A permutation on \([n] = \{1, 2, \ldots, n\}\) is \textit{stabilized-interval-free} (SIF) if it does not stabilize any proper subinterval of \([n]\). For example, \((1 2 3 4 5 6)\), or \((3, 5, 4)(1, 6, 2)\) in cycle notation, or \(6 1 5 3 4 2\) in one-line notation, fails to be SIF because it stabilizes the interval \([3, 5] = \{3, 4, 5\}\). On the other hand, the empty permutation is SIF, as is any cycle, and every SIF permutation on \([n]\) is fixed-point-free for \(n \geq 2\). Let \(a_n\) denote the number of SIF permutations on \([n]\) and \(A(x) = \sum_{n \geq 0} a_n x^n\) their generating function.

The first objective of this paper is to show that \(x^n - 1\) \(A(x) \equiv n!\) and hence that the number of SIF permutations on \([n]\) is given by \(A075834\). This generating function identity amounts to the existence of a decomposition of an arbitrary permutation into a list of SIF permutations. The second objective is to obtain a recurrence relation that permits efficient computation of \(a_n\):

\[
a_0 = a_1 = 1, \quad a_n = \sum_{j=2}^{n-2} (j - 1) a_j a_{n-j} + (n - 1) a_{n-1}, \quad n \geq 2.
\]

A little more generally, a permutation on a totally ordered set is SIF if it does not stabilize any proper saturated chain. Thus \(5 9 2 3\) is SIF on \(\{2, 3, 5, 9\}\) and its reduced form (replace smallest element by 1, second smallest by 2, and so on) is \(3 4 1 2\). The former is a \textit{labeled} SIF permutation and the latter is \textit{unlabeled}—we take \([n]\) as the standard \(n\)-element totally ordered set and call a permutation on \([n]\) unlabeled; \(S_{[n]}\) denotes the set of all permutations on \([n]\).

For each \(\sigma \in S_{[n]}\), one can partition \([n]\) into consecutive intervals \(I_1, \ldots, I_k\) such that \(\sigma\) stabilizes each \(I_j\). The intervals in the finest such partition are called the \textit{components} of \(\sigma\); a permutation with exactly one component is \textit{connected} (sometimes called indecomposable) \(A003319\). Note that the empty permutation is not connected. The restriction of \(\sigma\) to its components clearly gives a decomposition of \(\sigma\) into a
set of connected permutations on intervals that partition \([n]\), called the \textit{component permutations} of \(\sigma\). These permutations are labeled but we also have a decomposition into a \textit{list} of unlabeled connected permutations of total length \(n\) (since we can use position in the list to determine the labels) and this decomposition is bijective. For example, \(325147869 \leftrightarrow 32514 - 231 - 1\) (the dashes separate list items).

Now \([x^{n-1}] A(x)^n\) is the number of length-\(n\) lists (or simply \(n\)-lists) of unlabeled SIF permutations of total length \(n - 1\) (keep in mind the empty permutation has length 0). So, to show \([x^{n-1}] A(x)^n = n!\), it suffices to exhibit a bijection from \(S_n\) to \(n\)-lists of unlabeled SIF permutations of total length \(n - 1\), and we will do so below. This decomposition into unlabeled SIF permutations is analogous to the one above into unlabeled connected permutations but is not so obvious.

Before presenting the bijection we recall some relevant manifestations of the Catalan numbers \([1, p. 219, Ex. 6.19]\). A Murasaki diagram is a sequence of vertical lines some (all, or none) of which are joined at their tips by horizontal lines that never intersect the interior of a vertical line.

