In this work we reproduce the phenomenology of the electromagnetically induced transparency and dynamic Stark effect in a dissipative system composed by two coupled bosonic fields under linear and nonlinear amplification process. Such a system can be used as a quantum switch in networks of oscillators.

PACS number: 32.80.-t, 42.50.Ct, 42.50.Dv

Much of the recent work in quantum optics has been devoted to quantum coherence and interference as a result of the mastery gained in manipulating atom-field interaction, which allows us to probe fundamental quantum effects. Within this scenario, electromagnetically-induced transparency (EIT) plays an essential role in a variety of processes, ranging from lasing without inversion and enhanced nonlinear optics to quantum computation and communication. Relying on destructive quantum interference, EIT is a phenomenon in which the absorption of a probe-field atom resonant with an atomic transition is reduced or even eliminated by the application of a strong driving laser to an adjacent transition. This effect can be understood as arising from the ac-Stark splitting of an excited atomic state linking the two adjacent transitions. When the splitting is smaller than the excited state width, the two resulting levels are indistinguishable, leading to a destructive interference in the probe absorption spectrum. As the intensity of the driving field increases, the splitting is enlarged, eliminating the indistinguishability and, consequently, the absorption spectrum evolves to the Autler-Townes (AT) doublet. By a similar mechanism, although relying on nonlinear interactions, the strong excitation of a two-level atom induces a dynamic Stark effect (DSE) leading to the appearance of sidebands in the resonance fluorescence spectrum.

Recently, some effects of three-level atom optics, including EIT, were simulated via the tunneling interaction in the context of trapped atoms. In this connection, the phenomenology observed in EIT was reproduced in a system of two coupled dissipative classical oscillators. One of these oscillators, modeling the three-level atom, is subject to a linear driving force playing the role of the probe field. The pump field is simulated by the coupling between the oscillators. The quantum version of this classical analog of EIT, which helps to deepen our understanding of this phenomenon and its properties, will be analyzed in the present work. Here, the classical oscillators are replaced by two quantum resonators interacting through a Josephson-type coupling. Linear and nonlinear amplifications are employed as the probe fields, the former is used to emulate the EIT phenomenon, and the latter is applied to obtain the DSE — reproducing the phenomenology of the nonlinear mechanism related to resonance fluorescence from a strongly-driven two-level transition. The coupling parameter between the resonators plays the role of the driving field, by analogy with the standard EIT and DSE. We show that the signatures of these processes can be obtained by measuring the field quadratures.

The Hamiltonian of the coupled dissipative resonators, labeled by \( \ell = 1, 2 \), is given by (\( h = 1 \))

\[
H = \sum_\ell \omega_\ell a_\ell^{\dagger} a_\ell + \sum_{\ell,k} \omega_{\ell k} b_{\ell k}^{\dagger} b_{\ell k} \\
+ \lambda \left( a_1 a_2^{\dagger} + a_2 a_1^{\dagger} \right) + \sum_{\ell,k} V_{\ell k} \left( a_{\ell} b_{\ell k}^{\dagger} + a_{\ell k}^\dagger b_{\ell k} \right) \\
+ F \left( e^{-i\nu t} a_1^{\dagger} \right)^p + \left( e^{i\nu t} a_1 \right)^p,
\]

where \( a_\ell^{\dagger} (a_\ell) \) is the creation (annihilation) operator for the oscillator mode \( \ell \) of frequency \( \omega_\ell \), whereas \( b_{\ell k}^{\dagger} (b_{\ell k}) \) is the analogous operator for the \( k \)th bath mode of oscillator \( \ell \), whose corresponding frequency and coupling strength are \( \omega_{\ell k} \) and \( V_{\ell k} \), respectively. The coupling strength between the oscillators is \( \lambda \) and the classical driving field applied to oscillator 1 has intensity \( F \) and frequency \( \nu \), with the parameter \( p = 1 \) or 2 for the linear or nonlinear amplification process.

