(Dated: April 10, 2015)

We present and analyze a method of laser frequency stabilization via steady-state patterns of spectral holes in Eu$^{3+}$:Y$_2$SiO$_5$. Three regions of spectral holes are created, spaced in frequency by the ground state hyperfine splittings of $^{151}$Eu$^{3+}$. The absorption pattern is shown not to degrade after days of laser frequency stabilization. An optical frequency comparison of a laser locked to such a steady-state spectral-hole pattern with an independent cavity-stabilized laser and a Yb optical lattice clock demonstrates a spectral-hole fractional frequency instability of $1.0 \times 10^{-15} \tau^{-1/2}$ that averages to $8.5 \pm 1.8 \times 10^{-17}$ at $\tau = 73$ s. Residual amplitude modulation at the frequency of the RF drive applied to the fiber-coupled electro-optic modulator is reduced to less than $1 \times 10^{-6}$ fractional amplitude modulation at $\tau > 1$ s by an active servo. The contribution of residual amplitude modulation to the laser frequency instability is further reduced by digital division of the transmission and incident photodetector signals to less than $1 \times 10^{-16}$ at $\tau > 1$ s.

Frequency stable laser local oscillators (LLOs) are key tools in the field of metrology. Applications of such LLOs include optical atomic clocks [1–3], tests of general relativity [4, 5], searches for variation of fundamental constants [6, 7], and relativistic geodesy [8, 9]. The best stabilized lasers to date [10, 11] are obtained by locking their frequencies to Fabry-Pérot reference cavities, and their stability is intrinsically limited by thermomechanical length fluctuations of the cavity [12, 13].

Higher stability might be possible by the method of spectral-hole burning (SHB) [14, 15], where a narrow optical transition of rare-earth ions doped into a cryogenically cooled crystal is used as the frequency reference. Strains in the crystalline host inhomogeneously broaden the narrow absorption line by several gigahertz. For laser frequency stabilization, narrow transparencies (spectral holes) are created within the absorption line by frequency selective optical pumping [16]. These narrow spectral holes can be used for laser frequency stabilization by actively steering the frequency of the laser to maximize the transmission through the crystal.

Spectral holes in Eu$^{3+}$:Y$_2$SiO$_5$ [17] are particularly promising for laser frequency stabilization. At 4 K, this material supports spectral holes at 580 nm with linewidths as narrow as 122 Hz [18] and lifetimes of $10^6$ s [19]. The frequency shifts due to fluctuations in the ambient magnetic and electric fields, temperature, pressure, and acceleration are all small enough to allow laser frequency instabilities at the $10^{-17}$ fractional frequency level [20, 21]. However, prior laser frequency stabilization experiments with Eu$^{3+}$:Y$_2$SiO$_5$ have been limited to run-times of a few thousand seconds due to degradation of the spectral holes caused by noise and saturation of the probe laser [22].

In this work, we demonstrate frequency stabilization to a steady-state pattern of spectral holes in 1.0 atomic % Eu$^{3+}$:Y$_2$SiO$_5$ crystals at temperatures near 4 K. This pattern consists of three regions of spectral holes spaced in frequency by 46.2 MHz and 34.6 MHz (see Figure 1), corresponding to the ground-state hyperfine splittings of $^{151}$Eu$^{3+}$ positioned at crystallographic site 1 [23, 24]. The Eu$^{3+}$ population reaches steady-state as the spectral holes in the three regions are burned. Additional interleaved probing does not modify the absorption spectrum because, for a subset of the $^{151}$Eu$^{3+}$ ions with certain detunings within the inhomogeneously broadened absorption line, all three of the hyperfine ground states are addressed by the laser as it probes spectral holes in the three regions. Absorption does not accumulate between the spectral holes because they are spaced by only a few times the minimum observed spectral-hole width. This persistent and self-regenerating pattern is achieved by
utilizing probe pulses whose center frequency coincides with an absorption minimum. Weaker phase modulation sidebands are spaced to coincide with absorption maxima to yield a Pound-Drever-Hall type error signal. Using this spectral-hole pattern, laser frequency stabilization experiments can be made to run indefinitely.

Our SHB LLO employs a two-stage laser frequency stabilization scheme, as shown in Figure 2 and similar to that described in Reference [27]. A 1160 nm external cavity diode laser (ECDL) is frequency doubled to 580 nm, and pre-stabilized to a Fabry-Pérot cavity [25]. Two fiber-coupled electro-optic modulators (f-EOMs) are applied sidebands to the beams at 15 kHz for crystal one and 21 kHz for crystal two, for generation of a Pound-Drever-Hall (PDH) error signal [17, 26]. Detectors (DETs) I1 and I2 measure the power incident on the two crystals, which is stabilized by feedback to the RF power of the probe AOM drives. Detectors T1 and T2 measure the probe light transmitted through the crystals. For measurements of the laser frequency stability, visible laser light is sent to an independent high-finesse Fabry-Pérot reference cavity [27], and infrared laser light is sent to a frequency comb for comparison against other frequency references, each through a Doppler-cancelled optical fiber [28].