The diagram illustrated has 3 components; the first of which has 3 segments (connected figures), the second 1 and the last 2. A partition \(\{B_1, B_2, \ldots, B_n\}\) of \([n]\) is noncrossing if \(a < b < c < d\) with \(a, c \in B_i\) and \(c, d \in B_j\) implies \(i = j\). Murasaki diagrams correspond in an obvious way to noncrossing partitions: the one above corresponds to \(17 - 2356 - 48 - 91012 - 11\) and we may speak of the components of a noncrossing partition. A lattice path of upsteps \((1, 1)\) and downsteps \((1, -1)\) (starting at the origin for convenience) is balanced if it ends on the \(x\)-axis, nonnegative if it never dips below the \(x\)-axis, Dyck if it is both. A Dyck \(n\)-path \(P\) has \(n\) upsteps and \(n\) downsteps; each downstep \(d\) has a matching upstep \(u\): head horizontally west from \(d\) to the first upstep \(u\) that you encounter. Each \(x\)-axis point on \(P\) other than the starting point is a return of \(P\); \(P\) is strict if it has only one return. Its returns divide a nonempty Dyck path into a list of its components, each of which is a strict Dyck path. For any path, a nonzero ascent is a maximal sequence of contiguous upsteps (we assume a zero ascent between a pair of contiguous downsteps); similarly for descents.

Noncrossing partitions \(\pi\) on \([n]\) correspond to Dyck \(n\)-paths \(P\): arrange the blocks of \(\pi\) in increasing order of their maximal elements; let \((m_i)_{i=1}^{k}\) be these maximal elements and let \((n_i)_{i=1}^{k}\) be the corresponding block sizes. Then, with \(m_0 := 0\), the lists \((m_i - m_{i-1})_{i=1}^{k}\) and \((n_i)_{i=1}^{k}\) determine \(\pi\) and are, respectively, the nonzero
ascent lengths and nonzero descent lengths defining $P$. This correspondence preserves components.

An arbitrary permutation $\sigma$ can be split into a set of labeled SIF permutations whose underlying sets partition $[n]$. First, decompose $\sigma$ into its connected components $\sigma_1, \sigma_2, \ldots, \sigma_k$. Set aside all stabilized proper subintervals (if any) of each $\sigma_i$; what’s left will be $k$ nonempty SIF permutations. Repeat this procedure on the entire permutation that was set aside, continuing till nothing is set aside. The resulting set of SIFs corresponds to a Murasaki diagram in which an unlabeled SIF is associated with each segment; the segments record the underlying set $s$, the unlabeled SIFs the action of the permutation. For example, $(1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12)$ splits into $(1, 7), (2, 3, 5, 6), (4), (8), (9, 10, 12), (11)$. The Murasaki diagram is the one above and unlabeled SIFs are associated with segments as follows.

\[
\begin{array}{cccccccccccccc}
\text{segments by smallest element} & 1 & 2 & 4 & 8 & 9 & 11 \\
\text{corresponding unlabeled SIF} & 21 & 3412 & 1 & 1 & 231 & 1
\end{array}
\]

Now we are ready to present the bijection from $S_{[n]}$ to $n$-lists of unlabeled SIF permutations whose total length is $n - 1$, and we will use

\[
\sigma = \left(\begin{array}{cccccccccccccc}
1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 & 10 & 11 & 12 & 13 & 14 & 15 & 16 \\
2 & 4 & 3 & 1 & 8 & 7 & 6 & 5 & 13 & 10 & 9 & 16 & 11 & 15 & 14 & 12
\end{array}\right)
\]
as a working example with $n = 16$. First, decompose $\sigma$ into its components $(\sigma_i)_{i=1}^k$; note that $n$ will occur in the last one. Record the position $j$ of $n$ in $\sigma$ (here $j = 12$), then delete $n$ from $\sigma_k$ to get a permutation $\sigma'_k$ (deleting $n$ simply means erasing $n$ from its cycle and so $\sigma'_k(j) = \sigma(n)$) and $j$ is necessarily in the first component of $\sigma'_k$ because $\sigma_k$ is connected. Now draw the Murasaki diagrams for $\sigma_1, \ldots, \sigma_{k-1}, \sigma'_k$ and record the associated unlabeled SIF for each segment.

