Ceramide transfer protein (CERT) functions in the transfer of ceramide from the endoplasmic reticulum (ER) to the Golgi. In this study, we show that CERT is an essential gene for mouse development and embryonic survival and, quite strikingly, is critical for mitochondrial integrity. CERT mutant embryos accumulate ceramide in the ER but also mislocalize ceramide to the mitochondria, compromising their function. Cells in mutant embryos show abnormal dilation of the ER and degenerating mitochondria. These subcellular changes manifest as heart defects and cause severely compromised cardiac function and embryonic death around embryonic day 11.5. In spite of ceramide accumulation, CERT mutant mice do not die as a result of enhanced apoptosis. Instead, cell proliferation is impaired, and expression levels of cell cycle-associated proteins are altered. Individual cells survive, perhaps because cell survival mechanisms are activated. Thus, global compromise of ER and mitochondrial integrity caused by ceramide accumulation in CERT mutant mice primarily affects organogenesis rather than causing cell death via apoptotic pathways.

Introduction

Sphingolipids are important structural elements of cell membranes and provide mechanical and chemical stability (Acharya and Acharya, 2005; Riezman, 2006; Zeidan and Hannun, 2007; Hannun and Obeid, 2008). They also serve specific functions in cell–cell recognition and signaling (English et al., 2002; Futerman and Hannun, 2004; Hla, 2005; Zheng et al., 2006). Several intermediates of the sphingolipid metabolic pathway are known as second messengers that mediate processes such as angiogenesis, cell growth, differentiation, and apoptosis (Merrill, 2002; Alvarez et al., 2007; Haberkant et al., 2008; van Meer et al., 2008). Ceramide is a precursor for the synthesis of several sphingolipids. In addition to being an obligate intermediate in the de novo sphingolipid biosynthetic pathway, ceramide has been implicated as a mediator of stress responses, cell differentiation, and apoptosis (Hannun and Obeid, 2008). Its involvement in apoptosis is clinically significant: many chemotherapeutic agents for cancer appear to induce ceramide-dependent apoptosis, and some of the associated enzymes and proteins, including ceramide transfer protein (CERT), are being investigated as targets for cancer therapies (Ogretmen and Hannun, 2004; Savtchouk et al., 2007; Swanton et al., 2007; Zeidan and Hannun, 2007). Many of the fundamental questions pertaining to the study of ceramide and sphingolipid-mediated cell regulation remain unresolved.

Sphingolipids are vectorially synthesized in the cell. The de novo biosynthesis begins with the condensation of serine and...
a fatty acyl Co-A; a series of reactions follow that leads to the generation of ceramide in the ER (Menaldino et al., 2003; Hanada, 2006). The subsequent steps of sphingolipid biosynthesis, including those of sphingomyelin and complex sphingolipids, require ceramide to be transported from the ER to the Golgi complex. Because ceramide is highly insoluble, an energy barrier impedes the movement of ceramide from one membrane to another, and cells accumulate pools of ceramide in different membrane compartments.
subcellular compartments. Recently, Hanada et al. (2003) demonstrated that CERT, a member of the signal transduction and activation of the RNA family of proteins, is responsible for the bulk of the ceramide transport from the ER to the Golgi complex. It localizes to the ER and the Golgi complex. CERT has three functional domains known to be involved in ceramide transport. An amino-terminal pleckstrin homology domain recognizes phosphatidylinositol 4-phosphate and targets CERT to the Golgi. An FFAT motif near the middle of the molecule is thought to interact with vesicle-associated membrane protein–associated protein to recruit CERT to the ER (Kawano et al., 2006). The C-terminal steroidalogenic acute regulatory protein–related domain extracts ceramide from the ER membrane (Fig. 1 A; Hanada et al., 2003).

In this study, we evaluated the in vivo role of CERT in a mouse line lacking a functional Cert gene. We found that CERT is essential for embryonic survival, at least in part because of defects in proliferation and organogenesis with underlying ER and mitochondrial defects. Strikingly, this study also suggests that defects in the sphingolipid biosynthetic pathway that lead to ceramide accumulation can cause severe developmental disruption without inducing apoptosis.