Following the reasoning in Ref. 8, we obtain (in a rotating frame with frequency \( \nu \) and assuming the reservoir at zero temperature) the master equation for the system dynamics, given by

\[
\frac{d\rho_{12}(t)}{dt} = i \left[ \rho_{12}(t), H_0 \right] \\
+ \sum_\ell \frac{\Gamma_\ell}{2} \left( \left[ a_\ell \rho_{12}(t), a_\ell^\dagger \right] + \left[ a_\ell^\dagger \rho_{12}(t), a_\ell \right] \right),
\]

where \( \Gamma_\ell \) is the damping rate of resonator \( \ell \) and we have...
defined

\[ H_0 = \sum_\ell \Omega_\ell a_\ell^\dagger a_\ell + \lambda \left(a_1 a_2^\dagger + a_1^\dagger a_2\right) + F \left(\left(a_1^\dagger\right)^p + (a_1)^p\right), \tag{3} \]

with \( \Omega_\ell \equiv \omega_\ell - \nu \) being the effective frequency of the oscillator \( \ell \) shifted by the amplification process. Using the standard procedures and assuming Markovian white noise, we derive a c-number version of the master equation \( \dot{\chi} = \chi \) for the symmetric ordered characteristic function \( \chi(\{\eta_\ell\}, t) \), given by

\[
\frac{d\chi(\{\eta_\ell\}, t)}{dt} = \sum_\ell \left[ \left( C_\ell(\{\eta_\ell\}) \frac{\partial}{\partial \eta_\ell} + \text{c.c.} \right) \right.
\]

\[
+ iF \left( \eta_\ell + \eta_\ell^* \right) (\eta_1 - \eta_1^*)^{(p-1)} \delta_{\ell,1} \right] \times \chi(\{\eta_\ell\}, t), \tag{4} \]

where \( C_\ell(\{\eta_\ell\}) = \eta_\ell \Lambda_\ell + i\lambda \eta_\ell (-1)^\ell \pm 2i (p-1) F \eta_\ell^2 \), \( \Lambda_\ell = \Gamma_\ell / 2 + i\Omega_\ell \), and \( \eta_\ell \) is the complex parameter of the characteristic function. From the analytical solution of Eq. \( \Box \), obtained by standard techniques \( \Box \), we observe for the linear amplification \( (p = 1) \), that the modes in both resonators always evolve to stationary coherent states, characterized by the equilibrium between the amplification process and the dissipative mechanisms, mediated by the coupling strength \( \lambda \). These stationary coherent states, \( |\alpha\rangle \) and \( |\beta\rangle \), have the complex amplitudes \( \alpha = -iF \Lambda_2 / (\lambda^2 + \Lambda_1 \Lambda_2) \) and \( \beta = -\lambda F / (\lambda^2 + \Lambda_1 \Lambda_2) \).

The EIT-like phenomenon, which occurs in the region where \( \Gamma_1 \gg \lambda \gg \Gamma_2 \), is characterized by the state of the field in resonator 1 around the relaxation time \( \tau_R \) of the joint system. For the linear amplification case, the relaxation time, derived from the condition \( \partial_\chi(\{\eta_\ell\}, t) / \partial t \to 0 \) \( \Box \), is given by the simple expression \( \tau_R = 2\lambda^2 / (\lambda^2 + \Lambda_1 \Lambda_2) \). In Ref. \( \Box \), it is noted that the cavity-field states are interchanged between the resonators through state-swap and the state-recurrence dynamics. Before the relaxation time, the coherence dynamics of quantum states between the two resonators prevents the EIT from occurring. Therefore, the system must achieve a stationary state to enable the appearance of the destructive interference, which promotes the EIT. For this reason, from here on we will be interested in the states of resonator 1 around the relaxation time.

