(Dated: September 29, 2008)

While the topology of the Universe is at present not specified by any known fundamental theory, it may in principle be determined through observations. In particular, a non-trivial topology will generate pairs of matching circles of temperature fluctuations in maps of the cosmic microwave background, the so-called circles-in-the-sky. A general search for such pairs of circles would be extremely costly and would therefore need to be confined to restricted parameter ranges. To draw quantitative conclusions from the negative results of such partial searches for the existence of circles we need a concrete theoretical framework. Here we provide such a framework by obtaining constraints on the angular parameters of these circles as a function of cosmological density parameters and the observer’s position. As an example of the application of our results, we consider the recent search restricted to pairs of nearly back-to-back circles with negative results. We show that assuming the Universe to be very nearly flat, with its total matter-energy density satisfying the bounds $0 < \Omega_0 - 1 \lesssim 10^{-5}$, compatible with the predictions of typical inflationary models, this search, if confirmed, could in principle be sufficient to exclude a detectable non-trivial cosmic topology for most observers. We further relate explicitly the fraction of observers for which this result holds to the cosmological density parameters.

I. INTRODUCTION

One of the central open questions regarding our understanding of the Universe concerns its shape (topology), and in particular whether it is finite or infinite (see, e.g., the reviews [1]). A major difficulty in this regard is that general relativity, being a metric theory, does not specify the topology of the Universe.† Despite our present-day inability to predict the topology of the Universe from a fundamental theory, it may in principle be determined through observations. This requires high resolution observations, which have increasingly become available in recent years. Most notably, the on-going accumulation of data by the Wilkinson Microwave Anisotropy Probe (WMAP) [2] and other Cosmic Microwave Background (CMB) surveys have, on the one hand, provided strong support for the inflationary scenario [3], and the very near flatness of the Universe, and on the other hand made it feasible to perform systematic searches for possible evidence of a non-trivial topology of the Universe [4–8] (see also the related Refs. [9]).

In the context of general relativity, the observable Universe seems to be described by a 4-manifold $\mathcal{M} = \mathbb{R} \times M$ with locally homogeneous and isotropic spatial sections $M$ and endowed with a Robertson-Walker metric

$$ds^2 = -dt^2 + a^2(t) \left[ d\chi^2 + S_k^2(\chi)(d\theta^2 + \sin^2 \theta d\phi^2) \right],$$

where $a(t)$ is the scale factor and $S_k(\chi)$ takes the forms $\sin \chi$, $\sinh \chi$ or $\sinh \chi$ depending upon whether the geometry of the spatial sections is euclidian, spherical or hyperbolic with curvature parameters $k = 0, \pm 1$. These geometries in turn are determined by finding out whether the total energy-matter density of the Universe, $\Omega_0$, is equal to, greater than or smaller than 1. Often the homogeneous and isotropic spatial sections $M$ are assumed to be the simply connected 3-manifolds: euclidian $\mathbb{R}^3$, spherical $S^3$, or hyperbolic $\mathbb{H}^3$. However, given the metrical (local) nature of general relativity, they can also be multiply connected 3-manifolds (which we assume to be compact and orientable) $M = \widetilde{M}/\Gamma$, where the covering space $\widetilde{M}$ is respectively $\mathbb{R}^3$, $S^3$ or $\mathbb{H}^3$ depending on $k$, and $\Gamma$ is a discrete and fixed point-free group of isometries of $\widetilde{M}$ called the holonomy group. The local geometry of the spatial sections $M$ thus constrains, but does not dictate, its topology.

The immediate observational consequence of such multiple connectedness is that an observer could potentially detect multiple images of radiating sources. In particular, in a universe with a detectable non-trivial topology the last scattering surface (LSS) intersects its topological images in the so called circles-in-the-sky [9], i.e., pairs of matching circles of equal radii, centered at different points of the LSS with the same distribution of temperature fluctuations along both circles. In this way, to observationally probe a non-trivial topology on the largest
available scales, one needs to scrutinize the CMB sky-maps in order to extract such correlated circles in order to determine the topology of the Universe. Thus, a detectable non-trivial cosmic topology is an observable attribute, which can be probed through the circles-in-the-sky for all locally homogeneous and isotropic universes with no assumptions on the cosmological density parameters.

