Tunneling through molecules and quantum dots: master-equation approaches

Carsten Timm

(Dated: January 7, 2008)

An important class of approaches to the description of electronic transport through molecules and quantum dots is based on the master equation. We discuss various formalisms for deriving a master equation and their interrelations. It is shown that the master equations derived by Wangsness, Bloch, and Redfield and by König et al. are equivalent. The roles of the large-reservoir and Markov approximations are clarified. The Markov approximation is traced back to nonzero bias voltage and temperature, whereas interactions and the corresponding rapid relaxation in the leads are shown to be irrelevant for the transport under certain conditions. It is explained why the T-matrix formalism gives incomplete results except for diagonal density operators and to second order in the tunneling amplitudes. The time-convolutionless master equation is adapted to tunneling problems and a diagrammatic scheme for generating arbitrary orders in the tunneling amplitudes is developed.

I. INTRODUCTION

Most approaches employed for the description of tunneling through molecules and quantum dots fall into one of two conceptual classes: In the first, one focuses on the dynamics of individual electrons tunneling through the system. Their dynamics is often described with the help of single-particle nonequilibrium Green functions. This approach is sometimes combined with ab-initio methods or perturbation theory for the interactions on the dot. In the second, one focuses on the time evolution of the many-particle state of the dot and integrates out the effect of the leads. This allows one to treat the strong interactions on the dot exactly. Typically, the reduced density operator of the dot is considered. Its equation of motion is the master equation (ME). The two approaches become equivalent in the absence of interactions.

The ME approach involves two steps. First, one derives the ME from the von Neumann equation for the full system. It tells one how the reduced density operator changes, based on its present and often its past values. It is clear that this requires additional assumptions, since the dot is coupled to the leads, which can be in any state. It is of course desirable to get by with only weak assumptions.

Second, one solves the ME to find the time evolution or the stationary state. Finding the time evolution is more complicated if the ME contains the history of the dot. It is thus desirable to obtain a ME that is local in time. There exist both approximate and exact methods for achieving this.

The ME approach comes in a number of flavors, among them the original Wangsness-Bloch-Redfield (WBR) approach,12 the superoperator formalism, the T-matrix formalism, the Keldysh-contour formulation of König et al.13,14,15,16 and the so-called time-convolutionless (TCL) ME.12 The purpose of this paper is to clarify the interrelations between these different pictures and to analyze some of their problems. It is hoped that this will facilitate the comparison between results obtained with different methods. In addition, the TCL formalism is generalized to the tunneling case and is argued to provide a powerful tool for studying the dynamics of a dot under bias.

II. THE WANGSNESS-BLOCH-REDFIELD MASTER EQUATION

A. Conventional derivation

This approach is commonly described in textbooks though not in relation to particle transport. Several groups have recently applied it to tunneling through molecules.17,18,19,20,21,22,23 We start from a Hamiltonian $H = H_{\text{dot}} + H_{\text{leads}} + H_{\text{hyb}}$, where the terms describe the dot, the leads, and hybridization between them, respectively. $H_{\text{dot}}$ may contain vibrational or spin degrees of freedom and their coupling to the electrons. The time evolution of the density operator $\rho$ of the full system is described by the von Neumann equation $\dot{\rho} = -i[H, \rho]$, where $\hbar = 1$. We wish to find the ME for the reduced density operator $\rho_{\text{dot}}(t) \equiv \text{tr}_{\text{leads}} \rho(t)$, where the trace is over many-particle states of the leads.

The central assumption is that $H_{\text{hyb}}$ can be treated perturbatively. Operators $A$ are transformed into the interaction picture with respect to $H_{\text{hyb}}$,

$$A_I(t) = e^{i(H_{\text{dot}} + H_{\text{leads}})t} A(t) e^{-i(H_{\text{dot}} + H_{\text{leads}})t}. \quad (1)$$

The density operator in the interaction picture satisfies the equation

$$\dot{\rho}_I = -i [H_{\text{hyb}}, I, \rho_I]. \quad (2)$$

Integrating this equation from $t_0$ to $t$ yields

$$\rho_I(t) = \rho_I(t_0) - i \int_{t_0}^t dt' [H_{\text{hyb}}, I(t'), \rho_I(t')]. \quad (3)$$

Inserting this again into Eq. (2) one obtains

$$\dot{\rho}_I(t) = -i [H_{\text{hyb}}, I(t), \rho_I(t_0)] \quad \text{(4)}$$

The so-called time-convolutionless master equation is then obtained by using the identity

$$\text{tr}_{\text{hyb}} \int_{t_0}^t dt' [H_{\text{hyb}}, I(t'), \rho_I(t')] = \text{tr}_{\text{hyb}} \int_{t_0}^t dt' [H_{\text{hyb}}, I(t'), \rho_I(t')]$$

From this one obtains

$$\dot{\rho}_I(t) = -i [H_{\text{hyb}}, I(t), \rho_I(t_0)]$$

which is the time-convolutionless master equation.
Continuing the iteration, one generates equations containing arbitrary powers of $H_{\text{hyb}}$. However, in all of them all terms except for the one with the highest power contain $\rho_1$ only at time $t_0$. This is problematic when we introduce approximations. For example, if we describe cotunneling (fourth order), sequential tunneling (second order) would only appear in the dependence on the initial conditions. Section II B explains how to avoid this.

We now consider the initial condition that the system was in a product state at an early time $t_0$,

$$\rho(t_0) = \rho_{\text{dot}}(t_0) \otimes \rho_{\text{leads}}^0,$$

(5)

with $\rho_{\text{leads}}^0$ describing separate thermal equilibria of the two leads; their chemical potentials and temperatures can be different. A product state is equivalent to dot and leads being statistically independent at time $t_0$, which is natural if $H_{\text{hyb}}$ is switched on at time $t_0$. The initial condition (5) implies that

$$\text{tr}_{\text{leads}} H_{\text{hyb},1}(t) \rho_1(t_0) = 0,$$

(6)

since $H_{\text{hyb}}$ is a sum of terms containing a single lead-electron operator. Thus each term changes the lead electron number and thus gives zero under the trace, since $\rho_{\text{leads}}^0$ only contains states with sharp electron number.

The trace over lead states of Eq. (4) is

$$\dot{\rho}_{\text{dot},1}(t) = -\int_{t_0}^{t} dt' \text{tr}_{\text{leads}} \left[ H_{\text{hyb},1}(t), \left[ H_{\text{hyb},1}(t'), \rho_1(t') \right] \right].$$

(7)

The first term in Eq. (4) drops out due to Eq. (6). Up to this point, the results are exact.

The integral in every term in Eq. (7) is of the form

$$\pm \prod A_{\text{dot},1} \left( \prod B_{\text{leads},1} \right) \prod' A_{\text{dot},1},$$

(8)

where the first and last factors are products of zero or more dot electron operators and $\prod B_{\text{leads},1}$ is a product of two lead electron operators. The operators may have different time arguments. At this point it is usually argued that the tunneling should have negligible effect on the leads, since they form a large reservoir.\textsuperscript{21,22} Therefore, in any term one makes the replacement\textsuperscript{5,6,14,16}

$$\text{tr}_{\text{leads}} \prod B_{\text{leads},1} \rho_1 \approx \text{tr}_{\text{leads}} \prod B_{\text{leads},1} \rho_{\text{dot},1} \otimes \rho_{\text{leads}}^0,$$

(9)

Here, one replaces any two-time correlation function of the leads by the correlation function in equilibrium. Gardiner and Zoller\textsuperscript{21,22} point out that one only has to make this assumption in the second-order terms.

