(March 31, 2022)

We consider several topics concerning static magnetic dipole and electric quadrupole moments (\(\mu\) and \(Q\)) as signatures of the onset of nuclear collectivity. Having previously noted that in \(^{50}\text{Cr}\) there is an abrupt change of sign in \(Q\) of yrast states with \(J^r = 10^+, 12^+, \) and \(14^+\) relative to lower \(J\) states, we discuss whether these states are oblate or prolate. We next show that configuration mixing leads to much larger changes in \(Q\) than in \(\mu\). We then look for other bands of interest in \(^{50}\text{Cr}\). Finally we discuss the Jolos-von Brentano relationship which relates \(Q\) of \(2^+_1\) states to \(B(E2)\)'s for transitions from and to the \(2^+_1\) states.

I. COMMENT ON STATIC QUADRUPOLE MOMENTS IN \(J^r\)\(^{50}\)\text{Cr}: OBLATE OR PROLATE

In a recent publication \([1]\), the current authors noted that in shell model calculations for \(^{50}\text{Cr}\), in which up to three nucleons were allowed to be excited from the \(f_{7/2}\) shell to the rest of the \(f-p\) shell, the static quadrupole moments of the yrast states with \(J^r = 2^+, 4^+, 6^+\), and \(8^+\) were negative but those for \(J^r = 10^+, 12^+, \) and \(14^+\) were positive. However, the question of whether the latter three states were oblate or prolate was not answered definitively. We here address this issue.

With the FPD6 interaction \([2]\), and allowing up to three nucleons to be excited from the \(f_{7/2}\) shell (\(t=3\)), the static quadrupole moments (in \(\text{e fm}^2\)) were -27.5, -34.8, -8.1, -20.7 for \(J^r = 2^+, 4^+, 6^+\), and \(8^+\) respectively and were +45.7, +18.6, and +11.4 for \(J^r = 10^+, 12^+, \) and \(14^+\). With the KB3 interaction \([3]\), the corresponding values are -24.8, -30.0, -15.6, -14.7 for \(J^r = 2^+, 4^+, 6^+\), and \(8^+\) and +26.5, +13.0, and +8.2 for \(J^r = 10^+, 12^+, \) and \(14^+\). Note that there is not a smooth transition in going from \(J^r = 8^+_1\) to \(J^r = 10^+_1\). The value of \(Q\) for \(8^+_1\) is fairly large and negative while the value for \(10^+_1\) is large and positive.

If \(K\) were a good quantum number, we could use the rotational formula

\[
Q(J) = \frac{3K^2 - J(J + 1)}{(J + 1)(2J + 3)}Q_K,
\]

where \(Q_K\) is the intrinsic quadrupole moment, to determine \(K\). For \(J^r = 10^+, 12^+, \) and \(14^+\), if \(K\) is small (\(K \leq 6\)), then \(Q(J)\) and \(Q_K\) have opposite signs. But if \(K\) is sufficiently large, \(Q(J)\) and \(Q_K\) will have the same sign.

We expect considerable band mixing. Nevertheless we feel that a crude analysis using the above formula would be helpful in determining in which ball park we are. To reduce the ambiguity of the effective charges, we take ratios. Thus,

\[
\frac{Q(10^+)}{Q(12^+)} = 1.38\frac{3K^2 - 110}{3K^2 - 156},
\]

(2)

\[
\frac{Q(12^+)}{Q(14^+)} = 1.32\frac{3K^2 - 156}{3K^2 - 210}.
\]

(3)

For the FPD6 interaction \([2]\), the first equation in the above gives \(K = 8.5\) while the second one gives \(K = 12.1\). With the KB3 interaction \([3]\), the corresponding numbers are similar: \(K = 9.2\) and \(K = 12.8\). Thus this admittedly crude analysis favors a “high-\(K\) prolate” interpretation for these states.

It should be noted that the lower spin states, especially, \(J^r = 2^+\) and \(4^+\) are best described as low-\(K\) prolate states. Thus all the states are prolate but the nature of the \(J^r = 10^+, 12^+, \) and \(14^+\) “band” is quite different from that of \(J^r = 2^+, 4^+, 6^+,\) and \(8^+\). We clearly have a band crossing phenomenon and it is interesting to note that one shell model configuration \((f_{7/2})^{10}\) contains in some sense both of the two bands.