The conditions for the detectability of cosmic topology were studied in Refs. [10] for classes of hyperbolic and spherical manifolds, as a function of cosmological density parameters. These studies were extended to the case of generic manifolds and general qualitative results were obtained for the inflationary limit in Ref. [11] (see also Ref. [12]). Furthermore, the inverse question of whether the detection of a non-trivial cosmic topology can be used to set constraints on cosmological density parameters has been studied for specific topologies [13, 14].

Our aims here are twofold. Firstly, to extend the previous general results by the authors [11], in order to give, for generic detectable non-trivial topologies, a concrete relationship between the angular parameters associated with the circles-in-the-sky and the cosmological density parameters in the inflationary limit. Secondly, by using these relations, and taking into account the observer positions, we provide a set up to interpret the negative results of recent and future searches for circles-in-the-sky in the WMAP data. In this way, we can concretely specify, for example, the extent to which the recent searches for circles-in-the-sky may be used to exclude detectable non-trivial cosmic topologies for most observers.

The structure of the paper is as follows. In Section II we give a brief account of the pre-requisites necessary for the following sections, including a brief discussion of the so called inflationary limit, which we use to obtain bounds on the detectability of cosmic topology. In Section III we combine these bounds with our previous results to obtain bounds for the parameters of detectable holonomies in the inflationary limit. We quantify these bounds by giving a concrete measure of the observers for whom the detectability holds. In Section IV we recast our bounds on detectable holonomies in terms of bounds on the angular parameter that measures the deviation from antipodicy in pairs of matching circles generated by detectable holonomies. These bounds are then compared in Section V to the parameters adopted in the recent searches for circles-in-the-sky to determine whether and under which conditions it is possible to rule out a detectable non-trivial cosmic topology given the inflationary limit. Finally, in Section VI, we conclude with a brief discussion of the significance of our results to draw quantitative conclusions from such negative results of searches for circles.

II. PRELIMINARIES

A natural way to study the detectability of a topology is through the lengths of its closed geodesics. For a holonomy $γ \in Γ$ and a point $x \in M$, the length of the closed geodesic generated by $γ$ is given by its distance function $d(x, γx)$ in the covering space, i.e. the distance between $x$ and its image $γx$. This readily allows the definition of the local injectivity radius $r_{inj}(x)$ as half the length of the smallest closed geodesic passing through the point $x$.

A necessary condition for detectability of cosmic topology is then given by

$$r_{inj}(x) < \chi_{obs}, \quad (2)$$

where $\chi_{obs}$ is the redshift-distance evaluated at the maximum redshift ($z = z_{obs}$) of the survey used. We assume throughout a $Λ$CDM model. In globally homogeneous manifolds, $r_{inj}(x)$ is by definition position-independent, and in this case it suffices to use the global injectivity radius $r_{inj}$ (defined in general as $r_{inj} = \inf_{x \in M} r_{inj}(x)$, which is the radius of the smallest sphere inscribable in $M$) to determine sufficient conditions for detectability. There are, however, significant classes of 3–manifolds which are not globally homogeneous, including the totality of hyperbolic manifolds and the majority of the multiply-connected spherical manifolds. One must therefore allow for the fact that the detectability of cosmic topology may be dependent on the observer’s position.

Generally, a full systematic search for multiple images or pattern repetitions of topological origin is a daunting task, as the very diverse set of potential holonomies generate very different patterns often dependent on the observer’s position. Given, however, that the fraction of the universe which is effectively accessible to observations is limited, we shall in this work concentrate only on detectable holonomies, that is those for which at least two images of some radiating sources may be observable. In this connection, we have shown in Ref. [11] that, assuming

(i) The spatial sections of the Universe are not exactly flat;

(ii) The Universe has undergone a phase of inflationary expansion, such that $|Ω_0 − 1| \ll 1$, which ensures that $\chi_{obs} \ll 1$;

(iii) The cosmic topology, or more properly some element of its holonomy group, is detectable, i.e., Eq. (2) holds for some point $x \in M$;

then any detectable holonomy is (nearly) indistinguishable from a Clifford translation (or CT, defined as a holonomy $γ$ under which the distance between each point

\[ |k| H_\circ^{-1} |Ω_0 − 1|^{−1/2}. \]

Here and in the following we express distances in units of the curvature radius $a_0 = |k| H_\circ^{-1} |Ω_0 − 1|^{−1/2}$.\]
x and its image γx is constant for all points in the manifold for most observers. As a consequence, a generic compact non-flat manifold is “locally” well approximated by either a cylindrical (\( \mathbb{R}^2 \times S^1 \)) or toroidal (\( \mathbb{R} \times T^2 \)) manifold, irrespective of its global topology.

