Emerging role of adipokines as mediators in atherosclerosis

Hanrui Zhang, Jian Cui, Cuihua Zhang

Abstract

Atherosclerotic cardiovascular disease is a major health problem around the world. Obesity is a primary risk factor for atherosclerosis and is associated with increased morbidity and mortality of cardiovascular diseases. However, the precise molecular pathways underlying this close association remain poorly understood. Adipokines are cytokines, chemokines and hormones secreted by adipose tissue that couple the regulation of lipid accumulation, inflammation, and atherogenesis, and therefore serve to link obesity with cardiovascular disorders. Obesity-related disorders including metabolic syndrome, diabetes, atherosclerosis, hypertension, and coronary artery disease are associated with dysregulated adipokine(s) expression. Recent studies demonstrate the proinflammatory effects as well as atherogenic properties of adipokines. Adipokines also participate in the regulation of endothelial function, which is an early event in atherosclerosis. By contrast, adiponectin, an adipocyte-derived hormone, exerts anti-inflammatory, anti-atherogenic and vascular protective effects. Furthermore, there is an interactive association among adipokines, by which adipokines reciprocally regulate each other’s expression. Understanding this interplay may reveal plausible mechanisms for treating atherosclerosis and coronary heart disease by modulating adipokine(s) expression. In this review, we discuss insights into the role and the therapeutic potential of adipokines as mediators of atherosclerosis.
strongly indicate that adipose tissue is an active endocrine organ that secretes multiple bioactive factors categorized as adipokines\textsuperscript{[6-8]}. The adipokines include a large number of cytokines [e.g. tumor necrosis factor (TNF)-\textalpha and interleukin (IL)-6], chemokines [e.g. IL-8 and monocyte chemotactant protein (MCP)-1] and hormones (e.g. leptin, resistin and adiponectin)\textsuperscript{[6-8]}. This review focuses on the contribution of excess adipose tissue to the major underlying cause of cardiovascular death, atherosclerosis and the evidence regarding potential mechanisms by which excess adipose tissue and the dysregulated adipokine expression profile could adversely affect the vessel wall.

**OBESITY AND ATHEROSCLEROSIS**

Atherosclerosis is characterized by the progressive deposition of fatty substances, cholesterol, etc. (called plaques) in the intima and contributes to many cardiovascular diseases. Plaques can rupture and lead to formation of a blood clot, which can cause fatal complications, such as heart attack or stroke. The classical perception of atherosclerosis merely as a cholesterol storage disease has been replaced by the notion that inflammatory processes regulate all stages of atherosclerosis\textsuperscript{[9]}. Obesity is an independent risk factor for the development of coronary artery atherosclerosis \textsuperscript{[10,11]}. The fact that the prevalence of obesity is increasing among youth as well as adults, highlights the necessity for closely examining the association of obesity with atherosclerosis and the prevention of obesity\textsuperscript{[11]}. Abdominal adiposity in particular is a major factor associated with accelerated progression of atherosclerosis, which emphasizes the need to develop strategies to avoid abdominal obesity and prevent atherosclerotic diseases\textsuperscript{[12]}. There are a number of mechanisms by which obesity can adversely affect the vasculature and thereby increase cardiovascular mortality. Obesity has various consequences known to accelerate atherosclerosis, including hypertension, diabetes, and dyslipidemia\textsuperscript{[10,13]}. Adipokines released by adipose tissue can target distant organs, such as liver, skeletal muscle and hypothalamus. These adipokines impact the atherogenic environment of the vessel wall through metabolic changes, such as hyperlipidemia, hyperglycemia and insulin resistance. Moreover, systemic inflammation attributed to proinflammatory adipokines produced by inflamed adipose tissue serves as an important factor contributing to the adverse effects of adiposity on the vasculature\textsuperscript{[13]}. Visceral adipose tissue, with its favored access to the portal circulation, could be particularly important in this pathway. In addition to the systemic effects, perivascular adipose tissue exhibiting a proinflammatory phenotype may exert paracrine effects and promote inflammatory cell infiltration into the vascular wall, thereby exerting local effects\textsuperscript{[13]}. In addition to proinflammatory effects and atherogenic properties, the most abundant adipocyte protein, adiponectin, has potent anti-atherogenic as well as anti-atherogenic effects\textsuperscript{[14]}. Those adipose-derived factors influence gene expression and cell function in endothelial cells, arterial smooth muscle cells, and monocytes/macrophages, which represent the major cell types of the artery wall and are major components for defending vessel wall homeostasis.

Therefore, adipokines may provide a link between adipose tissue lipid accumulation and atherosclerotic plaque formation, as well as the crosstalk between perivascular adipose and blood vessels in the regulation of atherosclerotic disease\textsuperscript{[13]} (Figure 1).