In fact, we must only make it in the second-order terms: If we were to argue that since tunneling should have negligible effect on the leads we can replace $\rho(t)$ by $\rho_{\text{dot}}(t) \otimes \rho_{\text{leads}}^0$ globally in the von Neumann equation, we get trivial results. By taking the lead trace, we obtain

$$\dot{\rho}_{\text{dot}} = -i \text{tr}_{\text{leads}}[H, \rho_{\text{dot}} \otimes \rho_{\text{leads}}^0] = -i \text{tr}_{\text{leads}}[H_{\text{dot}}, \rho_{\text{dot}}] \otimes \rho_{\text{leads}}^0,$$
in an observable that couples strongly to the environment, unavoidable interactions lead to rapid decay of superpositions of these states and thus of $\rho^{\text{dot}}_{mn}$. The standard example is the charge. Due to Gauss’ law, the effect of the charge can in principle be measured equally well on any arbitrarily large surface surrounding the system. Therefore, superpositions of dot states with different charge are not observed.

On the other hand, the description of spin precession requires the off-diagonal components. Different spin states also differ in their long-range (dipole) fields, but these fall off more rapidly than the Coulomb field. This suggests that Gauss’ law is crucial for superselection rules and not just any algebraic decay.

If all off-diagonal components decay rapidly, one is left with the diagonal components $P_m = \rho^{\text{dot}}_{mm}$, i.e., the probabilities of dot many-particle states $|m\rangle$. The principal-value terms in Eq. (A1) then cancel and one obtains

$$\dot{P}_m = -2\pi \sum_{ij} \sum_p |\langle i|m|H_{\text{hyb}}|p\rangle| j\rangle|^2$$

$$\times (W_i P_m - W_j P_p) \delta(E_p + \epsilon_j - E_m - \epsilon_i). \quad (13)$$

Here, $W_i \equiv \langle \langle i|H_{\text{hyb}}|i\rangle\rangle$ is the probability to find the leads in state $|i\rangle$. Defining the transition rates

$$R_{n\rightarrow m} = 2\pi \sum_{ij} W_j |\langle i|m|H_{\text{hyb}}|n\rangle| j\rangle|^2$$

$$\times \delta(E_p + \epsilon_j - E_m - \epsilon_i), \quad (14)$$

we obtain the well-known rate equations

$$\dot{P}_m = \sum_n R_{n\rightarrow m} P_n - \sum_n R_{m\rightarrow n} P_m. \quad (15)$$

The first term describes transitions from other states $|n\rangle$ to state $|m\rangle$, whereas the second describes transition out of state $|m\rangle$. The rate equations imply local conservation of probability—$P_m$ only changes due to probability flowing into or out of state $|m\rangle$. This conservation law can be implemented in a gauge theory.

B. Discussion of the Markov approximation

The Markov approximation is usually motivated by rapid decay of the lead correlation functions. In the second-order approximation, each nonvanishing term contains one creation operator $a^\dagger$ and one annihilation operator $a$. The result is non-zero only if both belong to the same single-particle state. The trace $\tr_{\text{leads}}$ over lead many-particle states is replaced by a sum over single-particle states characterized by lead index $\alpha$, wave vector $\mathbf{k}$, and spin $\sigma$. As discussed in App. A, the correlation functions are Green functions $G^<, G^>$. If the leads are normal metals, these decay on the time scale of the quasiparticle lifetime. (The non-quasiparticle background in the spectral function is broader than the quasiparticle peak, corresponding to faster processes, which are less critical for the validity of the Markov approximation.) However, the quasiparticle lifetime becomes long at the low temperatures at which experiments are performed. Does the Markov approximation break down in the experimental temperature range? This question is also relevant because the lead Hamiltonian $H_{\text{leads}}$ used in actual calculations does not contain any interactions. Thus in our model, there is not broadening of the quasiparticle peak and $G^<, G^>$ do not decay in time.

While each term separately does not decay, their sum does. We replace the sum over $\mathbf{k}$ by an integral over energy, including the density of states. At low temperatures we can restrict the integral to the energy window between the two chemical potentials $\mu_<, \mu_>$. Assuming a constant density of states and $\mathbf{k}$-independent tunneling amplitudes, we end up with integrals of the type

$$\int_{\mu_>}^{\mu_>} dE e^{\pm iE\tau} = \pm \frac{e^{\pm i\mu_+\tau} - e^{\pm i\mu_-\tau}}{i\tau}. \quad (16)$$

This expression contains a typical time scale $h/eV \equiv \tau_{\text{leads}}$ for the decay of correlations, restoring Planck’s constant for the moment. Thus the energy governing the decay of correlations is the bias, not the electron-electron interaction. The same energy scale determines dephasing, i.e., the decay of superpositions due to different chemical potentials in the leads. For arbitrary temperatures, the limits of integration are roughly $\mu_+ - k_BT$ and $\mu_+ + k_BT$ and the characteristic time is the smaller of $h/eV$ and $h/k_BT$. Note that the contribution from the quasiparticle lifetime is proportional to $1/T^2$ and is thus irrelevant at low temperatures.

For weak tunneling, or specifically if the conductance is small compared to the quantum conductance,

$$I/V \ll e^2/h, \quad (17)$$

the typical time between two tunneling events is $\tau_0 = e/I \gg h/eV = \tau_{\text{leads}}$. Then the dot dynamics is indeed much slower than the decay of lead correlations and the Markov approximation is justified. It follows from the weak-tunneling approximation, which we have to make in any case to work in low-order perturbation theory.

This argument may fail if tunneling events are strongly correlated. In this case, two or more tunneling events can often take place during a time much shorter than $\tau_0 = e/I$ and the relation (17) does not guarantee the validity of the Markov approximation.

A related point is seen if we proceed slightly differently in the derivation. Starting from Eq. (4) and inserting Eq. (8) with renamed variables

$$\rho_I(t') = \rho_I(t) - i \int_t^{t'} dt'' H_{\text{hyb},I}(t''), \rho_I(t''), \quad (18)$$

we obtain

$$\dot{\rho}_I(t) = -i [H_{\text{hyb},I}(t), \rho_I(t_0)]$$
The choice of $\dot{t}$ is the Liouvillian defined by $L$ principle, again only expanding in Equation (20) can also be obtained from a variational formalism, in independent approximations. The rapid decay of the lead contributions. We can for example derive a ME containing sequential cotunneling contributions. We finally replace $t_0$ by $-\infty$. This is a remnant of the Markov approximation, but only if the “true” $t_0$ is finite. The choice of $t_0$ can be viewed as a part of our model as opposed to the approximations employed to solve it. Equation (20) can also be obtained from a variational principle, again only expanding in $H_{hyb}$ without explicit Markov assumption. We have obtained the same local ME in seemingly different ways. The explanation is that we have not made independent approximations. The rapid decay of the lead correlation functions follows from the assumption of weak tunneling, which also allows us to use perturbation theory in $H_{hyb}$. On the other hand, the large-reservoir (or Born) approximation $\rho_t(t) \equiv \rho_{dot,t}(t) \otimes \rho_{leads}$ is logically independent.

III. SUPEROPERATOR FORMALISM

The WBR ME can also be derived in the superoperator formalism which facilitates expansion to higher orders in $H_{hyb}$. We here define a superoperator as an operator acting on the space of linear operators on the Hilbert space. The von Neumann equation is written as

$$-\int_{t_0}^{t} dt' [H_{hyb}, t(t'), \rho_t(t) ]$$

$$+ i \int_{t_0}^{t} dt' \int_{t}^{t'} dt'' [H_{hyb}, t(t'), [H_{hyb}, t(t''), \rho_{t}(t'')]],$$

(19)

which is still exact. If we now restrict ourselves to the second order in $H_{hyb}$, we can drop the last term. We have obtained an equation that is local in time without invoking the Markov approximation. We have pushed non-local terms into higher orders in $H_{hyb}$. Iterating the procedure, we can achieve this to any order. All relevant terms contain $\rho_t(t)$ instead of $\rho_t(t_0)$, which appears in the naive expansion in Sec. II A. Thus we can for example derive a ME containing sequential and cotunneling contributions.