In typical inflationary scenarios, achieving a sufficient number of e-foldings required to generically solve the flatness and horizon problems imposes bounds on the total density parameter which is estimated as \( [3, 15] \) in its canonical form.

To obtain the holonomy parameters, we recall that the main outcome of our earlier results \([11]\) is that, for most observers (in the sense made precise below), the detectable holonomies of nearly flat manifolds will deviate only by a small amount from being Clifford translations (i.e., are CT-like), in the sense that within the observable Universe the lengths \( d(x, \gamma x) \) of the closed geodesics generated by any detectable holonomy \( \gamma \) will be such that

\[
\Delta d \lesssim \frac{2 \chi_{\text{obs}}}{|z_2||z_1|},
\]

and for hyperbolic manifolds

\[
\Delta d \lesssim 2 \chi_{\text{obs}}.
\]

In these expressions \( \Delta d \equiv d_{\text{max}} - d_{\text{min}}, \) where \( d_{\text{max}} \) and \( d_{\text{min}} \) are respectively the maximum and minimum lengths of the geodesics generated by this holonomy inside the detectable sphere of radius \( \chi_{\text{obs}}. \) \( d_0 \) is the distance function of the holonomy \( \gamma \) evaluated at the center of the sphere, and \( z_1 \) and \( z_2 \) are a pair of complex numbers that parametrize the 3-sphere (thus \( |z_1|^2 + |z_2|^2 = 1 \)), which are used to express the holonomy \( \gamma \) in its canonical form. Of course, for true Clifford translations, \( \Delta d/d_0 \approx 0 \) (for more details see Ref \([11]\)).

For all observers able to detect a holonomy \( \gamma \) in hyperbolic cusp-like manifolds, and for most such observers in a spherical manifold (i.e., those bounded away from the equators, so that \( |z_1|, |z_2| > \chi_{\text{obs}} \)), the bounds \((5)\) and \((6)\) imply that \( \Delta d/d_0 \) is very small, which means that the holonomy is CT-like. It is easy to show that the fraction of the volume of the manifold where \( |z_1| < Z \) or \( |z_2| < Z, \) for any \( Z \leq 1, \) is proportional to \( Z^2. \) This can be seen by writing \( Z = \sin \xi_{\text{max}}, |z_1| = \cos \xi, \) and \( |z_2| = \sin \xi, \) where \( 0 \leq \xi \leq \pi/2 \) and \( 0 \leq \xi_{\text{max}} \leq \pi/4. \) The holonomy group \( \Gamma \) of manifold \( S^3/\Gamma \) tiles the 3-sphere \( S^3 \) into \( \mathcal{O}(\Gamma) \) identical copies of the fundamental domain, where \( \mathcal{O}(\Gamma) \) is the order of \( \Gamma. \) Therefore, the volume of the region where \( \xi \leq \xi_{\text{max}} \) or, conversely, \( \xi \geq \pi/2 - \xi_{\text{max}}, \) corresponds to the sum of the volumes of two tori in the 3-sphere \( |z_1|^2 + |z_2|^2 = 1 \) centered at \( |z_1| = 0 \) and \( |z_2| = 0 \) (with radii \( \xi_{\text{max}} \) and \( \pi/2 - \xi_{\text{max}} \) respectively), divided by \( \mathcal{O}(\Gamma). \) In toroidal, or Hopf, coordinates, this volume is given by

\[
V_{\xi_{\text{max}}} = \frac{1}{\mathcal{O}(\Gamma)} \int_0^{2\pi} \int_0^{2\pi} \left( \int_0^{\pi/2} \left( \int_0^{\pi/2 - \xi_{\text{max}}} \right) \cos \xi \right) \sin \xi \ d\phi_1 \ d\phi_2 \ d\xi = \frac{4\pi^2 Z^2}{\mathcal{O}(\Gamma)}.
\]