**THE PROINFLAMMATORY CAPACITY OF ADIPOSE TISSUE**

Obesity is associated with a chronic low-grade inflammatory condition in adipose tissue\textsuperscript{[15]}. During obesity, adipose tissue is infiltrated by macrophages and displays secretion of proinflammatory cytokines\textsuperscript{[16,17]}. Very recently, T cells have also been detected in adipose tissue with increased infiltration in obesity\textsuperscript{[18-20]}, suggesting the potential role of adaptive immunity in obesity-related inflammation. Meanwhile, chemokines expressed in obese adipose tissue likely mediate the recruitment of these cells\textsuperscript{[21]}, supporting the view of the existence of feedback regulation in perpetuating inflammatory status. Although it remains unclear which inflammatory cell types play predominant roles in the regulation of adipose inflammation, it is widely accepted that adipose inflammation, especially visceral adipose inflammation, increases vascular risk of disease due to secretion of adipokines by cellular constituents of the adipose tissue\textsuperscript{[22]}. Atherosclerotic mice exhibit increased
inflammation in periadventitial and visceral adipose tissue. The transplanted fat depots revealed chronically increased macrophage infiltration with characteristics identical to those observed in fat harvested from obese animals. Interestingly, by transplanting epididymal fat depots into atherosclerosis-prone apolipoprotein E knockout (ApoE KO) mice, plasma levels of leptin, resistin, and MCP-1 were increased. Mice transplanted with visceral fat developed significantly more atherosclerosis compared with sham-operated animals. The above results further support the idea that adipose inflammation contributes to atherosclerosis formation.

The cellular source of adipokines released by adipose tissue is examined in several studies. Leptin and adiponectin are predominantly produced by adipocytes in adipose tissue and released to the blood as hormones. Over 90% of the adipokines released by adipose tissue, except for adiponectin and leptin, could be attributed to nonfat cells. The location of adipose depots also affects the production and release of adipokines. Visceral adipose tissue released greater amounts of vascular endothelial growth factor, IL-6, and plasminogen activator inhibitor 1 compared with abdominal subcutaneous adipose tissue.

Therefore, the proinflammatory properties may serve as the molecular basis for linking obesity with cardiovascular disorders. Knowledge of how alterations in the endothelial function of adipose tissue occur may help to identify mechanisms underlying the high cardiovascular risk associated with obesity.

**ROLE OF ADIPOKINES IN ENDOTHelial DYSFUNCTION DURING ATHEROSCLEROSIS**

Endothelial dysfunction is a key early event in the development of atherosclerosis, which can be detected before structural changes to the vessel wall are apparent using angiography or ultrasound. Atherosclerotic endothelial dysfunction, particularly in the early disease stages, is primarily due to dysregulation of endothelial nitric oxide synthase (eNOS) enzymatic activity and inactivation of nitric oxide (NO) through oxidative stress. Reduced bioavailability of NO is involved in the initiation, progression and complications of atherosclerosis. NO opposes the effects of endothelium-derived vasoconstrictors and inhibits oxidation of low-density lipoprotein (LDL). Thus, reduced NO bioavailability leads to endothelial dysfunction.

Recent studies by our and other groups suggest adipokines play a role in regulating atherosclerotic endothelial function by mediating NO production and oxidative stress. Adiponectin induces eNOS activation and NO production in endothelial cells. Adiponectin reduces reactive oxygen species (ROS) production as well as improving endothelial function in aortas of ApoE KO mice. Adiponectin deficiency increases leukocyte-endothelium interactions via upregulation of endothelial cell adhesion molecules. Adiponectin in inhibiting leukocyte-endothelium adhesion was abolished by the blockade of eNOS with N(omega)-nitro-L-arginine methyl ester. TNF-α (TNF-α) plays an important role in both atherogenesis and vascular dysfunction. Inhibition of TNF-α reduces atherosclerosis and improves endothelial function in ApoE KO mice (unpublished data). Aortic ROS formation and nuclear factor-κB (NF-κB) expression were higher in aortas of ApoE KO mice compared with control mice. Genetic deletion of TNF-α reduced aortic superoxide production and improved NO availability. Thus, vascular inflammation and oxidative stress may contribute to TNF-α-induced endothelial dysfunction.

Thus, maintaining endothelial health is important in preventing atherosclerotic diseases. The role of adipokines in atherosclerotic endothelial dysfunction warrants further attention.