Now we can make the large-reservoir approximation and replace $\rho_t(t)$ by $\rho_{dot,t}(t) \otimes \rho_{leads}$, as above. But here we perform this replacement only at time $t$. We then obtain, by tracing over the leads,

$$\dot{\rho}_{dot,t}(t) = -\int_{t_0}^{t} dt' \text{tr}_{leads}[H_{hyb}, t(t'), [H_{hyb}, t(t''), \rho_{dot,t}(t'')]],$$

(20)

$$\rho_{dot,t}(t) \otimes \rho_{leads}].$$

We finally replace $t_0$ by $-\infty$. This is a remnant of the Markov approximation, but only if the “true” $t_0$ is finite. If we now restrict ourselves to the second order in $H_{hyb}$, we can drop the last term. We have obtained an equation that is local in time without invoking the Markov approximation. We have pushed non-local terms into higher orders in $H_{hyb}$. Iterating the procedure, we can achieve this to any order. All relevant terms contain $\rho_t(t)$ instead of $\rho_t(t_0)$, which appears in the naive expansion in Sec. II A. Thus we can for example derive a ME containing sequential and cotunneling contributions.

We have obtained the same local ME in seemingly different ways. The explanation is that we have not made independent approximations. The rapid decay of the lead correlation functions follows from the assumption of weak tunneling, which also allows us to use perturbation theory in $H_{hyb}$. On the other hand, the large-reservoir (or Born) approximation $\rho_t(t) \equiv \rho_{dot,t}(t) \otimes \rho_{leads}$ is logically independent.

$$L = L_{dot} + L_{leads} + L_{hyb}$$

(21)

is the Liouvillian defined by $L_{dot}\rho \equiv [H_{dot}, \rho]$ etc. The solution reads $\rho(t) = e^{-i(L_{dot}+\rho_{leads})t} \rho(t_0)$. We define projection (super-) operators $\mathcal{P}$, $\mathcal{Q}$ by $\mathcal{P}(\rho(t)) \equiv \text{tr}_{leads}(\rho(t)) \otimes \rho_{leads}$ and $\mathcal{Q} \equiv 1 - \mathcal{P}$. Note that $\mathcal{P}$ maps a density operator onto one in product form with the leads in equilibrium, while retaining the information on the dot state. Conversely, $\mathcal{Q}\rho$ contains the information on the leads and the dot-lead correlations. It is easy to prove the identities

$$\mathcal{P}L_{dot} = L_{dot}\mathcal{P},$$

$$\mathcal{P}L_{leads} = L_{leads}\mathcal{P} = 0,$$

$$\mathcal{P}L_{hyb} = 0.$$
in powers of $\mathcal{L}_{\text{hyb}}$.) Equation (33) is an exact ME, which is non-local in time.

Starting from Eq. (33), the weak-coupling limit as discussed in Ref. [16] now consists of (a) neglecting all powers of $\mathcal{L}_{\text{hyb}}$, beyond the second and (b) dropping the dependence on the initial condition for $Q\rho(t_0)$. (a) is just the weak-tunneling approximation of Sec. II A, (b) neglects a term of linear order in $\mathcal{L}_{\text{hyb}}$ and has to be shown to be consistent. The rationale given in Ref. [16] is twofold: First, the term in $Q\rho(t_0)$ is a small (of order $H_{\text{hyb}}$) correction to $P\rho(t_0)$, and second, it is not accumulated over time, being a correction to the initial conditions. These arguments appear to be weak: $Q\rho(t_0)$ and $P\rho(t_0)$ lie in orthogonal subspaces and it is not obvious that their magnitudes can be meaningfully compared. Furthermore, Eq. (33) shows that $Q\rho(t_0)$ does affect $P\rho(t)$ for all $t > t_0$, even to first order.

Dropping the dependence on $Q\rho(t_0)$ is trivial if $Q\rho(t_0) = 0$. This is not an approximation but an initial condition, see Sec. II A.

With approximations (a) and (b), Eq. (33) becomes

$$\frac{d}{dt} P\rho \cong -i\mathcal{L}_{\text{dot}} P\rho(t)$$

$$- P\mathcal{L}_{\text{hyb}} \int_{t_0}^{t} dt' e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t-t')} \mathcal{L}_{\text{hyb}} P\rho(t').$$

(34)

Inserting the definition of $\mathcal{P}$ and writing the Liouvillians as commutators we obtain

$$\frac{d}{dt} \rho_\text{dot} \cong -i[H_{\text{dot}}, \rho_\text{dot}(t)]$$

$$- \int_{t_0}^{t} dt' \text{tr}_{\text{leads}}[H_{\text{hyb}}, e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t-t')}H_{\text{hyb}},$$

$$\rho_\text{dot}(t') \otimes 0_{\text{leads}}].]$$

(35)

Now for any Hamiltonian $H$ with associated Liouvillian $\mathcal{L}$ and any operator (not superoperator) $A$ the identity

$$e^{-i\mathcal{E} \tau} A e^{i\mathcal{E} \tau}$$

holds. In our case we thus get

$$\frac{d}{dt} \rho_\text{dot} \cong -i[H_{\text{dot}}, \rho_\text{dot}(t)] - \int_{t_0}^{t} dt' \text{tr}_{\text{leads}}[H_{\text{hyb}},$$

$$e^{-i(H_{\text{dot}} + H_{\text{leads}})(t-t')}H_{\text{hyb}}, e^{i(H_{\text{dot}} + H_{\text{leads}})(t-t')},$$

$$e^{-iH_{\text{dot}}(t-t')} \rho_\text{dot}(t') e^{iH_{\text{dot}}(t-t') \otimes 0_{\text{leads}}}.]$$

(37)

Compare this to the WBR result, Eq. (12). To get there, we have to replace $e^{-iH_{\text{dot}}(t-t')} \rho_\text{dot}(t') e^{iH_{\text{dot}}(t-t')} \rho_\text{dot}(t)$ by $\rho_\text{dot}(t)$. This is nearly the same: $\rho_\text{dot}(t)$ is described by the full Hamiltonian $H$, while Eq. (37) only contains the unperturbed time evolution due to $H_{\text{dot}}$. This is consistent with the second-order approximation, since any correction to the unperturbed time evolution adds more powers of $H_{\text{hyb}}$. Thus the Markov property again follows. We can extent the range of integration to $t_0 = -\infty$ arguing as in Sec. II B.

Note that we did not need the large-reservoir assumption $\rho(t) \cong \rho_{\text{dot}}(t) \otimes \rho_0^{\text{leads}}$ in this approach. We have only assumed the density operator to be of this product form at an early time $t_0$—a much weaker assumption.

IV. THE T-MATRIX APPROACH AND FERMI’S GOLDEN RULE

The T-matrix approach [32,34,35,36,42,43,44] and its leading-order approximation, Fermi’s Golden Rule [45,46,47] are used by several groups to describe tunneling processes, since they provide a straightforward derivation of the transition rates in the diagonal rate equations. The approach is presented in many textbooks. Bruus and Flensberg [32] discuss it in relation to the tunneling problem.