Now, the volume of the manifold \( S^3/\Gamma \) is given by the volume of the 3-sphere divided by \( \mathcal{O}(\Gamma), \) i.e., \( V_{S^3/\Gamma} = V_{S^3}/\mathcal{O}(\Gamma) = V_{\pi/2} = 2\pi^2/\mathcal{O}(\Gamma). \) Thus the fraction \( \mathcal{R} \) of \( S^3/\Gamma \) where \( |z_1| \leq Z \) or \( |z_2| \leq Z \) is given by

\[
\mathcal{R} = V_{\xi_{\text{max}}}/V_{S^3/\Gamma} = 2Z^2.
\]
is known, however, that any orientation-preserving flat isometry (and, in particular, any flat holonomy) can be expressed as a screw motion (10), which consists of a rotation around a suitable axis followed by a translation along the same axis. In what follows, we shall write a generic non-flat detectable holonomy γ in the limit (4) and (6) as a generic screw motion, and use our previous bounds on nearly flat detectable holonomies to constrain the parameters characterizing such holonomy.

Let us consider, without loss of generality, a typical observer at a point P (see Fig. 1) with coordinates chosen such that $P = (\rho, 0, 0)$, where $\rho$ is the distance from the axis of rotation. Let the image of the point P under the action of a holonomy $\gamma$ be $P' = \gamma P$ with coordinates $(\rho \cos \alpha, \rho \sin \alpha, L)$, where $\alpha$ is the phase angle and L is the translation length corresponding to the screw motion isometry. The length of the closed geodesic connecting $P$ and $P'$ is given by

$$d_0 = |P' - P| = |\rho(1 - \cos \alpha), \rho \sin \alpha, L| = \sqrt{2\rho^2(1 - \cos \alpha) + L^2}.$$  \hfill (9)

To proceed, we need to calculate not only the length of the geodesic passing through the observer’s position given by Eq. (9), but also the lengths of the longest and shortest closed geodesics within the observable Universe, which are respectively given by

$$d_{\text{max}} = \sqrt{2(\rho + \chi_{\text{obs}})^2(1 - \cos \alpha) + L^2},$$  \hfill (10)

$$d_{\text{min}} = \begin{cases} \sqrt{2(\rho - \chi_{\text{obs}})^2(1 - \cos \alpha) + L^2} & \text{if } \rho \geq \chi_{\text{obs}}, \\ L & \text{if } \rho \leq \chi_{\text{obs}}. \end{cases}$$  \hfill (11)

Since $L \leq [2(\rho - \chi_{\text{obs}})^2(1 - \cos \alpha) + L^2]^{1/2}$ holds identically, it follows that $d_{\text{min}} \leq [2(\rho - \chi_{\text{obs}})^2(1 - \cos \alpha) + L^2]^{1/2}$. Thus, combining Eqs. (9) – (11) we obtain

$$\frac{\Delta d}{d_0} \geq \sqrt{1 + \frac{1}{d_0^2}(4\rho\chi_{\text{obs}} + 2\chi_{\text{obs}}^2)(1 - \cos \alpha)} - \sqrt{1 + \frac{1}{d_0^2}( - 4\rho\chi_{\text{obs}} + 2\chi_{\text{obs}}^2)(1 - \cos \alpha)}.$$  \hfill (12)

The terms on the right hand side are respectively greater and smaller than 1. Also, according to (5) and (6), the difference between the two terms must be $\ll 1$. Therefore, both terms must be $\sim 1$, which allows them to be expanded to obtain

$$\frac{\Delta d}{d_0} \geq \frac{4\rho\chi_{\text{obs}}}{d_0^2}(1 - \cos \alpha) + O(\alpha^4).$$  \hfill (13)

Note that since $4 \rho \chi_{\text{obs}}/d_0^2 \gg 1$, then in order to keep the first term $< 1$ we must have $(1 - \cos \alpha) \ll 1$, which implies that $\alpha$ is very small.