II. MAGNETIC G FACTORS IN \(^{50}\)CR AND THE ONSET OF NUCLEAR COLLECTIVITY

In a recent experimental work, Pakou et al. \([4]\) measured \((g = \mu/J)\) factors of states in \(^{50}\text{Cr}\) with the following results:

\[
\begin{align*}
J^r & \quad g \\
2^+ & \quad 0.54(11) \\
4^+_1 & \quad 0.43(9) \\
6^+_1 & \quad 0.54(16) \\
8^+_1 & \quad 0.54(9)
\end{align*}
\]

For \(4^+_1, 6^+_1,\) and \(8^+_1\), these are much smaller than the \(g\) factors calculated in the single \(j\) shell model \([3]\). The suggestion was made in the 1994 paper \([5]\) that the onset of nuclear collectivity brought the \(g\) factors close to the rotational result for a \(K = 0\) band of \(g \approx g_R = Z/A\).
This result has motivated us here to calculate the \( g \) factors in larger shell model spaces. We allow up to \( t \) nucleons to be excited from the \( f_{7/2} \) shell to the rest of the \( f-p \) shell and show results for \( t = 0, 1, 2, \) and 3 for the \( g \) factors in Table I.

We should first remark that from our previous work on static quadrupole moments \( Q \), we agree that there is an onset of nuclear collectivity, in the sense that the \( B(E2) \)'s become bigger as \( t \) increases, the energy levels look more rotational and \( Q \) for \( J \) up to 8 become more negative relative to \( t = 0 \). In that work, the FPD6 interaction \([2]\) was used. In this work, we show the behavior of \( Q \) using the KB3 interaction \([3]\). This also shows the increase in magnitude of \( Q \) for \( J^\pi = 2^+, 4^+, 6^+, \) and \( 8^+ \) (more negative).

However, when we look at the \( g \) factors, the change is not so drastic. Even for \( t = 3 \) one still gets large \( g \) factors. The values for \( 2^+_1, 4^+_1, 6^+_1, \) and \( 8^+_1 \) using free \( g_{l,\pi}, g_{l,\nu}, g_{s,\pi}, \) and \( g_{s,\nu} \) values are 0.58, 0.80, 0.79, and 0.83, respectively. These are considerably larger than the experimental values.

If we use quenched spin \( g \) factors \( g_{s,\pi/\nu} = 0.7 g_{s,\pi/\nu} \), along with \( g_{l,\pi} = 1.1 \) and \( g_{l,\nu} = -0.1 \), the corresponding results for \( g \) decrease somewhat to 0.54, 0.76, 0.74, and 0.78. But they are still substantially larger than experiment.

Thus the calculated onset of nuclear collectivity consists of large changes in the \( B(E2) \)'s and \( Q \), but much smaller changes in magnetic \( g \) factors. With the bare \( g_l \) and \( g_s \) values, the percent change for the \( g \) factors in going from \( t = 0 \) to \( t = 3 \) for \( 2^+_1, 4^+_1, 6^+_1, 8^+_1 \) are 18.1%, 15.3%, 10.4%, and 7.6%, respectively. As can be seen from Table II, there are more than a factor of two changes for \( Q \).

It would be nice in the near future to bring about a reconciliation between theory and experiment.

### III. OTHER “BANDS” IN \( ^{50}\text{Cr} \)

In our previous work \([1]\), we focused on yrast states in \( ^{50}\text{Cr} \) and showed that whereas the \( 2^+_1, 4^+_1, 6^+_1, \) and \( 8^+_1 \) states have negative static quadrupole moments \( Q \), the \( 10^+_1, 12^+_1, \) and \( 14^+_1 \) have positive \( Q \)'s. There is a band crossing and, to some extent, even the simplest configuration \((f_{7/2})^6\) has in it both the ground-state band and the second band which overrides the ground-state band at \( J^\pi = 10^+ \).

In Table III we showed for \( t = 3 \) a common feature of the states \( 2^+_1, 4^+_2, 6^+_2, \) and \( 8^+_2 \). They have rather large, positive quadrupole moments. This result contradicts with the yrast band calculation for which the \( Q \)'s are comparable in magnitude but are negative.

We also show in Table III the values of \( Q \) for the \( 10^+_1, 12^+_1, \) and \( 14^+_1 \) states. They are also positive. It is not clear how to extend the band \( 8^+_1 \) – whether to include the \( 10^+_1 \) or \( 12^+_1 \) state. Since the two \( 10^+ \) states are rather close in energy, it could be that some admixture of these looks most like a member of the band.

There have been measurements in other parts of the periodic table where the \( g \) factors for even-even nuclei differ substantially from \( Z/A \). For example, for \( ^{150}\text{Sm} \), Vass et al. \( ^{[1]} \) reported that \( g(4+)/g(2+) = 1.60(12) \) whilst \( g(6+)/g(2+) = 1.14(34) \). Of course, since in this calculation we are dealing with \( ^{50}\text{Cr} \) we cannot say that their measurement supports our calculation or vice versa. But at least it suggests that one should be on the lookout for the types of behaviours that both works seem to find.