In atomic samples the EIT phenomenon is characterized by the permittivity of the medium, associated with the complex quantity \( n + ik \), where the dispersive and the absorptive responses follow, respectively, from the real part of the refractive index \( n \) and the absorption coefficient \( k \) \( \Box \). Here, the role of the permittivity is played by the quantity \( \varepsilon_\ell^{1/2} e^{i\Theta_\ell} \) representing the center of the quasi-probability distribution of the cavity-field state in the phase space defined by its quadratures \( X_\ell = (a_\ell + a_\ell^\dagger) / 2 \) and \( Y_\ell = (a_\ell - a_\ell^\dagger) / 2i \). The absorption coefficient is directly associated with the mean energy of the cavity field \( \ell \), given by the correlation function \( \varepsilon_\ell = \langle X_\ell^2 + Y_\ell^2 \rangle \) (in units of \( \hbar \omega_\ell \)). The dispersive response is associated with the angle \( \Theta \) through the correlation function \( \chi(\{\eta_\ell\}, t) / \varepsilon_\ell = \sin (2\Theta_\ell) \).

In Ref. \( \Box \), the dispersive response \( \text{Re} [x_\ell (\tilde{w} - \tilde{w}_1)] \) is derived from the real part of the frequency dependence of the amplitude \( x_\ell (\tilde{w} - \tilde{w}_1) \) of one oscillator (frequency \( \tilde{w}_1 \)), submitted to a linear driving force (frequency \( \tilde{w} \)), and coupled to another oscillator (frequency \( \tilde{w}_2 \) and amplitude \( x_2 \)). In the present model, the equivalent mean value \( \varepsilon_\ell \) also leads to the required dispersive response, as in \( \Box \), for the linear amplification process \( (p = 1) \). However, in the case of nonlinear amplification \( (p = 2) \), the mean value \( \varepsilon_\ell \) is not a convenient quantity to measure the dispersive response since it is null when the initial excitation of the cavity field \( \ell \) is also null (vacuum state). To circumvent this problem, we have considered the correlation function \( \chi(\{\eta_\ell\}, t) / \varepsilon_\ell \) to describe the dispersive response in a quite general way. In fact, its classical analog, proportional to \( \text{Re} [x_\ell p_\ell] \) (where \( p_\ell \) is the momentum of the classical oscillator \( \ell \)), also leads to the usual dispersion exhibiting a very steep slope in the EIT regime. The absorptive and dispersive responses given by the correlation functions \( \langle X_\ell^2 + Y_\ell^2 \rangle \) and \( \langle X_\ell Y_\ell + Y_\ell X_\ell \rangle / \varepsilon_\ell \), respectively, are computed from the characteristic function \( \chi(\{m_\ell\}, t) \) \( (m = 1, 2) \) as

\[
E_\ell = - \frac{\partial^2}{\partial \eta_\ell \partial \eta_\ell^*} \chi(\{m_\ell\}, t) \bigg|_{\eta_\ell \to 0}, \tag{5a} \]

\[
\sin (2\Theta_\ell) = \frac{1}{E_\ell} \left( \frac{\partial^2}{\partial (\eta_\ell)^2} - \frac{\partial^2}{\partial (\eta_\ell^*)^2} \right) \chi(\{m_\ell\}, t) \bigg|_{\eta_\ell \to 0}. \tag{5b} \]

**Linear amplification.** To characterize the EIT, we plot the mean values \( E_\ell \) and \( \sin (2\Theta_\ell) \), for resonator 1, against the detuning \( \Delta = (\nu - \omega_1) / \Gamma_1 \). Before the relaxation time \( \tau_R \) \( \ell \), i.e., \( t \ll \tau_R \), the EIT is inhibited by the coherence dynamics between the cavity-field states. Near the relaxation time, the EIT starts appearing, evolving to its standard shape at the relaxation time, as displayed in Fig. 1(a). In Fig. 1(b) we assume the non-degenerate case \( \omega_1 = \omega_2 - \epsilon \) at the relaxation time, where the hole burned when \( \nu = \omega_1 \) in the degenerate case [Fig. 1(a)], shifts to \( \nu = \omega_1 + \epsilon \) (where \( \epsilon / \Gamma_1 = 3 \)). It is interesting to note, that in the non-degenerate case [Fig. 1(b)], the EIT happens when the linear amplification \( \nu \) is in resonance with resonator 2 \( (\omega_2) \). A complete transparency occurs only when \( \Gamma_2 = 0 \), since the minimum of the hole burned in the peak of the absorptive response is given by \( E_\ell^{\text{min}} = \left[ 2\Gamma_2 / (4\lambda^2 + \Gamma_1 \Gamma_2) \right]^{1/2} \). Assuming the same parameters as those in Fig. 1(a) but a stronger coupling strength \( \lambda / \Gamma_1 = 1 \), the EIT evolves to the AT regime as shown in Fig. 1(c). Finally, the dispersion curves, in
the critical amplification amplitude for the solutions of Eq. (4), which
\[ \frac{\xi}{\xi} \geq \xi \geq \xi \]

the amplification case (p \( \xi \))