The derivation starts out by writing

$$H(t) = H_{\text{dot}} + H_{\text{leads}} + H_{\text{hyb}} e^{\eta t},$$

$$= H_0 + V(t)$$

(38)

where $\eta$ is small and positive. Thus the hybridization is switched on very slowly. We assume that the system was in an eigenstate $|i\rangle$ of $H_0$ at time $t_0$. The probability that it is in another eigenstate $|f\rangle$ at time $t$ reads

$$|\langle f | i \rangle(t)|^2 \equiv |\langle f | T \exp \left(-i \int_{t_0}^{t} dt' V(t') \right) |i\rangle|^2,$$

(39)

where $T$ is the time-ordering operator. The transition rate between states $|i\rangle$ and $|f\rangle$ is then defined as

$$\Gamma_{fi} \equiv \frac{d}{dt} |\langle f | i \rangle(t)|^2.$$  

(40)

Taking the limit $\eta \to 0^+$ and defining the $T$-matrix

$$T(E_i) \equiv H_{\text{hyb}} + H_{\text{hyb}} \frac{1}{E_i - H_0 + i0^+} H_{\text{hyb}}$$

$$+ H_{\text{hyb}} \frac{1}{E_i - H_0 + i0^+} H_{\text{hyb}}$$

$$+ \ldots$$

(41)

one obtains

$$\Gamma_{fi} = 2\pi \delta(E_i - E_f) |\langle f | T |i\rangle|^2,$$

(42)

where $E_i$ and $E_f$ are the eigenenergies of states $|i\rangle$ and $|f\rangle$, respectively. The leading order is obtained by replacing $T$ by $H_{\text{hyb}}$.

$$\Gamma_{fi} = 2\pi \delta(E_i - E_f) |\langle f | H_{\text{hyb}} |i\rangle|^2,$$

(43)

which is Fermi’s Golden Rule.

To draw the connection with the rate equations, we choose the states $|i\rangle$, $|f\rangle$ as product states of many-particle states of the dot, $|m\rangle$, and of the leads, $|\nu\rangle$.  

Summing $\Gamma_{fi}$ over the lead states we obtain the transition rates
\[
\bar{R}_{n \rightarrow m} = 2\pi \sum_{sf} W_i \left| \langle f | (m | T | n) | i \rangle \right|^2 \delta(E_n + \epsilon_i - E_m - \epsilon_f)
\] (44)
from state $|n\rangle$ to $|m\rangle$. Here, $E_m$ ($\epsilon_i$) are eigenenergies of dot (lead) states and $W_i$ is the probability to find the leads in initial state $|i\rangle$ at time $t_0 \rightarrow -\infty$. To write down Eq. (44), one has to make the assumption that the probability $W_i$ is independent of the state of the dot. This means that the system is in a product state $\rho = \rho_{\text{dot}} \otimes \rho_{\text{leads}}$ at time $t_0$. This is the same assumption usually made in density-operator approaches. If the leads are in equilibrium at time $t_0$ one can express $W_i$ in terms of Fermi functions.

In the next step, $\bar{R}_{n \rightarrow m}$ is identified with the transition rate $R_{n \rightarrow m}$ appearing in the rate equations. However, what is actually calculated is the rate of change of the probability of state $|m\rangle$ under the condition that the dot was in state $|n\rangle$ at time $t_0 \rightarrow -\infty$, cf. Eqs. (40) and (44). On the other hand, in the density-operator approach one calculates the rate of change of the probability of state $|m\rangle$ under the condition that it is in state $|n\rangle$ at the same time $t$, immediately before a possible transition. The two are the same only if the dot remains in state $|n\rangle$ from time $t_0$ through $t$. This is of course not usually the case.

In the sequential-tunneling approximation, one evaluates the rates to second order in $H_{\text{hyb}}$. Since two powers of $H_{\text{hyb}}$ are required for the final transition to state $|m\rangle$, no transitions can occur between $t_0$ and $t$. Therefore, to second order, where the $T$-matrix approach reduces to Fermi’s Golden Rule, it gives the same transition rates $R_{n \rightarrow m}$ as the WBR approach. Beyond leading order, $R_{n \rightarrow m}$ and $\bar{R}_{n \rightarrow m}$ describe different quantities.

To leading order, $T \equiv H_{\text{hyb}}$, the rates $\bar{R}_{n \rightarrow m}$ in Eq. (44) are indeed identical to the the WBR result, Eq. (43). The latter has been obtained under the Markov assumption. One might wonder where the Markov assumption entered in the $T$-matrix formalism. It is implied in the derivation, since to second order $\rho$ does not change between times $t_0$ and $t$ anyway.

The rate equations (15) appear to be obvious. However, can they be derived in the $T$-matrix framework? Certainly not without further assumptions, since they omit the off-diagonal components of $\rho_{\text{dot}}$ necessary for a complete description.

V. THE KELDYSH-CONTOUR APPROACH OF KÖNIG ET AL.

König et al. have developed a diagrammatic technique to generate a perturbative expansion in the tunneling amplitudes. This approach has also been applied to tunneling through molecules. In the present section we show how it is related to WBR theory. Reference 8 concerns a quantum dot with electron-electron and electron-vibration interactions. A unitary transformation replaces the latter with an exponential operator in the tunneling Hamiltonian. We do not consider this transformation here. This does not restrict the models covered by our discussion—we include any bosonic modes and electron-boson interactions into $H_{\text{dot}}$.

As usual, the system is assumed to be in a product state at an early time $t_0$ with the leads in separate equilibria. The propagator $\Pi$ of $\rho_{\text{dot}}$ from time $t_0$ to $t \geq t_0$ is defined by
\[
\rho_{\text{dot}}(t) = \Pi(t, t_0) \rho_{\text{dot}}(t_0).
\] (45)
(We use the same notation and time ordering as elsewhere in this paper.) $\Pi(t, t_0)$ is represented by a diagram on the Keldysh contour between times $t_0$ and $t$, Fig. 3 in Ref. 9. König et al. then identify the irreducible part $\Sigma_K$ of $\Pi$ (a subscript is added to distinguish $\Sigma_K$ from $\Sigma$ introduced above), defined as the sum of all diagrams that cannot be cut at an intermediate time without cutting a lead line representing the pairing of $a_{sk}^\dagger$ and $a_{sk}$. $\Pi$ is expressed in terms of $\Sigma_K$ by a Dyson-type equation,
\[
\Pi(t, t_0) = \Pi^{(0)}(t, t_0) + \int_{t_0}^{t} dt_2 \int_{t_0}^{t_2} dt_1 \Pi^{(0)}(t, t_2) \times \Sigma_K(t_2, t_1) \Pi(t_1, t_0),
\] (46)
containing the bare propagator
\[
\Pi^{(0)}(t, t_0)[n_{mn'}]_{mm'} = \delta_{mm'}\delta_{nn'} e^{-i(E_n - E_m)(t-t_0)}.
\] (47)
In Ref. 10, Eqs. (45)–(47) are presented for arbitrary initial time $t' \geq t_0$. Equation (45) would then imply $\Pi(t, t'') = \Pi(t, t') \Pi(t', t'')$, which contradicts Eq. (46). This is not a problem since the equations with initial time $t_0$ are sufficient for the derivation of the ME.

We want to find the propagator $\Pi$ explicitly. Clearly, we have $\mathcal{P}[\rho(t) = \rho_{\text{dot}} e^{-i\mathcal{L}(t-t_0)} \rho(t_0)]$. Since the initial condition $\mathcal{Q}[\rho(t_0) = 0] = 0$ is assumed, we find
\[
\mathcal{P}[\rho(t) = \rho_{\text{dot}} e^{-i\mathcal{L}(t-t_0)} \mathcal{P}[\rho(t)] \equiv \Pi(t, t_0) \mathcal{P}[\rho(t_0)]].
\] (48)
This defines the propagator $\Pi$ for initial time $t_0$. The last factor $\mathcal{P}$ in $\Pi$ is expendable.

