Strong anomalies of the thermal expansion coefficients at the magnetic and ferroelectric transitions have been detected in multiferroic $RMn_2O_5$. Their correlation with anomalies of the specific heat and the dielectric constant is discussed. The results provide evidence for the magnetic origin of the ferroelectricity mediated by strong spin-lattice coupling in the compounds. Neutron scattering data for $HoMn_2O_5$ indicate a spin reorientation at the two low-temperature phase transitions.

Abstract:

Frustrated magnetic systems have recently attracted the attention of solid state physicists with regard to the observed magneto-electric couplings and the induced ferroelectricity in some orthorhombic rare earth manganites$^{1-5}$ and other frustrated compounds. These materials are of fundamental interest since it has been demonstrated that an external magnetic field can rotate the ferroelectric (FE) polarization$^{6,7}$. Despite intense experimental investigations, the physical origin of the large magneto-electric coupling and the ferroelectricity arising at the magnetic lock-in transitions is not yet understood. The giant magneto-dielectric effects and the ferroelectricity in these compounds require the existence of sizable atomic displacements and structural distortions, the magnetic origin of which is believed to lie in extraordinarily strong spin-lattice interactions. The experimental verification of these structural anomalies is essential to prove the suggested intimate correlation between the magnetic and FE orders.

The search for structural distortions by neutron scattering experiments have indicated some anomalies in the temperature dependence of the lattice parameters of $TbMn_2O_5$ and $DyMn_2O_5$, however, due to the limited resolution of such scattering experiments a unique assignment to the various phase transitions in these compounds appears extremely difficult. Other investigations of $HoMn_2O_5$ and $YMn_2O_5$ have failed completely to resolve structural anomalies. It is, therefore, one of the key issues to detect and to characterize the structural distortions in $RMn_2O_5$ manganites giving rise to ferroelectricity and to investigate the coupling between magnetic, dielectric, and lattice degrees of freedom.

In this communication we present our results of high-resolution thermal expansion measurements along the three crystallographic orientations in $RMn_2O_5$ ($R=Ho$, $Dy$, $Tb$). Sharp structural anomalies are detected at all magnetic and FE phase transitions, the strongest anomalies appearing at the transitions into the FE phases associated with a significant change of the electric polarization. Single crystals of $RMn_2O_5$ have been prepared by the high-temperature solution growth method as described elsewhere$^{11,12}$. Thermal expansion measurements were conducted employing a high-resolution capacitance dilatometer. The experimental techniques have been described earlier$^{12}$. With our current device we achieved a resolution (above the noise level) of 4 Å. The expansion data were correlated to anomalies of the $b$-axis dielectric constant and the heat capacity measured for the same crystals.

In orthorhombic $RMn_2O_5$ the spins of the $Mn^{4+}$ and $Mn^{3+}$ ions and the $R^{3+}$ moments are coupled via the predominantly antiferromagnetic (AFM) superexchange interactions giving rise to a complex magnetic phase diagram$^{2}$. The common features for all $RMn_2O_5$ are a transition into a high-temperature Néel phase (HTIC) with a two-component incommensurate (IC) magnetic modulation characterized by a wave vector $q = (q_x, 0, q_z)$ at $T_{C1} \approx 43$ K followed by a lock-in transition into a commensurate (CM) phase with $\vec{q} = (0.5, 0, 0.25)$ at $T_{C1}$ only a few degrees lower where ferroelectricity arises. With further decreasing temperature, at $T_{C2}$, the CM phase becomes unstable towards a low-temperature IC phase (LTIC) with a magnetic modulation $\vec{q} \approx (0.48, 0, 0.3)$ and additional anomalies have been observed indicating an even more complex magnetic structure that has yet to be explored$^{11,15}$.