Translate each Murasaki diagram $\rightarrow$ noncrossing partition $\rightarrow$ Dyck path, recalling that segment $\rightarrow$ block $\rightarrow$ nonzero descent, so each nonzero descent is associated with an SIF, and mark upstep $j$ (in red in the following figure) unless $j = n$ in which case $\sigma'_k$ is the empty permutation.
Dyck paths, upsteps labeled in order, nonzero descents labeled with corresponding SIF permutation (its length = length of descent). The matching upsteps for a nonzero descent give a block of the noncrossing partition and identify a segment of the Murasaki diagram.

All but the last are strict Dyck paths. The marked upstep (here 12) is in the first component of the last path (unless the last path is empty).

We can use a cut-and-paste technique to massage these Dyck paths into a balanced path in a reversible way (making critical use of the marked upstep). The process will preserve all nonzero descents and so we can carry their SIF labels along with them. Cut the last Dyck path just before its marked upstep into two paths $R, S$. For each preceding Dyck path, remove its last upstep thereby forming a path $P_i$ and a nonzero descent $D_i$, $1 \leq i \leq k - 1$, and $k - 1$ removed upsteps $u$. Then rearrange in the following order to form a balanced path $Q$: $D_1 u D_2 u \ldots D_{k-1} u S R P_1 P_2 \ldots P_{k-1}$.

The original Dyck paths can be recovered from the balanced path. In brief, the center point $p$ of the first double rise (= consecutive pair of upsteps) identifies the initial vertex of the marked upstep. The path from $p$ to the rightmost lowest point of $Q$ following $p$ is $S$ (this relies on the fact that the marked upstep was in the first component); from there to the rightmost point $q$ at $p$’s level is $R$. The descents preceding $p$ are $D_1, \ldots, D_{k-1}$ and their lengths determine how far to proceed from $q$ to recover $P_1, \ldots, P_{k-1}$.

The preceding outline needs a little elaboration to cover special cases. More precisely, prepend and append upsteps to $Q$ to guarantee the existence of a double rise and the point $p$. If $Q$ starts with an upstep, then $p$ will be the origin, the list $D_1, \ldots, D_{k-1}$ will be vacuous and the original permutation $\sigma$ will be connected. If $p$ is the last point of $Q$, then $Q$ will have a sawtooth shape, \(\backslash\backslash\backslash\backslash\backslash\backslash\), and $\sigma$ = identity. If $n$ is a fixed point of $\sigma$, then the last Dyck path is empty (there is no marked upstep) and $Q$ proceeds from $p$ with an upstep and never drops back to the level of $p$. Also, of course, either one of the paths $R, S$ may be empty.
Finally, scan all descents of the balanced path $Q$, recording $\emptyset$ (the empty permutation) for each zero descent and its associated unlabeled SIF permutation for each nonzero descent.

\[ n\text{-list of SIF permutations of total length } n - 1 \]

We have shown that the generating function for the number $a_n$ of SIF permutations on $[n]$ is that of A075834 but to calculate values of $a_n$ it is more efficient to develop a recurrence relation. Let $a_{n,k}$ denote the number of permutations on $[n]$ that do not stabilize any proper subinterval beginning at $i$ for $i < k$. Thus $a_{n,1} = n!$ A000142, $a_{n,2}$ is the number of connected permutations on $[n]$ A003319 (apart from the first term—we need to set $a_{1,2} = 0$), and $a_{n,n} = a_n$. Counting permutations by their first stabilized subinterval, it is straightforward to obtain the following recurrence (given in Mathematica code).

```mathematica
c[0]=0; c[n_]/;n>=1 := c[n] = n!-Sum[c[i](n-i)!,{i,n-1}]
(* c[n] = # connected perms on [n] *)
a[n_,k_]/;n>=0 && k==n+1 := 0;
a[n_,1]/;n>=1 := n!;
a[n_,k_]/;2<=k<=n := a[n,k] =
n!-Sum[c[j-i+1]a[n-(j-i+1),i],{i,k-1},{j,i,n}];
```

However, there is also a direct recurrence for $a_n$ (vacuous sums are 0):

\[ a_0 = a_1 = 1, \quad a_n = \sum_{j=2}^{n-2} (j - 1)a_j a_{n-j} + (n - 1)a_{n-1}, \quad n \geq 2. \]

The right hand side above counts SIF permutations $\sigma$ on $[n]$ by the parameter $j = n - 1 - s$ where $s$ is the size of the largest proper subinterval $I$ of $[n - 1]$ such that $\sigma$ stabilizes $I \cup \{n\}$. ($I$ is necessarily an interior interval of $[n - 1]$ and may be empty.)