**ROLE OF ADIPOKINES IN ATHEROGENESIS**

Some adipokines are atherogenic while others have atheroprotective effects. Adiponectin exerts atheroprotective effects. In *in vitro* studies, adiponectin inhibited TNF-α-induced increase in endothelial expression of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and E-selection. Adiponectin also suppresses vascular smooth muscle cell proliferation, as well as macrophage to foam cell transformation. Adiponectin reduces lipid accumulation in macrophage foam cells and prevents atherosclerosis by increasing cholesterol efflux from macrophages. *In vivo* studies further demonstrated that apolipoprotein E/adiponectin double-deficient mice had increased plasma IP-10 levels, accelerated T-lymphocyte accumulation in atheromata, and augmented atherosclerosis compared with ApoE single-deficient mice. Indeed, adiponectin inhibits the production of CXC Receptor 3 chemokine ligands in macrophages and reduces T-lymphocyte recruitment in atherogenesis. Adiponectin prevents adventitial fibroblasts from proliferating, transforming to myofibroblasts, and migrating to the intima, thus worsening atherosclerosis. Macrophage adiponectin transgenic mice exhibited reduced macrophage foam cell formation in the arterial wall when these transgenic mice were crossed with a LDL receptor knockout (fdr−/−) mouse model and were fed a high-fat diet. A previous study suggested that an adenosinergic-mediated increase in plasma adiponectin significantly suppressed the progression of atherosclerotic lesions in aortic sinus by 30% in ApoE KO mice. Globular adiponectin also showed effects on amelioration of atherosclerosis, which was associated with decreased expression of class A scavenger receptor and TNF-α. Thus, adiponectin modulates multiple pathways to impact the development of atherosclerosis.

There is some discrepancy regarding the role of leptin in atherogenesis. One study suggested that leptin treatment of ApoE KO mice did not affect lesion size and surface area occupied by atherosclerotic lesions, but did
increase lesion calcification and the expression of the osteoblast-specific markers, osteocalcin and osteopontin. Thus, leptin may increase cardiovascular risk by promoting osteogenic differentiation and vascular calcification\textsuperscript{[47]}. Another study showed that recombinant leptin treatment resulted in an increase in atherosclerosis (lesion surface coverage) and a shortened time to occlusive thrombosis after vascular injury, which promotes atherosclerosis and thrombosis in ApoE KO mice\textsuperscript{[48]}. Leptin deficient hyperlipidemic mice (ob/ob; ApoE KO mice) developed significantly less atherosclerosis than ApoE KO mice, when fed an atherogenic diet for 16 wk from 8 wk of age. Histological analysis revealed that most of the atherosclerotic lesions in leptin deficient ApoE KO mice remained as fatty streaks, while those in ApoE KO mice were mainly fibrous plaques\textsuperscript{[49]}. Leptin-deficiency (ob/ob) in LDL receptor deficient mice induces an unexpected 2.2- to 6-fold reduction in atherosclerotic lesion development\textsuperscript{[50]}. The above findings support the notion that leptin accelerates atherosclerosis. However, one previous study reported that leptin deficiency in atherosclerosis-susceptible LDL receptor knockout or ApoE knockout background resulted in the development of larger atherosclerotic lesions\textsuperscript{[51]}, suggesting a protective role for leptin in atherosclerosis. These results identify a critical role for the leptin/leptin receptor pathway in the modulation of atherogenesis, and further studies are needed before drawing conclusions. Resistin is a cardiovascular and atherosclerotic risk factor\textsuperscript{[52]}. Resistin is a 12.5 kDa protein originally found to be secreted by mouse adipocytes\textsuperscript{[53]}. Whereas in rodents the adipocyte is the major source of resistin, in humans resistin is mainly expressed in macrophages\textsuperscript{[54]}. Resistin protein is present in both murine and human atherosclerotic lesions. ApoE KO mice had significantly higher resistin mRNA and protein levels in their aortas, and elevated serum resistin levels. Incubation of murine aortic endothelial cells with recombinant resistin increased MCP-1 and soluble VCAM-1 protein levels in the conditioned medium, suggesting a possible mechanism where resistin contributes to atherosclerotic disease\textsuperscript{[55]}.

TNF-\(\alpha\) also plays an important role in atherosclerosis\textsuperscript{[56]}. TNF-\(\alpha\) has been detected in atherosclerotic lesions throughout all stages of human atherosclerosis\textsuperscript{[57,58]}, and was found to be associated with atherosclerosis in mouse models\textsuperscript{[59,59]}. Mice deficient in both ApoE and TNF-\(\alpha\) showed less advanced atherosclerosis than ApoE KO mice\textsuperscript{[60]}. mRNA levels of pro-atherosclerotic factors, i.e. IL-1\(\beta\), interferon-\(\gamma\), ICAM-1, VCAM-1, MCP-1, GM-CSF and NF-\(\kappa\)B (p65) were significantly downregulated in ApoE and TNF-\(\alpha\) double-knockout mice\textsuperscript{[60]}. Lectin-like oxidized LDL receptor-1 (LOX-1) is an important mediator of atherogenesis. TNF-\(\alpha\)-induced increase in LOX-1 expression was demonstrated in various cell types, including endothelial cells, macrophages, vascular smooth muscle cells, etc\textsuperscript{[61-63]}.