It is characteristic for all $RMn_2O_5$ compounds that the various magnetic phase changes are reflected in sharp and distinct anomalies of the dielectric constant, as shown in Figs. 1a to 3a for $R=Ho$, $Dy$, and $Tb$. This is a clear indication of strong magneto-electric coupling due to large spin-lattice interactions. The thermodynamic signature
of the various transitions is obvious from the peaks of the specific heat $C_p$, Figs. 1a to 3a. Several transitions show pronounced hysteresis effects, not shown in the figures (for enhanced clarity only warming data are included in Figs. 1 to 4). The thermal expansivities, displayed in Figs. 1b to 3b, exhibit distinct anomalies at all magnetic transitions with the strongest peaks observed at the FE transitions. Our data provide striking evidence for the existence of extraordinarily large spin-lattice interactions in $RMn_2O_3$ resulting in macroscopic displacements along all three crystallographic axes. They further prove that the magnetic and lattice degrees of freedom are strongly coupled and the simultaneous magnetic and FE transitions at $T_{C1}$ and $T_{C2}$ have to be considered as the phase change of one highly correlated system.

The thermal expansion data for the three manganites ($R$=$Ho$, $Dy$, $Tb$) exhibit similarities but also distinct differences depending on the rare earth ion. The changes of the lattice parameters have to be discussed with respect to the magnetic orders derived from neutron scattering experiments.\textsuperscript{8,9,13,14,15} The first transition from the paramagnetic (PM) and paraelectric (PE) phase into the HTIC phase at $T_{N1}$ $\approx$ 43 K is characterized by a peak of $C_p$, an increase of $\varepsilon$, and a sudden increase of the expansivities along $a$- and $c$-axes. Considering the spiral IC magnetic order below $T_{N1}$ with the wave vector $\mathbf{q} = (0.5 + \beta, 0, 0.25 + \delta)$, the increase of $\alpha_a$ and $\alpha_c$ with the onset of AFM order can be explained by the magnetoeelastic effect. There is no anomaly of $\alpha_b$ which is consistent with the lack of the magnetic modulation along $b$.

The FE transition at $T_{C1}$ coincides with the lock-in of the magnetic wave vector into commensurate values. It is well marked by sharp peaks of $C_p$ and $\varepsilon$ as well as strong peaks of the expansivities along all three axes (Fig. 1 to 3). We define the abrupt length change, $\Delta L$, at the transition as the difference of the lengths in the low- and high-temperature phases extrapolated to $T \gtrsim T_C$ and at $T \lesssim T_C$, respectively. The measured values for $\Delta L$ along $a$, $b$, and $c$ are listed in table 1. For $R$=$Ho$ and $Dy$ the $c$-axis contracts while $a$ and $b$ expand at $T_{C1}$ (Figs. 1b and 2b). However, the opposite is observed for $R$=$Tb$ (Fig. 3b). This behavior has its origin in the different spin modulations along $c$, given by $q_e = 0.25 + \delta$. For $Ho$ and $Dy$ $\delta$ is negative but for $Tb$ $\delta$ is positive.\textsuperscript{16} The length change of the $c$-axis is directly correlated with the deviation of the magnetic wave length $\lambda_m$ along $c$ from its commensurate value of $4c$. The spin-lattice coupling leads to an attraction between the IC spin wave and the underlying lattice period along $c$ between $T_{N1}$ and $T_{C1}$ resulting in a stress on the lattice. This stress is tensile for $R$=$Ho$, $Dy$ ($\lambda_m$>4$c$) but compressive for $R$=$Tb$ ($\lambda_m$<4$c$). At the lock-in transition the stress is suddenly released ($\lambda_m$=4$c$) resulting in an abrupt decrease (increase) of $c$ for $R$=$Ho$, $Dy$ ($Tb$). This transition at $T_{C1}$ is of first order as indicated by the volume change derived from the expansion data, the jump of $q_x$ and $q_y$,\textsuperscript{14} and the thermal hysteresis observed in $\varepsilon(T)$. Mediated by the elastic forces of the lattice, $a$ and $b$ contract ($Tb$) or expand ($Ho$, $Dy$) opposite to $c$. In $Ho$- and $TbMn_2O_3$ the length change along $c$ dominates whereas in $DyMn_2O_3$ it is rather minor (table 1). This qualitative difference has its origin in the $Mn^{4+}$ spin alignment along $c$ that polarizes the rare earth moments. For $R$=$Ho$, $Tb$ there are alternating ferromagnetic (FM) and AFM links along $c$ that may cause a positional modulation of $R$ and the connecting oxygen, O(2), which is seen in $\alpha_c$ at $T_{C1}$ whereas in $DyMn_2O_3$ the $Mn^{4+}$ spins are only AFM along $c$ and the expansion anomaly is accordingly small.\textsuperscript{14} Strong lattice anomalies have also been observed in $GdMnO_3$ at the transition into the FE phase that happens in this multiferroic compound at higher magnetic fields.\textsuperscript{17}