To see this, first note that if $\sigma_{n-1}$ is SIF on $[n-1]$ and $n$ is inserted anywhere into a cycle of $\sigma_{n-1}$ ($n - 1$ possible ways) to form $\sigma \in S_{[n]}$, then $\sigma$ is also SIF. This accounts for the last term. Now suppose $\sigma$ is SIF on $[n]$ and the result $\sigma_{n-1} \in S_{[n-1]}$ of deleting $n$ from its cycle in $\sigma$ fails to be SIF. Consider the maximal proper subintervals of $[n - 1]$ stabilized by $\sigma_{n-1}$. There is at least one such by assumption and at most one, call it $I$, because otherwise $\sigma$ itself would stabilize all but one of them. Let $\rho$ denote the restriction of $\sigma_{n-1}$ to $I$ and $\tau$ the restriction of $\sigma_{n-1}$ to $[n - 1] \setminus I$. Then $\sigma$ is obtained from the pair $\tau, \rho$ by inserting $n$ into a cycle of $\rho$, not $\tau$, otherwise $\sigma$
would stabilize $I$. We may write the interval $I$ as $\lceil k + 1, n - j + k - 1 \rceil$ for some $1 \leq k < j \leq n - 2$ so that the size of $I$ is $s := n - j - 1$ and $I$ is clearly the largest proper subinterval of $[n - 1]$ such that $\sigma$ stabilizes $I \cup \{n\}$. Now $\tau$ is SIF on $[n - 1] \setminus I$ by definition of $\rho$. We claim $\rho' := \sigma$ restricted to $I \cup \{n\}$ is SIF also: if $\rho'$ stabilized a proper subinterval of $I$, then $\sigma$ would too, and if $\rho'$ stabilized a proper terminal subinterval (containing $n$), then $\sigma$ would stabilize the corresponding initial subinterval. All told, for each $j \in [2, n - 2]$, we have $j - 1$ choices for $k$ and every permutation $\sigma$ formed in this way from SIF permutations $\rho'$ on $I \cup \{n\}$ ($a_{n-j}$ choices) and $\tau$ on $[n - 1] \setminus I$ ($a_j$ choices) is SIF. The recurrence follows. We note that it implies the differential equation

$$xA'(x) = A(x) - x - \frac{x}{A(x) - 1}$$

for the generating function $A(x)$.

Asymptotically, the proportion of permutations on $[n]$ that are connected (indecomposable) is $1 - \frac{2}{n} + O\left(\frac{1}{n^2}\right)$ [2, p. 295, Ex. 16] and there is a simple heuristic explanation: the easiest way for a permutation on $[n]$ to be decomposable is for it to fix $1$ or $n$ and there are $2(n - 1)! - (n - 2)!$ permutations that do so. Far fewer permutations stabilize any other initial interval and so the dominant term in the number of decomposable permutations on $[n]$ is $2(n - 1)!$. Similarly, the easiest way for $\sigma \in S[n]$ to fail to be SIF is for it to have a fixed point. The proportion of fixed-point-free permutations on $[n]$ is well known to be very near $\frac{1}{e}$, suggesting that the proportion of SIF permutations on $[n]$ is $\frac{1}{e} + O\left(\frac{1}{n}\right)$, and indeed computer calculations suggest it is $\frac{1}{e}(1 - \frac{1}{n}) + O\left(\frac{1}{n^2}\right)$ and maybe $\frac{1}{e}(1 - \frac{1}{n} - \frac{5}{2n^2}) + O\left(\frac{1}{n^3}\right)$. It would be interesting to prove this.