IL-6 contributes to both atherosclerotic plaque development and plaque destabilization via a variety of mechanisms\textsuperscript{[64]}, which involve the release of other pro-inflammatory cytokines and prothrombotic mediators, oxidation of lipoproteins by phospholipases, stimulation of acute phase protein secretion, and the activation of matrix metalloproteinases\textsuperscript{[65]}. MCP-1 plays a key role in monocyte/macrophage infiltration to the sub-endothelial space of the blood vessel wall, which is a crucial initial step in atherosclerosis\textsuperscript{[66]}. Anti-MCP-1 gene therapy inhibits vascular smooth muscle cell proliferation\textsuperscript{[67]}, suggesting it has atheroprotective potential.

In summary, adiponectin is anti-atherogenic, but resistin, TNF-\(\alpha\), IL-6 and MCP-1, etc exert atherogenic effects through profound mechanisms. The role of leptin in atherogenesis remains to be controversial. The role of various adipokines in the pathogenesis of atherosclerosis and the therapeutic potential of modulating adipokine expression warrants further investigation (Figure 1).

**ADIPOKINES INTERPLAY**

Reciprocal regulation may occur among adipokines. Transgenic mice that specifically express the gene coding for human adiponectin in mouse macrophages exhibit enhanced whole-body glucose tolerance and insulin sensitivity with reduced MCP-1 and TNF-\(\alpha\) levels both in macrophages and serum\textsuperscript{[68]}. Resistin (pre-B cell colony-enhancing factor) has recently been identified as a new adipocytokine affecting insulin resistance\textsuperscript{[69]}. Visfatin (pre-B cell colony-enhancing factor) has recently been identified as a new adipocytokine affecting insulin resistance\textsuperscript{[70]}. Visfatin treatment increased the level of circulating IL-6 without affecting that of TNF\textsuperscript{[71]}. In addition to systemic effects, adipokines showed interactive regulation in various cell types. Both full length and globular adiponectin attenuated IL-6 and MCP-1 production from inflamed adipocytes\textsuperscript{[72]}. IL-1\(\beta\) promotes the expression of MCP-1 in human aortic smooth muscle cells via the NF-\(\kappa\)B signaling pathway\textsuperscript{[73]}. Thus, the interplay among adipokines may be an important contributor in the pathogenesis of atherogenesis (Figure 2).

**FUTURE PERSPECTIVES**

A strong correlation is observed between obesity and atherosclerosis. However, the existence and nature of a communication/linkage between adipose tissue-derived factors and pathogenesis of atherosclerosis warrants further investigation. Future studies may better elucidate the
mechanisms of this communication by delving into these aspects: (1) Direct and specific evidence is needed to determine if/how adipose communicates with vasculature through adipose proinflammatory cells and/or various adipose-derived cytokines, hormones and lipid signals; (2) The role of adipose, as an endocrine organ, results in altered levels of systemic regulators of chronic inflammation and energy metabolism. Therefore, the metabolic parameters associated with adipose dysfunction may indirectly affect the vascular tissues. Thus, studies are needed to examine the local pathogenic effects of perivascular fat vs. the systemic effects of obesity-induced metabolic changes in the pathophysiology of atherosclerosis; (3) Investigate using animal models relevant to atherosclerosis in human beings; and (4) If obesity is rescued, can that rescue atherosclerosis?

Of particular importance is the need to identify novel adipokines that play crucial roles in atherogenesis or exert atheroprotective effects and to improve the translation of the exciting scientific results to patients.

CONCLUSION

Obesity, especially visceral obesity, is associated with dyslipidemia, impaired glucose metabolism, and hypertension, all of which exacerbate atherosclerosis. One plausible mechanism involves adipokines, produced by adipose tissue in obesity that can directly impact the atherogenic environment of the vessel wall by regulating gene expression and function in endothelial, arterial smooth muscle, and macrophage cells, etc. Thus, this review explores the connection between adipose and atherosclerosis with particular emphasis on the role of adipokines as mediators in the development of atherosclerosis. We suggest that the proinflammatory capacity of adipose tissue provides new insights in the pathophysiology of atherosclerosis.