Can we find $\Sigma_K$ to satisfy Eq. (46)? We expand the exponential in Eq. (48), noting that all lead creation and annihilation operators must be paired for the result to be nonzero since $\mathcal{P}[L_{\text{hyb}}] = 0$. Diagrammatically, this is represented by a lead-fermion line connecting two $H_{\text{hyb}}$ insertions. The lead trace then gives a Fermi factor for any pair of insertions. With regard to this pairing, we can identify the irreducible part $\Sigma_K$ and write
\[
\mathcal{P}[\rho_{\text{dot}} e^{-i\mathcal{L}(t-t_0)} \mathcal{P}] = \rho_{\text{dot}} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{E}_{\text{leads}})(t-t_0)} + \mathcal{P} \int_{t_0}^{t} dt_2 \int_{t_0}^{t_2} dt_1
\]
\[
\times e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{E}_{\text{leads}})(t-t_2)} \Sigma_K(t_2, t_1)
\]
\[
\times e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{E}_{\text{leads}})(t_1-t_0)} + \ldots
\]
\[
= \mathcal{P}[\rho_{\text{dot}} e^{-i\mathcal{L}_{\text{dot}} + \mathcal{E}_{\text{leads}}})(t-t_0)] + \mathcal{P} \int_{t_0}^{t} dt_2 \int_{t_0}^{t_2} dt_1
\]
\[
\times e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{E}_{\text{leads}})(t-t_2)} \Sigma_K(t_2, t_1) e^{-i\mathcal{L}(t_1-t_0)} \mathcal{P}. \] (49)
If we insert \( \mathcal{P} \) at some intermediate time \( t_n \) in Eq. (49) this forces all lead-fermion operators to be paired for times smaller than and larger than \( t_n \) separately. This is equivalent to the diagram being reducible at time \( t_n \).

Conversely, if a diagram is reducible at time \( t_n \), inserting \( \mathcal{P} \) there does not change the result. Consequently,

\[
\mathcal{P} e^{-i \mathcal{L}(t-t_0)} \mathcal{P} = \mathcal{P} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leada}})(t-t_0)} + \mathcal{P} \int_{t_0}^{t} dt_2 \int_{t_0}^{t} dt_1 e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leada}})(t-t_2)} \Sigma_K(t_2, t_1) \mathcal{P} e^{-i \mathcal{L}(t_1-t_0)} \mathcal{P}.
\]

(50)

Here, we can identify the bare propagator

\[
\Pi^{(0)}(t, t') = \mathcal{P} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leada}})(t-t')}.
\]

(51)

These two equations correspond to Eqs. (40), (47) except that we had to introduce another projection \( \mathcal{P} \) at the final time. Apart from this, we recover the Dyson-type equation of Ref. 9 for initial time.

Inserting the Dyson-type equation (50) for the propagator into Eq. (48) and taking the time derivative, one obtains a ME, 2

\[
\frac{d}{dt} \rho(t) = -i \mathcal{L}_{\text{dot}} \rho(t) + \mathcal{P} \int_{t_0}^{t} dt' \Sigma_K(t, t') \mathcal{P} \rho(t').
\]

(52)

This corresponds to Eq. (25) in Ref. 9 (a factor of \( \mathcal{P} \) on the left can be included into the definition of \( \Sigma_K \)).

We can gain further insight by returning to Eq. (52), restricted to the case \( \mathcal{Q} \rho(t_0) = 0 \),

\[
\frac{d}{dt} \mathcal{P} \rho(t) = -i \mathcal{L}_{\text{dot}} \mathcal{P} \rho(t) - \mathcal{P} \mathcal{L}_{\text{hyb}} \int_{t_0}^{t} dt' \times e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leada}} + \mathcal{Q} \mathcal{L}_{\text{hyb}} \mathcal{Q})(t-t')} \mathcal{L}_{\text{hyb}} \mathcal{P} \rho(t').
\]

(53)

Comparing to Eq. (52) we find

\[
\mathcal{P} \Sigma_K(t, t') \mathcal{P} = \mathcal{P} \mathcal{L}_{\text{hyb}} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leada}} + \mathcal{Q} \mathcal{L}_{\text{hyb}} \mathcal{Q})(t-t')} \mathcal{L}_{\text{hyb}} \mathcal{P}.
\]

(54)

Thus the ME of Ref. 9 is equivalent to the WBR ME to all orders in \( H_{\text{hyb}} \) and we have derived an explicit expression for the irreducible part. For later, we introduce in Fig. II a diagrammatic representation for the second term in Eq. (53).

Now the factors of \( \mathcal{Q} \) in the exponential find a natural interpretation: They remove all reducible terms from the expansion of Eq. (53). This is because at a point where a diagram is reducible, one can insert a \( \mathcal{P} \). But if a \( \mathcal{Q} \) is present at this point, we obtain \( \mathcal{P} \mathcal{Q} = \mathcal{Q} \mathcal{P} = 0 \). Thus all diagrams in the expansion that are reducible to the left or to the right of an insertion of \( \mathcal{L}_{\text{hyb}} \) vanish.

VI. THE TIME-CONVOLUTIONLESS MASTER EQUATION

This approach leads to a ME that is local in time and exact, and thus avoids the Markov assumption. The Markov assumption is valid for weak tunneling and not strongly correlated tunneling events, as discussed above, but becomes increasingly dubious at higher orders in \( H_{\text{hyb}} \) or in resummation or non-perturbative schemes.

The approach was developed by Tokuyama and Mori and others and is discussed in Ref. 15. This section adapts it to the tunneling problem.

We again start from Eqs. (25) and (26) and express \( \mathcal{Q} \rho(t) \) in the first equation in terms of \( \mathcal{P} \rho(t) \) and \( \mathcal{Q} \rho(t_0) \) with the help of the second. We do not make any assumptions on \( \mathcal{Q} \rho(t_0) \). The solution of Eq. (26) reads

\[
\mathcal{Q} \rho(t) = e^{-i \mathcal{Q} \mathcal{Q}(t-t_0)} \mathcal{Q} \rho(t_0) - i \int_{t_0}^{t} dt' e^{-i \mathcal{Q} \mathcal{Q}(t-t')} \mathcal{Q} \mathcal{P} \rho(t')
\]

(55)

Next, we express \( \rho(t') \) by propagating the full density operator backward in time,

\[
\mathcal{Q} \rho(t) = e^{-i \mathcal{Q} \mathcal{Q}(t-t_0)} \mathcal{Q} \rho(t_0) - i \int_{t_0}^{t} dt' e^{-i \mathcal{Q} \mathcal{Q}(t-t')} \times \mathcal{Q} \mathcal{L} \mathcal{P} e^{-i \mathcal{Q}(t-t')} [\mathcal{P} \rho(t) + \mathcal{Q} \rho(t)].
\]

(56)

Moving all terms in \( \mathcal{Q} \rho(t) \) to the left we obtain

\[
(1 - \Sigma) \mathcal{Q} \rho(t) = e^{-i \mathcal{Q} \mathcal{Q}(t-t_0)} \mathcal{Q} \rho(t_0) + \Sigma \mathcal{P} \rho(t)
\]

(57)

with the superoperator

\[
\Sigma(t - t_0) = -i \int_{t_0}^{t} dt' e^{-i \mathcal{Q} \mathcal{Q}(t-t')} \mathcal{Q} \mathcal{L} \mathcal{P} e^{-i \mathcal{Q}(t-t')}.
\]

(58)

The time argument \( t - t_0 \) will be suppressed if confusion is unlikely. The integral can be performed, giving

\[
\Sigma(t - t_0) = \int_{t_0}^{t} dt' \left( e^{-i \mathcal{Q} \mathcal{Q}(t-t')} \frac{\partial}{\partial t'} e^{-i \mathcal{Q}(t-t')} \right)
+ \left[ \frac{\partial}{\partial t'} e^{-i \mathcal{Q} \mathcal{Q}(t-t')} \right] e^{-i \mathcal{Q}(t-t')}.
\]

(59)

The integral form (58) is more suitable for the expansion in \( \mathcal{L}_{\text{hyb}} \), though.
Applying the inverse \((1 - \Sigma)^{-1}\) to Eq. \((57)\), we obtain
\[
Q\rho(t) = (1 - \Sigma)^{-1} e^{-iQ\mathcal{L}Q(t-t_0)} Q\rho(t_0) + (1 - \Sigma)^{-1}\Sigma \rho(t).
\] (60)

This remarkable equation asserts that we can reconstruct \(Q\rho\) and thus \(\rho = \mathcal{P}\rho + Q\rho\) at time \(t\) from \(\mathcal{P}\rho\) at time \(t\) and \(Q\rho\) at some arbitrarily early time \(t_0\), even though \(\mathcal{P}\rho\) only contains information on the dot state.