If \( \xi \) \( \xi \)

the right side of Fig. 1(a,b,c), display the well-known signature of the EIT effect.

**Nonlinear amplification.** In the nonlinear or parametric amplification case (p = 2), there is a well-known threshold in the dynamics of the system \( \xi, \xi \)

which is reached when the rescaled amplification parameter, \( \xi = 4 \xi \)

equals the critical value \( \xi_c \) (which depends on the critical amplification amplitude \( F_c \)). We obtain three different dynamics for the solutions of Eq. (4), which depend on whether the rescaled amplification is strong (\( \xi > \xi_c \)), critical (\( \xi = \xi_c \)), or weak (\( \xi < \xi_c \)). When \( \xi \geq \xi_c \), the asymptotic solution diverges for any physical quantity whereas we obtain stationary solutions when \( \xi < \xi_c \). In the degenerate resonance case, \( \omega_1 = \omega_2 = \omega \), the critical amplification parameter is given either by \( \xi_c = 1 + 4 \lambda^2 / (\Gamma_1 \Gamma_2) \) (for \( \lambda < \Gamma_2 / 2 \)) or \( \xi_c = 1 + \Gamma_2 / \Gamma_1 \) (if \( \lambda \geq \Gamma_2 / 2 \)). Evidently, when \( \lambda = 0 \) we recover the usual result \( \xi_c = 1 \) for an uncoupled system under nonlinear amplification. In these three regimes the state of oscillator 1 evolves to a squeezed coherent state (SCS) which is stationary for \( \xi < \xi_c \) and whose energies increase monotonically for \( \xi \geq \xi_c \).

Now, in order to analyze the behavior of the absorptive and dispersive curves of resonator 1, in the three regimes exposed above, we plot the rate \( E_1/E \), instead of \( E_1 \), where \( E \) stands for the value of \( E_1 \) when the detuning \( \Delta = 0 \). In this case, the EIT occurs only in a narrow interval \( |\xi| \lesssim \xi_c = 10^{-4} \) around the threshold given by the critical parameter \( \xi_c \), i.e., around \( F_c = (\Gamma_1 + 4 \lambda^2 / \Gamma_2) / 4 \) for \( \lambda < \Gamma_2 / 2 \), or \( F_c = (\Gamma_1 + \Gamma_2) / 4 \) for \( \lambda \geq \Gamma_2 / 2 \). Differently from the linear amplification process, where the EIT can be achieved independently of the ratio \( F/\Gamma_1 \), the strong dependence of this effect upon the amplitude of the nonlinear driving field follows from the two-photon nature of this amplification process. As far as the coupling strength is concerned, although it must be much smaller than \( \Gamma_1 \) as in the linear amplification case, here it can be around \( \Gamma_2 \), obeying the relation \( \Gamma_2 \lesssim \lambda \ll \Gamma_1 \).

In the nonlinear case the relaxation time \( \tau_R \) can only be obtained from the condition \( \partial (\{ \eta_n \}, t) / \partial t \rightarrow 0 \) in the weak amplification regime. This time will be used as a reference to compare the three different amplification regimes, since there is no stationary dynamics when \( \xi \gtrsim \xi_c \). We can see in Fig. 2(a), the absorptive curve for the weak amplification regime, that the EIT is not so pronounced as in the linear amplification case. In fact, it can barely be characterized as an EIT, since the maximum of the ratio \( E_1/E \) is close to unity (i.e., the minimum of the hole burned in the peak of the absorptive curve, when \( \Delta = 0 \)). The absorptive curve remains immovable for \( t > \tau_R \) due to the stationary solution achieved in the