Now let the angle between the axis of the screw motion and the segment $(P' - P)$ be $\sigma$ (see Fig. 1), such that $\cos \sigma = L/d_0$. It can then be shown that

$$\tan \sigma = \frac{\rho}{L} \sqrt{2(1 - \cos \alpha)}.$$  \hfill (14)

Using (14) to express $\alpha$ in terms of $\sigma$, it is possible to

FIG. 1: Depiction of a screw motion isometry $\gamma$, whose action takes point the $P$ to $P'$. This amounts to a translation by $L$ along the axis of isometry (dotted line), and a rotation by $\alpha$ around the same axis. The LSS sphere (thick solid line) centered at $P$ intersects its images (also in thick solid lines) centered at $\gamma P$ and $\gamma^{-1} P$ along two matched circles-in-the-sky.
write equation (13) as

$$\frac{\Delta d}{d_0} \geq \frac{2\chi_{\text{obs}}}{\rho} \sin^2 \sigma + \mathcal{O}(\alpha^4).$$  

(15)

Combining the above results with the bounds (14) and (16) we finally obtain

$$\frac{\rho}{|z_2||z_1|} \geq \sin^2 \sigma, \quad \text{for spherical manifolds},$$

(16)

$$\rho \geq \sin^2 \sigma, \quad \text{for hyperbolic manifolds}.$$  

(17)

IV. BOUNDS ON THE PARAMETERS OF THE CIRCLES-IN-THE-SKY

In the previous section we used our previous bounds (c.f. [11]) on $\Delta d/d_0$ to constrain the screw motion parameters ($\rho, \alpha, L$). To relate these to the corresponding parameters ($\theta, \nu, \phi$) for the circles-in-the-sky (see Fig. 2), one needs the relations between the circles-in-the-sky and the screw motion parameters, which are given by [17]

$$\cos \theta = 1 - \sin^2 \sigma(1 - \cos \alpha),$$

(18)

and

$$\cos \nu = \frac{L}{2 \chi_{\text{obs}} \cos \sigma}.$$

(19)

Now, in the inflationary limit $\alpha$ is small, which according to (18) implies that $\theta$ is small. We can then write, up to the second order in $\theta$,

$$\theta = 1 - \sqrt{2} \sin \sigma \sqrt{1 - \cos \alpha}.$$  

Using (14) and employing the bounds on $\sin \sigma$ from (16) and (17), together with the expression (19) for $\cos \nu$, we obtain

$$\theta \leq \frac{\sqrt{2} \cos \nu}{|z_2||z_1|} \chi_{\text{obs}} \quad \text{for spherical manifolds},$$

(20)

$$\theta \leq \sqrt{2} \cos \nu \chi_{\text{obs}} \quad \text{for hyperbolic manifolds}.$$  

(21)

Clearly, these inequalities provide upper bounds on the values of the angle $\theta$ that characterizes the deviation from antipodicity of pairs of circles-in-the-sky as a function of the circles’ radii $\nu$, the distance to the LSS $\chi_{\text{obs}}$, and the observer’s position (for the spherical case). The dependence of these bounds on $\theta$ on the density parameters can be made explicit by recalling that for the small values of $|\Omega_0 - 1|$ given by the bound (3), the contour curve $\chi_{\text{obs}}(\Omega_{m0}, \Omega_{\Lambda 0}) = \tau_{\text{lnj}}$ can be well-approximated by the secant line joining its intersections with the $\Omega_{m0} = 0$ and $\Omega_{\Lambda 0} = 0$ axes [16]. Using this approximation we obtain

$$\chi_{\text{obs}} \simeq 2 \sqrt{\frac{|\Omega_0 - 1|}{\Omega_{m0}}},$$

(22)

which can be substituted in inequalities (20) and (21) to give the bounds

$$\theta \leq \frac{2\sqrt{2} \cos \nu}{|z_2||z_1|} \sqrt{\frac{|\Omega_0 - 1|}{\Omega_{m0}}},$$

(23)

and

$$\theta \leq \sqrt{2} \cos \nu \sqrt{\frac{\Omega_0 - 1}{\Omega_{m0}}},$$

(24)

for, respectively, spherical and hyperbolic manifolds.

Thus given observational bounds on the density parameters they allow constraints to be set on the parameter $\theta$ for any radii $\nu$ of matching circles to be considered in order to perform a comprehensive search for matching circles in the observable Universe.

Finally, as is clear from our discussion in Section III there are some observers in spherical manifolds — namely those close to the equators ($z_1 \simeq 0$ or $z_2 \simeq 0$) — for whom the bounds on $\theta$ derived here are not applicable. However, as can be seen from Eq. (8) the set of such observers is very small in the inflationary limit.