Inserting Eq. \((60)\) into Eq. \((23)\) we obtain an equation of motion for \(\mathcal{P}\rho\) alone,
\[
\frac{d}{dt} \mathcal{P}\rho(t) = -i\mathcal{P}\mathcal{L}(1 - \Sigma)^{-1}\mathcal{P}\rho(t)
- i\mathcal{P}\mathcal{L}(1 - \Sigma)^{-1} e^{-i\mathcal{Q}\mathcal{L}Q(t-t_0)} Q\rho(t_0),
\] (61)

which, together with Eq. \((63)\) or \((64)\), constitutes the TCL ME. It indeed only contains the inverse of \(1 - \Sigma\), which, together with Eq. \((58)\) or \((59)\), constitutes the 
\[
\frac{d}{dt} \mathcal{P}\rho(t) = -i\mathcal{P}\dot{\rho}(t) - i\mathcal{P}\mathcal{L}_{\text{hyb}}[1 - (1 - \Sigma)^{-1}]\mathcal{P}\rho(t).
\] (64)

It is then tempting to take the limit \(t_0 \to -\infty\). One has to check whether this limit exists for \(\Sigma(t-t_0)\).

As advertized, the TCL ME \((62)\) is local in time, although the dynamics is generally not Markovian. The memory effects have been shifted into the time dependence of the coefficients of \(\mathcal{P}\rho\). This works because the integro-differential WBR ME is linear. One can then show that a purely differential equation with the same solution exists. \[\text{Maniscalco et al.}\] use the exact solution for the damped harmonic oscillator to illustrate that non-Markovian dynamics is indeed compatible with a TCL formulation. This and related results do not involve transport.

We briefly comment on the question of positivity of the reduced density operator, i.e., the requirement that all its eigenvalues are non-negative. As in Ref. \([53]\), the coefficients in the TCL ME are time-dependent. Thus Lindblad’s criterion for positivity does not apply. However, the TCL ME is exact so that its solution for \(\mathcal{P}\rho\) satisfies \(\mathcal{P}\rho = [\mathcal{T}\rho_{\text{leads}}]\otimes \rho_{\text{hyb}}\) at all times and thus certainly satisfies positivity. It is an important question whether perturbative approximations destroy this property.

To obtain the sequential-tunneling approximation to Eq. \((62)\), we expand to second order in \(\mathcal{L}_{\text{hyb}},\)
\[
\frac{d}{dt} \mathcal{P}\rho(t) \cong -i\mathcal{L}_{\text{dot}}\mathcal{P}\rho(t) - \mathcal{L}_{\text{hyb}} \int_{t_0}^t dt' e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t-t') \mathcal{L}_{\text{hyb}} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t'-t)} \mathcal{P}\rho(t)}
- i\mathcal{L}_{\text{hyb}} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t-t_0)} Q\rho(t_0) - \mathcal{L}_{\text{hyb}} \int_{t_0}^t dt' e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t-t') \mathcal{L}_{\text{hyb}} e^{-i(\mathcal{L}_{\text{dot}} + \mathcal{L}_{\text{leads}})(t'-t_0)} Q\rho(t_0)}. \] (65)

The first term describes the unperturbed time evolution. The two inhomogeneous terms describe the effect of a deviation of the state at time \(t_0\) from a product state with leads in equilibrium. The third term is the only one of first order in the tunneling amplitudes, thus for \(Q\rho(t_0) = 0\) there are no first-order terms. For readers familiar with optical response theory this may seem surprising. We briefly discuss first-order terms in App. \([53]\).
A. Perturbative expansion

Since expansions beyond second order are clearly cumbersome to write down, a diagrammatic representation is helpful. We here assume the simplifying initial condition $\mathcal{Q}\rho(t_0) = 0$. We first expand Eq. (63) in powers of $\Sigma$,

$$\frac{d}{dt} \mathcal{P}\rho(t) = -i\mathcal{L}_\text{dot}\mathcal{P}\rho(t) - i\mathcal{P}\mathcal{L}_\text{hyb}(\Sigma + \Sigma\Sigma + \Sigma\Sigma\Sigma + \ldots)\mathcal{P}\rho(t). \quad (66)$$

The first-order term vanishes since $\mathcal{P}\mathcal{L}_\text{hyb}\mathcal{P} = 0$. Note that the series $1 + \Sigma + \Sigma^2 + \ldots$ might not converge even if the inverse of $1 - \Sigma$ exists.

![FIG. 2: Diagram for the superoperator $\Sigma(t-t_0)$](image)

The interpretation of symbols is given in the caption of Fig. 1. The right-most superoperator in Eq. (63) corresponds to the lower right corner of the diagram.

![FIG. 3: Contributions to the TCL ME (66) containing (a) one and (b) two powers of the superoperator $\Sigma$. The filled semicircle denotes the density operator $\mathcal{P}\rho(t)$. In (b), no time ordering of $t'$ and $t''$ is implied.](image)

The superoperator $\Sigma$, Eq. $(63)$, first propagates the density operator backward in time, projects it, inserts a perturbation $\mathcal{L}_\text{hyb}$, and then propagates it forward again. Its diagrammatic representation is shown in Fig. 2. The contributions to Eq. (66) with one and two powers of $\Sigma$ are represented by the diagrams in Fig. 3. It is obvious how the series continues.

![FIG. 4: General form of all terms involving tunneling in the TCL ME (66). Here, the filled semicircle denotes the projected density operator $\mathcal{P}\rho$ at time $t'$.](image)

This is a good place to compare to the approach of WBR and König et al. The contribution from the tunneling is in this case given by the last term in Eq. (63) or the diagram Fig. 1. To show its consistency with the TCL equation, we note that all tunneling contributions in the TCL approach are of the form shown in Fig. 4. This is indeed just a deformation of Fig. 1 (the “Q” adjacent to the final $\mathcal{L}_\text{hyb}$ is expendable). The upper part of $\Sigma$ is thus equivalent to the irreducible part $\Sigma_K$ without the final $\mathcal{L}_\text{hyb}$. This is also seen by comparing the algebraic expressions (64) and (68).