### IV. JOLOS-VON BRENTANO RELATIONSHIP

Recently R.V. Jolos and P. von Brentano (hereinafter referred to as J-vB) \([5]\) have presented a formula which relates quadrupole moments of the \( 2^+_1 \) states to various \( B(E2) \) values. This connection is of great interest because it is much more difficult to measure static quadrupole moments than it is to measure \( B(E2) \)'s. They feel that the formula should be extremely accurate (better than 1.5%) for deformed nuclei for which \( E^*(4^+_1)/E^*(2^+_1) \geq 2.9 \), where \( E^*(4^+_1) \) and \( E^*(2^+_1) \) are the excitation energies of the \( 4^+_1 \) and \( 2^+_1 \) states relative to the ground state. Also for “realistic cases” the predictions given by the formula agree with IBM-1 results to better than 2% for \( N = 12 \) and 6% for \( N = 6 \). Their relationship can be written as

\[
\frac{|Q(2^+_1)|}{\sqrt{B(E2 : 2^+_1 \rightarrow 0^+_1)}} = \frac{8}{7} \sqrt{\pi G(1 + R_1 - W)},
\]

where

\[
G = \left( \frac{7}{10} \right) \frac{B(E2 : 4^+_1 \rightarrow 2^+_1)}{B(E2 : 2^+_1 \rightarrow 0^+_1)},
\]

\[
R_1 = \frac{B(E2 : 2^+_2 \rightarrow 0^+_1)}{B(E2 : 2^+_1 \rightarrow 0^+_1)},
\]

and

\[
W = \frac{B(E2 : 2^+_3 \rightarrow 2^+_1)}{B(E2 : 4^+_1 \rightarrow 2^+_1)}.
\]

Of course the rotational formulae of Bohr and Mottelson can also be combined to give a relationship between \( B(E2) \) and \( Q(2^+_1) \). These are Eq.\((1)\) and

\[
B(E2 : KJ_1 \rightarrow KJ_2) = \frac{5}{16\pi} e^2 Q_0^2 (J_1K20|J_2K)^2,
\]

where \( (J_1K20|J_2K) \) is the Clebsch-Gordon coefficient. For a \( K = 0 \) band, one gets

\[
|Q(2^+_1)| = \sqrt{\frac{64\pi}{49} B(E2 : 2^+_1 \rightarrow 0^+_1)}.\]

Note that in the rotational limit, \( G = 1 \). If one also takes \( R_1 = W = 0 \), i.e., if one neglects interband transitions,
one then recovers the above rotational formula from the J-vB equation \( (\text{1}) \). It is interesting to find out if, for a non-perfect rotor, the J-vB relation would yield a more accurate \( Q(2^+_1) \). To this end, we conduct a theoretical experiment by performing shell-model calculations for the \( B(E2) \) values that go into Eqs. \( (\text{4}) \) and \( (\text{5}) \) and comparing the predictions of these two formulae for \( |Q(2^+_1)| \) to the “exact” values obtained in the shell-model calculations. We do this calculation for selected deformed nuclei in the \( s\)-\( d \) \( (^{20}\text{Ne}, ^{22}\text{Ne}, ^{24}\text{Mg} \text{ and } ^{28}\text{Si}) \) and \( f\)-\( p \) \( (^{46}\text{Ti}, ^{48}\text{Ti}, \text{ and } ^{50}\text{Cr}) \) region. For the \( s\)-\( d \) shell, we use the Brown-Wildenthal interaction \( (\text{3}) \); for the \( f\)-\( p \) shell, we use the modified Kuo-Brown interaction KB3 \( (\text{3}) \). For the \( s\)-\( d \) shell nuclei, the calculations are carried out in the full one-major-shell space. For the \( f\)-\( p \) shell nuclei, the full space calculation is only done for \( ^{46}\text{Ti} \). For the other two nuclei, a maximum number of \( t \) nucleons are allowed to leave the \( f_{7/2} \) orbital and occupy the rest of the \( f\)-\( p \) shell with \( t = 4 \) for \( ^{48}\text{Ti} \) and \( t = 3 \) for \( ^{50}\text{Cr} \).