V. IMPLICATIONS OF OUR RESULTS AND SEARCHES FOR CIRCLES-IN-THE-SKY

To illustrate the application of the bounds (20) and (21), we consider the recent search for circles-in-the-sky using the WMAP data [5], in order to determine the sets of topologies that can be ruled out. Given the prohibitive numerical cost of a full search, this search was confined to antipodal or nearly-antipodal circles with deviation from antipodcity $\theta \leq 10^\circ$ and with radii $\nu \geq 18^\circ$. This search found no statistically significant pairs of matching circles.
If confirmed, an important question regarding this search would be to determine concretely whether it is sufficient to rule out detectable non-trivial, non-flat, cosmic topologies, assuming the inflationary limit \( \text{[3]} \). To answer this question we have, employing the inequalities \( \text{(20)} \) and \( \text{(21)} \), plotted in Fig. \( \text{3} \) an upper bound, \( \theta_{\text{max}} \), for the maximum deviation from antipodicity of a pair of matching circles as a function of the fraction of the observers in spherical and hyperbolic manifolds. As can be seen from this figure, and concretely estimated from inequalities \( \text{(20)} \) and \( \text{(21)} \), in the inflationary limit \( \text{[3]} \), the angle \( \theta_{\text{max}} \) is less than 0.8° for any observer in a hyperbolic manifold.\(^4\) On the other hand, for 98.7% of the observers in spherical manifolds \( \theta_{\text{max}} \leq 10^6 \). In both cases we have confined ourselves to circles with radii \( \nu \geq 18^\circ \) (following \( \text{[3]} \)); but had we considered circles of arbitrarily small radii, the upper bounds on \( \theta \) would increase only by a factor of 1.05. This implies that, if one accepts the negative result of the search for circles of Ref. \( \text{[5]} \), then the assumption of inflationary limit considered here is sufficient to rule out detectable non-trivial cosmic topologies for overwhelming majority of the potential observers. Thus to detect a non-trivial topology an observer must either live in a restricted region of some spherical manifolds or the Universe must have a total density parameter which is not too close to the critical density. This latter statement can be made precise by plotting \( \theta_{\text{max}} \) as a function of the density parameter \( (\Omega_0 - 1) \) for different sets of observers (Fig. \( \text{3} \)). So, for instance, the search undertaken in Ref. \( \text{[3]} \) is sufficient to rule out a detectable cosmic topology for all observers in hyperbolic manifolds, and for at least 99.9% of the observers in spherical manifolds, if \( |\Omega_0 - 1| \leq 10^{-4} \). On the other hand, if \( |\Omega_0 - 1| \leq 10^{-15} \), then such a detectable topology is still definitively excluded for all observers in hyperbolic manifolds, but only for 90% of observers in spherical manifolds.

\( \text{FIG. 3:} \) Upper bound \( \theta_{\text{max}} \) for the maximum deviation from antipodicity as a function of the fraction of potential observers for which \( \theta \leq \theta_{\text{max}} \) in the inflationary limit. This figure shows, for example, that for 98.7% of all observers in spherical manifolds, \( \theta \leq 10^6 \). It also shows that for all observers in hyperbolic manifolds, \( \theta \leq 0.8^\circ \). In this figure, we have taken \( \Omega_{\text{m0}} = 0.28 \) and circles with radii \( \nu \geq 18^\circ \), but for circles with arbitrarily small radii, the value of \( \theta_{\text{max}} \) would increase by a factor of at most 1.05.

\( \text{FIG. 4:} \) Upper bound \( \theta_{\text{max}} \) for the maximum deviation from antipodicity as a function of the total density parameter \( \Omega_0 \), calculated for the sets of 90%, 99% and 99.9% of observers (respectively, \( R = 0.1, 0.01 \) and 0.001), and for the totality of observers in hyperbolic manifolds. The shaded region corresponds to the inflationary limit as defined in the text. Again, we have taken \( \Omega_{\text{m0}} = 0.28 \) and circles with radii \( \nu \geq 18^\circ \).