In order to expand the ME in powers of $\mathcal{L}_\text{hyb}$, we next expand the exponentials as

$$e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})\mathcal{Q}}(t-t') = e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})}(t-t')$$

$$-i\int_{t'}^{t} dt_1 e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t-t_1)} \mathcal{L}_\text{hyb}\mathcal{Q}$$

$$\times e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t_1-t')}$$

$$Q\int_{t'}^{t} dt_2 \int_{t_2}^{t_1} dt_1 e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t-t_2)} \mathcal{L}_\text{hyb}\mathcal{Q}$$

$$\times e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t_2-t_1)} \mathcal{L}_\text{hyb}\mathcal{Q}$$

$$\times e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t_1-t')}$$

and

$$e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads} + \mathcal{L}_\text{hyb})(t-t')} = e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t'-t)}$$

$$+ i\int_{t'}^{t} dt_1 e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t-t_1)} \mathcal{L}_\text{hyb}\mathcal{Q}$$

$$\times e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t_1-t')} + \ldots \quad (67)$$

$$\times e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads} + \mathcal{L}_\text{hyb})(t-t')} = e^{-i(\mathcal{L}_\text{dot} + \mathcal{L}_\text{leads})(t'-t)}$$

The odd terms in Eq. (68) obtain an additional minus sign, since the reversed time order gives an additional minus sign for each integral.

As discussed earlier, any insertion of $\mathcal{P}$ forces an expression to be reducible at that point and any insertion of $\mathcal{Q}$ means that the diagram must not be reducible at that point. $\mathcal{P}$ and $\mathcal{Q}$ thus govern the construction of non-vanishing diagrams but do not affect their values. For the case of a single factor of $\Sigma$ the only diagrams up to fourth order in $\mathcal{L}_\text{hyb}$ are the ones shown in Figs. 5(a)–(d). The only fourth-order contribution from the term with two $\Sigma$ is shown in Fig. 5(e). The second insertion of $\mathcal{L}_\text{hyb}$ counting from the lower right comes from the upper factor of $\Sigma$ due to the right-most “Q” in Fig. 3(b).

The diagrams in Figs. 5(d) and (e) are topologically equivalent but differ in the time ordering. Diagram (d)
FIG. 5: Diagrams for all terms in the TCL ME up to fourth order in the tunneling amplitudes. The dashed lines denote the pairing of lead-electron operators $a$, $a^\dagger$ with the same quantum numbers.

has $t \equiv t_4 > t_1 > t_2 > t_3$, whereas (e) has $t_4 > t_1$ and $t_4 > t_2 > t_3$. In addition, (e) has an odd number of $\mathcal{L}_{\text{hyb}}$ on the lower branch of the upper $\Sigma$, leading to an additional minus sign from Eq. (68). If we add (d) and (e), contributions with $t_1 > t_2$ cancel and we obtain $t_4 > t_2 > t_1$ and $t_2 > t_3$ and an overall minus sign. Higher-order Diagrams are constructed in the same manner.

VII. SUMMARY

In this paper various approaches to the ME for tunneling through molecules and quantum dots have been discussed and compared. The standard derivation of the WBR ME relies on two assumptions: (1) Weak tunneling—allows one to use low-order perturbation theory in the tunneling amplitude and generally implies the Markov assumption of temporal locality. (2) The leads form large energy and particle reservoirs—together with the first assumption and an initial density operator at time $t_0$ of product form with the leads in equilibrium this allows one to write the density operator as a product at all times. Assumption (2) must only be made when calculating expressions of the desired order in $H_{\text{hyb}}$. Making it globally leads to trivial dynamics.

The Markov approximation does not require one to invoke rapid relaxation due to electron-electron or electron-phonon interaction in the leads. In fact, under rather weak conditions, these interactions are shown to be irrelevant for the tunneling. A short time scale describing the decay of correlation in the leads emerges naturally, given by the inverse bias or the inverse thermal energy, whichever is smaller. At low temperatures, this dominates over the contribution from the finite quasiparticle lifetime. A more careful analysis is needed if tunneling events are highly correlated in time.

The superoperator derivation of the WBR ME clarifies the role of the Markov approximation. No assumptions beyond weak tunneling and an initial density operator of product form are made. The large-reservoir assumption (2) is not required, beyond this initial condition. The resulting WBR ME is non-local in time. An explicit Markov approximation is required to make it local.

The ME of König et al. is equivalent to the WBR ME to all orders in tunneling. Its memory kernel, given as a diagrammatic perturbation series in Ref. [9], has been written down in superoperator form.

The $T$-matrix approach only gives rates for the diagonal components of the reduced density operator. The large-reservoir assumption of a product state enters in the guise of statistical independence of dot and lead states. The $T$-matrix approach gives the same expression for these rates as WBR theory with the Markov assumption only to leading (second) order in $H_{\text{hyb}}$, corresponding to Fermi’s Golden Rule. This is because in the $T$-matrix approach one calculates a subtly different quantity than in the WBR approach.

The TCL ME has been adapted to the transport problem. It is an exact equation for the dynamic reduced density operator that is local in time but does not require a Markov assumption. It thus works to arbitrary orders in perturbation theory. The superoperator $\Sigma(t-t_0)$ playing a pivotal role in the TCL ME has been given in an explicit form.

A number of technical questions regarding the TCL formalism applied to transport are still open. First, under what conditions does the inverse of the superoperator $1 - \Sigma(t-t_0)$ exist, which appears in the ME? Second, if we assume the system to be in a product state with leads in equilibrium at time $t_0$, can the limit $t_0 \to -\infty$ be taken? And third, is positivity of probabilities satisfied in perturbative approximations to the TCL ME? Of course, this may be asked for any approach. We leave these questions for future work.

The assumption of a product state with leads in equi-
librium at time $t_0$ is not required in this approach, but simplifies the results. There are processes of first order in $H_{\text{hyb}}$ that are physically reasonable but are omitted if we make this assumption. They can be incorporated by choosing non-standard initial conditions.

A diagrammatic scheme for generating arbitrary orders in $H_{\text{hyb}}$ in the TCL ME has been developed. The relation to the diagrams of König et al. and thus to the WBR ME is easily seen. Our diagrams have interesting additional structure, since the projected density operator is propagated backward in time to make the equation local. The diagrammatic expansion to fourth order is shown explicitly.

Acknowledgments

The author would like to thank J. Koch, F. Elste, J. König, and J. P. Ralston for valuable discussions and helpful comments on the manuscript and the KITP, Santa Barbara, and the Freie Universität Berlin for their hospitality. This work was supported in part by NSF Grant No. PHY99-07949.

APPENDIX A: THE WBR MASTER EQUATION TO SECOND ORDER

Equation (12) is the WBR ME to second order in $H_{\text{hyb}}$. We here give two more explicit forms. First, we derive a fully general expression useful for later comparisons. We introduce dot states $|m\rangle$ and lead states $|i\rangle$ with eigenenergies $E_m$ and $E_i$, respectively, open the commutators, and perform the time integral,

$$
\rho_{mn}^{\dot{\rho}} = -i(E_m - E_n) \rho_{mn}^{\dot{\rho}} - \pi \sum_{ij} \left\{ W_i \langle i|m|H_{\text{hyb}}|p\rangle \langle j|(p|H_{\text{hyb}}|q)i\rangle \rho_{qn}^{\dot{\rho}} \delta(E_p + \epsilon_j - E_q - \epsilon_i) - W_j \langle i|m|H_{\text{hyb}}|p\rangle \rho_{pq}^{\dot{\rho}} \langle j|(q|H_{\text{hyb}}|n)i\rangle \delta(E_q + \epsilon_j - E_n - \epsilon_i) \right. \\
- W_j \langle i|(m|H_{\text{hyb}}|p)i\rangle \rho_{pq}^{\dot{\rho}} \langle j)|(q|H_{\text{hyb}}|n)i\rangle \delta(E_m + \epsilon_i - E_p - \epsilon_j) + W_i \rho_{mp}^{\dot{\rho}} \langle i|(p|H_{\text{hyb}}|q)j\rangle \langle j|(q|H_{\text{hyb}}|n)i\rangle \delta(E_m + \epsilon_i - E_q - \epsilon_j) \} \\
+ i \sum_{ij} \left\{ W_i \langle i|(m|H_{\text{hyb}}|p)j\rangle \langle j|(p|H_{\text{hyb}}|q)i\rangle \rho_{qn}^{\dot{\rho}} P \frac{1}{E_p + \epsilon_j - E_q - \epsilon_i} - W_j \langle i|(m|H_{\text{hyb}}|p)j\rangle \rho_{pq}^{\dot{\rho}} \langle j|(q|H_{\text{hyb}}|n)i\rangle \delta(E_q + \epsilon_j - E_n - \epsilon_i) \} \\
- W_j \langle i|(m|H_{\text{hyb}}|p)j\rangle \rho_{pq}^{\dot{\rho}} \langle j|(q|H_{\text{hyb}}|n)i\rangle \delta(E_m + \epsilon_i - E_p - \epsilon_j) + W_i \rho_{mp}^{\dot{\rho}} \langle i|(p|H_{\text{hyb}}|q)j\rangle \langle j|(q|H_{\text{hyb}}|n)i\rangle \delta(E_m + \epsilon_i - E_q - \epsilon_j) \right\}. \quad (A1)
$$

