C and I) from the \textit{Salmonella} ΔflhB ΔflgD ΔfliT strain expressing FlhB N269A and FlhD/FlhC, then prepared the IMVs without the pH and ion concentration gradient. In the PMF-depleted condition, surprisingly, FlgD transport activity was still retained when the FliH$_2$/FliI complex, FliJ and ATP-Mg$^{2+}$ were present in the external solution. In order to further confirm the protein export without PMF, we added CCCP in the assay solution with the FliH$_2$/FliI complex, FliJ and ATP-Mg$^{2+}$. FlgD transport was not affected by CCCP addition. Moreover, the polyhook formation was observed in the PMF-depleted condition when FlgD and FlgE were added in the assay solution, indicating that the flagellar T3SS can transport proteins without PMF if the FliH$_2$/FliI complex, FliJ and ATP-Mg$^{2+}$ are present in solution. To confirm whether ATP hydrolysis by FliI ATPase contributes to protein export, FliI E211Q mutant protein, which binds ATP but does not hydrolyze it, was added to the assay solution. Unlike wild-type FliI, the protein transport didn’t occur. These results indicate that protein export by T3SS can be driven by only ATP hydrolysis energy produced by FliI ATPase even in the absence of PMF (Fig. 3). Our study clearly revealed that T3SS can drive protein export by using either PMF or ATP hydrolysis energy, although they are both needed for the maximum export activity. It is still unclear how the ATP hydrolysis energy by FliI ATPase is utilized to drive protein transport in IMV was driven by PMF as well as that in cell. Next, we investigated whether the FliH$_2$/FliI complex and FliJ in the assay solution affect on the protein transport because FliI shows turn-over between the ATPase complex attached on the export gate and the cytoplasmic pool \cite{31}. Transport activity was significantly enhanced when both the FliH$_2$/FliI complex and FliJ were added in the assay solution, but transport activity was little changed by adding the FliH$_2$/FliI complex or FliJ alone in the assay solution. The IMVs pre-incubated with the FliH$_2$/FliI complex and FliJ showed only slight enhancement of transport activity. These results indicate that the presence of FliH, FliI and FliJ in the cytoplasmic pool is required for efficient protein export. Although the IMVs show protein export activity, it is still obscure whether the protein export proceeds as in the cell. If the protein export process in IMV fully retains that in cell, the transported proteins would be assembled into the axial structure. Therefore, we added FlgE with/without FlgD to the assay solution, and then observed the IMVs by electron cryo-tomography. The transported FlgE molecules assembled into the hook on the rod in IMV. Next, we tried to regulate the hook length by adding FliK in the assay solution. IMVs were prepared from a \textit{Salmonella} ΔflhB ΔflgD ΔfliT mutant strain expressing wild-type FlhB, instead of FlhB N269A, to switch the substrate specificity upon completion of the hook. In the absence of FliK, the polyhook, the abnormally long hook structure, was formed in IMV; but in the presence of 4 μM FliK, the average length of the hook was controlled at c.a. 55 (+22) nm. These results indicate that only FliK is required to terminate the transport of the rod-hook type proteins. These \textit{in vitro} experiments clearly show that our \textit{in vitro} assay system fully reproduces the T3SS protein export and following events, such as the hook assembly process and substrate specificity switching as in the cell.

export. Thus, further investigations are needed for understanding the role of ATP hydrolysis energy.

Conclusion

Our in vitro protein transport assay system based on IMVs reproduced protein export and flagellar assembly as well as those seen in cell. Although the previous in vivo studies have shown that T3SS is primarily driven by PMF and facilitated by ATP hydrolysis energy, the transport analyses using IMVs revealed that the export apparatus can export the substrates using only ATP hydrolysis energy. This suggests that T3SS is a “hybrid-engined” protein translocator that is capable of using either PMF or ATP hydrolysis energy as the energy source. The energetic robustness may contribute to maintain the protein export activity of T3SS against environmental perturbations.