The superexchange interactions between neighboring $Mn^{3+}$ and $Mn^{4+}$ ions in the $a$-$b$ plane are all AFM and the smallest closed loop of neighboring $Mn$ spins involves 5 ions. Therefore, magnetic frustration must exist as, for example, revealed by the spin order in $HoMn_2O_3$, displayed in the inset of Fig. 4.\textsuperscript{12} The spins of two $Mn^{3+}$ per unit cell are each frustrated with two neighboring $Mn^{4+}$ with the same spin direction. Reducing this frustration by moving the two $Mn^{3+}$ away from the $Mn^{4+}$ (along the arrows labeled $P$ in Fig. 4) generates a dipolar moment $P$ between the $Mn^{3+}$ and the surrounding oxygen ions. The $a$-components of $P$ cancel out while the $b$-components add up to the macroscopic polarization along $b$ and ferroelectricity. The proposed displacement lowers the symmetry to $Pb2_1m$. This empirical picture is supported by recent Mössbauer experiments on $YMn_2O_3$ showing that neighboring $Mn^{3+}$ ions are magnetically inequivalent.\textsuperscript{12} The corresponding displacement vector of only two of the four $Mn^{3+}$ is a superposition of the basis vectors of the $\Gamma_{1g}$ and $\Gamma_{3u}$ irreducible representations of the space group $Pbam$ in contrast to the model proposed for $YMn_2O_3$ where the displacement of all four $Mn^{3+}$ ions was assumed ($\Gamma_{3u}$ representation).\textsuperscript{2} We would like to emphasize that the AFM modulation along $a$ with $q_e$=0.5 is crucial for the above discussion, as it leads to the frustration and displacement of both $Mn^{3+}$ and the net polarization along $b$. Considering the role of magnetic frustration to stabilize ferroelectricity in $RMn_2O_3$ there are interesting similarities to multiferroic $Ni_3V_2O_8$ and $TbMnO_3$. For the latter compounds it was shown that the transition from sinusoidal to helical magnetic modulation can introduce a third order coupling giving rise to FE order.\textsuperscript{6,18} By symmetry the same argument holds also for two non-collinear spin density waves with the same propagation vector but different

| $\Delta L/L$ ($10^{-6}$) | $HoMn_2O_3$ | $DyMn_2O_3$ | $TbMn_2O_3$ |
|--------------------------|-------------|-------------|-------------|
| $T_{C1}$ | $T_{C2}$ | $T_{C1}$ | $T_{C2}$ | $T_{C1}$ | $T_{C2}$ |
| $\Delta a/a$ | 2.1 | 13.5 | 3.8 | -67.1 | -1.1 | 11.3 |
| $\Delta b/b$ | 2.5 | 5.7 | 2.0 | 16.3 | -2.0 | 11.5 |
| $\Delta c/c$ | -6.6 | -8.3 | -2.0 | 65.0 | 10.2 | -41.5 |
phases. In fact, neutron scattering experiments have revealed the existence of a non-collinear spin structure in $RMn_2O_5$ ($R=$Ho, Dy, Tb) with $\vec{q}$ along the $a$-axis which shows that ferroelectricity below $T_{C1}$ is not forbidden by symmetry. However, it is not clear yet if the magnetic structure between $T_{C1}$ and $T_{N1}$ is sinusoidal and the transition into the FE phase follows the same mechanisms as in $Nt_3V_2O_5$ or $TbMnO_3$. Furthermore, the magnetic modulation in the FE phase of $RMn_2O_5$ is commensurate whereas it is incommensurate in $Nt_3V_2O_5$ or $TbMnO_3$.