Our results are listed in Table IV where we also list the experimental values for the ratio \( E^*(4^+_1)/E^*(2^+_1) \) and \( Q(2^+_1) \). The calculated values for various \( B(E2) \)'s that go into the J-vB formula \( (\text{4}) \) and the rotational formula \( (\text{1}) \) are listed in Table V where the experimental \( B(E2 : 2^+_1 \rightarrow 0^+_1) \) values are also shown. With one notable exception, the J-vB predictions agree with the shell model results to better than 12%. However, for all the nuclei that are considered here, only for one nucleus \( (^{46}\text{Ti}) \) has the J-vB formula done a better job than the rotational formula. This is surprising because one would expect that there is more physics put into the J-vB formula.

The biggest disagreement between the rotational formula and the shell model results occurs in \( ^{46}\text{Ti} \) and \( ^{48}\text{Ti} \), where the discrepancies are 34% and 37% respectively. The J-vB formula seems to cure the problem for \( ^{48}\text{Ti} \) but not for \( ^{46}\text{Ti} \). The problem in the latter case is that \( R_1 \) and \( W \) are almost the same and so cancel each other out.

In Table VI we apply the J-vB relation to experimental input in the \( f\)-\( p \) shell which are obtained from the Nuclear Data Sheets \( (\text{12}) \). Note that the experimental \( B(E2) \)’s are somewhat larger than those calculated with the KB3 interaction with effective charges of \( e_p=1.5 \) and \( e_n=0.5 \). The experimental values of \( G \) are considerably smaller than the calculated values. In other words, \( B(E2 : 4^+_1 \rightarrow 2^+_1)_{\text{exp}} \) is smaller than \( B(E2 : 4^+_1 \rightarrow 2^+_1)_{\text{theory}} \). There are considerable differences in the values of \( R_1 \) and \( W \) as well.

Using the J-vB relation with experimental data the values of \( Q(2^+_1) \) are significantly smaller than those using the rotational model. For \( ^{46}\text{Ti}, ^{48}\text{Ti}, ^{50}\text{Cr} \), the J-vB (rotational) values of \( Q(2^+_1) \) are respectively 20.5 (28.7), 12.7 (24.3), and 22.5 (29.8). For \( ^{46}\text{Ti} \) and \( ^{48}\text{Ti} \), the J-vB analysis gives an improved fit. For \( ^{50}\text{Cr} \), the J-vB analysis gives too small a value of \( Q(2^+_1) \) compared with experiment.

It is difficult to give a definite assessment of the J-vB relation in the regions that we have considered (which in some cases are beyond what the authors envisioned). One problem is that the error bars on the data are rather large and they may be systematic errors beyond those taken into account. But it would seem that the J-vB relation works better when experimental data is used rather than “theoretical data” from shell model calculations.

| $^{22}\text{Ne}$ | 61.53 (46) | 4.57 | 0.55 | 82.62 | 0.94 | 0.074 | 0.006 |
| $^{24}\text{Mg}$ | 96.48 (86.4) | 8.63 | 21.07 | 128.23 | 0.93 | 0.089 | 0.164 |
| $^{28}\text{Si}$ | 99.92 (65.2) | 0.36 | 13.86 | 141.41 | 0.99 | 0.004 | 0.098 |
| $^{46}\text{Ti}$ | 131.32 (201) | 4.48 | 70.25 | 173.59 | 0.93 | 0.034 | 0.405 |
| $^{48}\text{Ti}$ | 99.10 (144) | 23.44 | 40.99 | 148.02 | 1.05 | 0.236 | 0.277 |
| $^{50}\text{Cr}$ | 172.82 (216) | 11.27 | 2.13 | 245.72 | 1.00 | 0.065 | 0.0087 |

TABLE VI. Same as Table V but using experimental input. Only the results for the f-p shell nuclei are listed.

| Nucleus | $B(E2: 2_1^+ \rightarrow 0_1^+)$ | $G$ | $R_1$ | $W$ | $|Q(2_1^+)_{\text{J-vB}}|$ | $|Q(2_1^+)_{\text{rot}}|$ |
|---------|-------------------------------|-----|------|-----|-----------------|-----------------|
| $^{46}\text{Ti}$ | 201 | 0.686 | 0.003 | 0.260 | 20.5 | 28.7 |
| $^{48}\text{Ti}$ | 144 | 0.564 | 0.060 | 0.580 | 12.6 | 24.3 |
| $^{50}\text{Cr}$ | 216 | 0.516 | 0.106 | 0.000 | 22.5 | 29.8 |

$^a$ We consider only $2_1^+ \rightarrow 0_1^+$ transition to determine $W$.

$^b$ We add $2_3^+ \rightarrow 0_1^+$ and $2_3^+ \rightarrow 0_1^+$ transitions. The states are close together: $E(2_2^+) = 2.924\text{MeV}$ and $E(2_3^+) = 3.161\text{MeV}$.