Here, $W_i \equiv \langle i|\rho_{\text{leads}}^{\dot{\rho}}|i\rangle$ is the probability to find the leads in state $|i\rangle$ and $P$ denotes the principal value.

Second, we consider a specific model with electrons in the leads $\alpha = L, R$ characterized by wave vector $\mathbf{k}$ and spin $\sigma$ and with molecular orbitals enumerated by $\nu$. The hybridization is described by the Hamiltonian

$$
H_{\text{hyb}} = -\frac{1}{\sqrt{N}} \sum_{\alpha k \sigma} \left( t_{\alpha k \sigma} a_{\alpha k}^{\dagger} c_{\nu \sigma} + \text{h.c.} \right), \quad (A2)
$$

where $N$ is the number of sites in each lead. $a_{\alpha k}^{\dagger}$ ($c_{\nu \sigma}^{\dagger}$) creates an electron in lead $\alpha$ (in molecular orbital $\nu$). If we insert $H_{\text{hyb}}$ into Eq. (12), only a single sum over $\alpha, \mathbf{k}, \sigma$ survives, due to the conservation of momentum, spin, and lead index. We introducing dot states $|m\rangle$ with eigenenergies $E_m$ and open the commutators. We only give the first of eight terms, the others are analogous:

$$
\rho_{mn}^{\dot{\rho}} = -i(E_m - E_n) \rho_{mn}^{\dot{\rho}} - \int_0^\infty d\tau \sum_{\alpha k \sigma} \sum_{\nu \nu'} \frac{1}{N} \left\{ \sum_{\alpha k} \sum_{\nu} \left( t_{\alpha k \sigma} a_{\alpha k}^{\dagger} m|c_{\nu \sigma}^{\dagger} (p|H_{\text{leads}}\tau e^{iE_\nu \tau} e^{-iH_{\text{hyb}}\tau} \rho_{qn}^{\dot{\rho}} \otimes \rho_{\text{leads}}^{\dot{\rho}} a_{\alpha k} \rho_{\alpha k}^{\dot{\rho}} \rho_{\alpha k}^{\dot{\rho}} \rho_{\alpha k}^{\dot{\rho}} \rho_{\alpha k}^{\dot{\rho}} \right) \right\}. \quad (A3)
$$
The second-order term contains the expression
\[ t_{\text{leads}} a_{\alpha k \sigma}^\dagger e^{-iH_{\text{leads}} \tau} a_{\alpha k \sigma} e^{iH_{\text{leads}} \tau} \rho_{\text{leads}} = -i G_{\alpha k \sigma}^<(\tau) . \] (A4)

All terms contain lesser or greater Green functions, \( G^< \) or \( G^> \), respectively, which describe the lead correlations discussed in Sec. II. Their Fourier transforms can be expressed in terms of the Fermi function \( n_F \) and the spectral function of the leads, \( A_{\alpha k \sigma}(\omega) \), as

\[
\begin{align*}
G_{\alpha k \sigma}^<(\omega) &= i n_F(\omega - \mu_\alpha) A_{\alpha k \sigma}(\omega - \mu_\alpha), \\
G_{\alpha k \sigma}^>(\omega) &= -i [1 - n_F(\omega - \mu_\alpha)] A_{\alpha k \sigma}(\omega - \mu_\alpha),
\end{align*}
\]

where \( \mu_\alpha \) is the chemical potential of lead \( \alpha \). Performing the integral over \( \tau \), we obtain

\[
\rho_{mn}^{\text{dot}} = -i (E_m - E_n) \rho_{mn}^{\text{dot}} + i \sum_{pq} \frac{1}{N} \sum_{\alpha k \sigma \nu \nu'} \int \frac{d\omega}{2\pi} \sum_{\alpha k \sigma \nu \nu'} \left\{ n_F(\omega - \mu_\alpha) \frac{t_{\alpha k \sigma \nu \nu'}^{\text{dot}}}{\omega + E_p - E_q - i0^+} \rho_{qn}^{\text{dot}} + \ldots \right\}.
\]

where \( P \) indicates a principal value integral.

We find that if the large-reservoir approximation is valid and if the tunneling amplitudes \( t_{\alpha k \sigma \nu} \) do not depend on \( k \), only the lead density of states enters. Strong correlations in the leads, resulting in broad features in the spectral function, do not affect the tunneling. Under these conditions all information on \( k \) is lost so that it is only important whether states at a given energy (and \( \alpha, \sigma \)) exist. As discussed in Sec. II.B, broad features in the spectral function do not invalidate the Markov approximation made here, since they correspond to rapid processes.

**APPENDIX B: FIRST-ORDER TERMS**

We briefly discuss first-order terms in the ME. Equation (24) shows that the only first-order term comes from the initial condition for \( \rho(t_0) \). The origin of the vanishing of first-order terms is that they contain equilibrium averages of single lead-fermion operators, cf. Eqs. (3) and (24).

The absence of first-order terms might be surprising. Let us consider \( \rho_{\text{dot}} \) with component \( \rho_{mn}^{\text{dot}} \neq 0 \), corresponding to the superposition of two states with electron number differing by one. If \( \langle n|H_{\text{hyb}}|m\rangle \neq 0 \), a single power of \( H_{\text{hyb}} \) is sufficient to lead to a change in \( \rho_{mn}^{\text{dot}} \) and \( \rho_{\text{nn}}^{\text{dot}} \), analogous to the interaction of a superposition having an oscillating dipole moment with the light field. Superselection rules suggest that superpositions of states with different charge dephase so rapidly that they are unobservable. However, this does not help us at a fundamental level, since we would obtain the same equation if the tunneling fermions were neutral.

A first-order term is present if we expand the equation for the full density operator, \( \rho(t) = e^{-i\mathcal{L}(t-t_0)} \rho(t_0) \), in powers of \( \mathcal{L}_{\text{hyb}} \). Since first-order processes thus exist, while \( \mathcal{P} \rho \) does not describe them, the required information must be contained in \( \rho(t) \). If they happen to be relevant, we must choose \( \rho(t_0) \neq 0 \).

24. The term “Born approximation” is sometimes used for the weak-tunneling assumption, specifically for the expansion to second order or for locality in time (usually considered part of the Markov approximation), or for the large-reservoir assumption. The first usage is more in line with the Born approximation in scattering theory.

50. The relation $\Pi(t, t''') = \Pi(t, t')\Pi(t', t'')$ is inconsistent with Eq. (48) since $\Pi(t, t'')$ contains contributions that are irreducible at time $t'$, whereas $\Pi(t, t')\Pi(t', t'')$ does not. The origin of the problem is that $\Pi$ contains a projection $\mathcal{P}$ or lead state $\rho_{\text{leads}}$ at the final time.