During a SHB laser frequency stabilization run, several hundred spectral holes are created. A hole is then randomly selected, and the laser spends a few milliseconds probing the center of the spectral hole. Frequency corrections from the two crystals are averaged and applied to the pre-stabilization cavity AOM. In order to reduce laser frequency degradation due to the Dick effect [29], probe pulses for the two crystals are interleaved with a 100% duty cycle, as shown in Figure 3. To reduce frequency instability caused by error signal transients at the beginning of each probe pulse, the error signal generated during the first several hundred microseconds of each pulse is not used for frequency feedback.

A schematic diagram of the error signal generation and residual amplitude modulation (RAM) servo is shown in Figure 4. The transmission detector signal is digitally divided by the incident detector signal on a field-
programmable gate array (FPGA) in order to suppress laser intensity noise. This also provides some suppression of the RAM caused by the f-EOM. After filtering, this signal is multiplied with the local oscillator to produce the PDH error signal. The incident detector signal is independently demodulated in order to control the RAM through a servo-loop by applying a DC bias to the f-EOM [30]. This suppresses the contribution of RAM, converted to fractional frequency instability of a laser locked to a steady-state hole pattern, to less than $1 \times 10^{-16}$ at averaging times greater than 1 s, and to less than $1 \times 10^{-17}$ at averaging times greater than 100 s.

To reduce frequency instability due to temperature fluctuations [21], the Eu$^{3+}$:Y$_2$SiO$_5$ crystals are housed in a sealed copper pillbox with a fixed amount of helium gas. The temperature of the cryocooler is servo controlled to keep the copper pillbox within 5 mK of the first-order insensitive temperature (3.941 K). The measured out-of-loop temperature instability, converted to fractional frequency instability, is less than $1 \times 10^{-16}$ at averaging times greater than 1 s, and less than $1 \times 10^{-17}$ at averaging times between 100 s and $10^4$ s.

The time-evolution of an unperturbed spectral hole at 3.941 K is shown in Figure 5. The top plot of Figure 5 shows a decrease in hole depth (in units of $\alpha L$ from maximum absorption of the crystal) and an increase in hole width. The bottom plot of Figure 5 shows the time-evolution of the normalized area of the spectral hole. The hole area is fit to a three-part exponential decay with empirically determined time constants of 2.7 h, 53.3 h, and 856.2 h. During a steady-state laser frequency stabilization run, the entire spectral-hole pattern must be probed frequently enough to re-burn all of the spectral holes before they decay. Spectral diffusion [31, 32] causes the spectral holes to broaden, limiting the minimum frequency spacing of holes within the steady-state pattern.

The absorption pattern of the three-region steady-state spectral-hole pattern after three hours of laser frequency stabilization run-time is shown in Figure 1. Each of the three regions has 201 holes spaced by 6 kHz. As the pattern reaches steady-state, the spectral holes increase from an initial 1.7 kHz full-width at half-maximum (FWHM) to their steady-state FWHM of 3.3 kHz after ten hours of run-time.

In contrast, a subset of the single-region spectral-hole pattern used in previous work [22] is shown in Figure 6 after three hours of run-time. The 603 holes of this pattern are spaced by 270 kHz. Starting from an initial width similar to that of the three-region pattern, the spectral holes have broadened to 5.6 kHz after three hours of run-time. The spectral holes continue to broaden indefinitely, which degrades the frequency stability of the laser locked to this single-region spectral-hole pattern.

Interspersed periodically between probe pulses used for laser frequency stabilization are scan pulses of individual spectral holes, which allow for the hole shape and error signal slope to be monitored as a run progresses. The top plot of Figure 7 shows a comparison between the slope of the error signal of a single-region pattern and a three-region steady-state pattern, as a function of the duration of time that the pattern has been used for laser frequency stabilization. These values are an average of the error signal slope at the center of each spectral hole within the pattern. For both patterns, the error signal slope reaches a maximum as the absorption at the center of the holes approaches zero, then decreases as the holes start to broaden. The three-region steady-state pattern asymptotically approaches a non-zero error signal slope, with a time constant that indicates how long it takes the pattern to reach steady-state. The single-region pattern error signal slope decreases until the lock can no longer be maintained after approximately 70 hours of run-time. The bottom plot of Figure 7 shows the 1 second averaging
We have demonstrated steady-state SHB laser frequency stabilization with a short-term fractional frequency instability of $1.0 \times 10^{-15} \tau^{-1/2}$ that averages down to $8.5^{+4.8}_{-1.8} \times 10^{-17}$ at $\tau = 73$ s. The steady-state spectral-hole pattern successfully prevents degradation of the laser frequency stability out to run-times of many days. RAM is suppressed to less than $1 \times 10^{-6}$ fractionally at 1 s averaging time using an active servo, and the digital division of transmitted and incident photodetector signals further suppresses laser frequency instability due to RAM.

We thank J. Bergquist, R. Fox, and D. Wineland for useful discussions. Special thanks go to T. Fortier and S. Diddams for operation of the frequency comb used in the three-cornered hat measurement, and to the NIST Yb optical lattice clock team.