Future searches for pairs of correlated circles may of course study different regions of the circles-in-the-sky parameter space. As Fig. \( \text{4} \) illustrates, for all observers in hyperbolic manifolds, even searches restricted to small values of \( \theta \) (if confirmed) would be sufficient to exclude a detectable non-trivial cosmic topology for relatively large values of total density, i.e. for \( 1 - \Omega_0 \sim 10^{-4} \). On the other hand, the fraction of observers in spherical manifolds that may observe pairs of circles with \( \theta \geq \theta_{\text{max}} \) varies significantly with the value of \( \theta_{\text{max}} \). Thus, for example, a search for pairs with \( \theta \leq 5^\circ \) would be able to exclude a detectable non-trivial cosmic topology for 99.9% of observers only if \( \Omega_0 - 1 \leq 1.2 \times 10^{-7} \), a value almost one order of magnitude smaller than that for \( \theta \leq 10^6 \). Conversely, it would take a search for \( \theta \leq 35^\circ \) to exclude a detectable non-trivial topology for the same 99.9% of observers for the range of values of \( \Omega_0 \) given by the infla-

\(^4\) We note, however, that for most such observers the topology is undetectable to begin with (see Ref. \( \text{[13]} \) for details).
tionary limit\textsuperscript{3}.  
Of course, for sufficiently low values of $|\Omega_0 - 1|$, a detectable non-trivial (non-flat) topology can be excluded for an arbitrarily small fraction of potential observers and arbitrarily small values of $\theta_{\max}$. However, one can not completely exclude all potentially detectable spherical holonomies for all observers, since one can always find one such holonomy that is well-approximated in some neighborhood around the equator $z_1 = 0$ by a screw motion of arbitrarily large twist, which will in turn generate, for some values of $\chi_{obs}$, circle pairs with arbitrary deviation from antipodicity.

A non-detection in a limited search for pairs of correlated circles would likewise not rule out the possibility of a detectable flat non-trivial topology. Since flat holonomies lack a characteristic scale factor, there is some considerable leeway in choosing the holonomy parameters, and it is easy to obtain holonomies that produce circle pairs of arbitrary $\theta$ for typical observers. Indeed, if one assumes the inflationary limit, then the detection of a pair of correlated circles with high $\theta$ would strongly suggest that the Universe has flat spatial sections, since pairs of correlated circles with high values of $\theta$ would be present for no observers in a hyperbolic Universe, and for only a small fraction of observers in a spherical Universe.

Although it is not possible to exclude the possibility of detection of the cosmic topology by all observers, the combination of such negative results of any search (present or forthcoming), together with the results derived in this paper, would allow precise bounds to be put on the fraction of the potential observers for whom a non-trivial cosmic topology would be ruled out, for any given value of the density parameters.

VI. FINAL REMARKS

An important model-independent observational signature of a detectable non-trivial cosmic topology is the occurrence of pairs of matching circles of temperature fluctuations in maps of the cosmic microwave background radiation. Here, by employing some recent results concerning the local nature of generic non-flat detectable non-trivial topology in the inflationary limit, we have obtained concrete bounds on the angular parameter characterizing the deviation from antipodicity of circles-in-the-sky as a function of the cosmological density parameters and the position of the observer, for any radius $\nu$ of the circles.

As an example of the application of our results, we have considered the most recent search restricted to nearly back-to-back circles, which has found no statistically significant pairs of matching circles. Using our bounds we have found that, assuming the total density parameter satisfies $0 < |\Omega_0 - 1| \lesssim 10^{-5}$, this search, if confirmed, could in principle be sufficient to exclude a detectable non-trivial cosmic topology for most observers.

Our results also provide a framework to draw quantitative conclusions from the negative results of such partial searches, past and future, for circles-in-the-sky as a generic signature of non-trivial cosmic topology. More specifically, they allow us to quantify the fraction of the potential observers for which the absence of pairs of matching circles-in-the-sky in CMB maps rules out a non-trivial (non-flat) topology for the spatial sections of the Universe, as a function of the cosmological density parameters. We emphasize that these results apply generally to all potential non-flat manifolds with non-trivial topology rather than specific classes. In particular, if the negative results of the recent searches are confirmed, then in the inflationary limit a detectable non-trivial (non-flat) topology is excluded for all observers apart from a very small subset, if the Universe has positively-curved spatial sections, and for all observers if the spatial sections turn out to be negatively-curved.

Acknowledgments

This work is supported by Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq) – Brasil, under grant No. 472436/2007-4. M.J. Rebouças and R. Tavakol thank CNPq and PCT-CBPF/MCT/CNPq for the grants under which this work was carried out. We would also like to thank G. Gomero for fruitful discussions.