**Note:** The text continues with a discussion of the results from Fig. 2(a), highlighting the differences between the linear and nonlinear regimes, and the implications for EIT. The diagrams in Fig. 1 illustrate the absorptive and dispersive-like curves for the linear amplification process, demonstrating the changes in behavior across different regimes. The figures are used to support the theoretical analysis, showing how the system transitions from one regime to another. The images in Fig. 2 further elaborate on these behaviors, with graphs illustrating the absorptive-like curves for the nonlinear amplification process, comparing weak, critical, and strong regimes.
weak amplification regime. Differently from Fig. 2(a), we observe that in the critical regime, Fig. 2(b), the maximum of the ratio $E_1/E$ is about two orders of magnitude larger than unity ($E_1 = E$) for $t = \tau_R$ (solid line), increasing as time goes on. However, as in the weak amplification regime, the behavior observed here can hardly be characterized as an EIT, but rather a mixing of EIT and AT effects, since the hole burned in the peak of the absorptive response presents a significant width compared to the usual EIT. In Fig. 2(c), for the strong amplification regime, a mixing of the EIT and the AT effects is observed again, but the ratio $E_1/E$ does not increase as quickly as in the critical regime — even so, $E_1$ and $E$ increase, independently, as faster as they do in the critical regime. The maximum of the rate $E_1/E$ is (only) about one order of magnitude larger than unity ($E_1 = E$) for $t = \tau_R$ and decreases as the time goes on. We note that the range of the detuning $\Delta$, in Figs. 2(b) and (c) — where the absorptive curves assume significant values — is considerably smaller than that in Fig. 2(a) for the weak regime. Therefore, as the rescaled amplification parameter $\xi$ increases, the range $\Delta$ of the absorptive curve decreases. From this perspective, it is not difficult to understand why the range $\Delta$ of the absorptive curve in the linear amplification regime (Fig. 1) is larger than those in the nonlinear one. Regarding the dispersive curve, it happens to be practically the same for the three parametric amplification regimes and the steep slope characteristic of the EIT effect is lost.

Finally, in Fig. 2(d) we display the absorptive curve in the weak amplification regime at the relaxation time $\tau_R$, but increasing the coupling strength such that $\lambda/\Gamma_1 = 10^{-2}$ (instead of $5 \times 10^{-5}$). We thus observe the well-known pattern exhibited by the resonance fluorescence spectrum of a two-level atom driven by an incident field whose Rabi frequency is comparable to, or larger than, the atomic linewidth. After all, as the phenomenology of the EIT can be reproduced in a system of two coupled dissipative oscillators, the same occurs with the phenomenology of resonance fluorescence. Resonator 1 again plays the role of the two-level atom, while the strong driving field (whose intensity leads to a modulation of the quantum dipole moment inducing sidebands in the spectrum) is simulated by the nonlinear amplification together with resonator 2. In fact, high-intensity driving fields give rise to nonlinear interactions which may be attributed to two laser fields, modeled by the actual parametric field plus resonator 2. The pattern displayed in Fig. 2(d) can also be obtained in the critical and strong amplification regimes but, of course, it does not occur with linear amplification, whatever its intensity. The parametric amplification field is the only nonlinear ingredient in our system of two coupled dissipative oscillators.

We have shown that a system of two coupled dissipative oscillators, under linear and parametric amplification, can reproduce the phenomenology of EIT and DSE, respectively. Such phenomena can be, at principle, implemented in several physical contexts, such as: cavity quantum electrodynamics \[14\], trapped ions \[15\], and nanomechanical oscillators \[16\]. The system presented here can be used for quantum switching purposes, since the hole burned in the EIT regime can be shifted by external means, feeding or draining the field in resonator 1. For example, the dispersive interaction of a fermionic particle with the field in oscillator 2 can pull both oscillators out of resonance, changing the profile of the absorption curve of oscillator 1 from Fig. 1(a) to 1(b). Therefore, these effects have the potential to be used as a control mechanism in networks of quantum oscillators, a subject which attracts great attention nowadays \[17\].