The FE transition at $T_{C1}$ is followed by additional phase changes at lower $T$ as indicated by characteristic changes of $\varepsilon$ and $C_p$ and distinct anomalies of the expansion coefficients (Figs. 1 to 3). For $R=$Ho and Dy a step-like increase of both, $\varepsilon$ and $C_p$, at $T_{N2}=$22 K and 27 K, respectively, is followed by another increase of $\varepsilon$ at $T_{C2}=$16 K (Ho) and 17 K (Dy) with a significant change of the FE polarization. The $\varepsilon$-anomaly at $T_{C2}$ is largest in Ho$Mn_2O_5$ but there is no equivalent signature in $C_p$ of Ho$(Dy)Mn_2O_5$. Recent neutron scattering experiments on Dy$Mn_2O_5$ indicate that a spin reorientation takes place at $T_{N2}$ and also at $T_{C2}$. Our neutron scattering results shown in Fig. 4 provide clear evidence for spin reorientations in Ho$Mn_2O_5$ at $T_{N2}$ and $T_{C2}$. The integrated intensity of the (1,3,0,0,25) peak suddenly increases at both transitions whereas that of the (0,5,0,2,25) peak shows a sharp drop. The details of the magnetic orders in the various phases have yet to be determined. In Tb$Mn_2O_5$ the spin reorientation transition at $T_{N2}$ appears to be missing, however, from the distinct step of $C_p$ at 24 K (similar to the $C_p$ anomalies in Ho- and Dy$Mn_2O_5$ at $T_{N2}$) we conclude that this transition coincides with the FE transition at $T_{C2}$ (determined by the sharp increase of $\varepsilon$).

The FE transition at $T_{C2}$ is accompanied by another change of the magnetic modulation that becomes incommensurate again, $\vec{q} \approx (0.48, 0.0, 0.3)$ (LTIC phase). The strongest anomalies of the expansion coefficients appear at $T_{C2}$ for $R=$Ho and Tb (Figs. 1 and 3, table 1) indicating a sizable distortion of the lattice due to the CM $\rightarrow$ LTIC phase change. The corresponding anomalies are less pronounced in Dy$Mn_2O_5$ (Fig. 2). Instead, another low-$T$ transition at $T_{C3}=$ 7.5 K is associated with giant changes of the lattice constants, a large contraction of the $a$-axis and an expansion of $b$ and $c$ (table 1). This phase transition is the onset of strong AFM order of the Dy-moments along $a$ ($\vec{q}_{(Dy)}=(0.5,0,0)$) and the $a$-contraction is explained by large magnetostrictive effects. $C_p$ exhibits a sharp peak at $T_{C3}$ and $\varepsilon$ drops to its high-temperature value ($T>T_{N1}$). It was suggested that the low-$T$ state in Dy$Mn_2O_5$ is paraelectric and it appears conceivable that the lattice strain below $T_{C3}$ is dominated by the Dy order, as evidenced by the huge expansion anomalies at $T_{C3}$. The AFM order of the Dy moments with $q_x=0.5$ appears to dominate the low-temperature magnetic structure and the associated lattice distortions which could explain the FE low-$T$ phase in Dy$Mn_2O_5$. However, neutron scattering experiments have found that the Dy magnetic order coexists with the CM and IC orders of the Mn spins and further investigations are needed for a final conclusion.

The strongest lattice anomalies observed in our thermal expansion measurements occur at the FE transitions involving a significant change of the polarization. They are highly anisotropic and prove the existence of an extraordinarily strong spin-lattice coupling. The magnetic and FE orders have to be considered as one highly correlated system that is coupled by magnetoelastic interactions.