**Results**

**Generation of Cert<sup>−/−</sup> mice**

The mouse Cert gene is on chromosome 13 and is encoded by 18 exons. The transcript has a short and a long form, with the short form containing 2,668 bp and the long form containing 2,746 bp. The respective proteins contain 624 and 598 amino acids. To generate a mouse mutant of Cert (affecting both forms), we used the gene trap embryonic stem (ES) cell line RRF047 from BayGenomics (Stryke et al., 2003). We obtained the ES cell line and confirmed the insertion of the gene trap vector (pGT2Lxf) by RT-PCR and sequencing (Fig. 1 A). The vector carries a splice acceptor sequence upstream of a galactosidase reporter gene, β-geo (a fusion of β-galactosidase and neomycin phosphotransferase II). A PCR genotyping strategy differentiated the mutant and wild-type alleles from DNA extracted from embryos (Fig. 1 B). The deleted allele was null or severely hypomorphic because embryos homozygous for this allele, Cert<sup>−/−</sup>, labeled −/− in figures) embryos, did not generate full-length RNA as determined by RT-PCR, and there was little or no CERT detectable by Western analysis (Fig. 1, C and D). In contrast, CERT was clearly expressed in heterozygotes, Cert<sup>+/−</sup>, although the amount was lower than in the wild type, Cert<sup>+/+</sup>. Because the expression of the inserted β-galactosidase gene is under the control of the endogenous Cert promoter, we expected β-galactosidase to be expressed in all of the tissues that normally express CERT. β-Galactosidase staining of embryonic day 9.5 (E9.5) embryos showed strong staining in homozygous mutant embryos, intermediate staining in heterozygotes, and none in wild-type embryos (Fig. S1 A, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1). Sections through homozygous mutant embryos showed ubiquitous expression of CERT (Fig. S1 B), which was detectable between E8.5 and E10.5 by Western blotting (not depicted).

**Cert<sup>−/−</sup> is an early embryonic lethal mutation**

Genotypic analysis of >500 live-born progeny from heterozygote intercrosses revealed that 35% were wild type, 65% were heterozygous, and none were homozygous mutant (Table I), indicating that the Cert<sup>−/−</sup> mutation is a recessive embryonic lethal trait. Heterozygous mice, Cert<sup>+/−</sup>, were viable, fertile, and morphologically identical to wild-type Cert<sup>+/+</sup> littermates. To determine the developmental stage at which the Cert<sup>−/−</sup> fetuses die, embryos derived from Cert<sup>+/−</sup> intercrosses were genotyped at different stages of gestation. We noticed several Cert<sup>−/−</sup> fetuses degenerating and beginning to be absorbed at E11.5. Moreover, between E7.5 and E10.5, all three genotypes were present in the expected Mendelian ratio (1:2:1; although the size of the homozygotes appeared somewhat reduced throughout this time; Fig. 1 E and Table I). Therefore, we concluded that Cert<sup>−/−</sup> embryos die around E11.5.

We probed for molecular and cellular links between the observed defects and Cert’s function. Therefore, we measured the sphingolipids in wild-type and mutant E10.5 embryos 24 h before the mutant embryos begin to die.

**Sphingolipid metabolism is defective in Cert<sup>−/−</sup> mutant embryos**

The sphingomyelin and ceramide levels in tissue extracts of E10.5 wild-type and mutant littermates were measured using nonpolar liquid chromatography (LC), electrospray ionization (ESI), and single reaction monitor (SRM) tandem mass spectrometry (MS) as described in Materials and methods (Han and
Amide level were lower than normal in the Golgi complex and the plasma membrane and higher than normal in the ER. Therefore, we measured the ceramide levels in these organelles from E10.5 wild-type and mutant embryos by MS. In the plasma membrane, the levels of ceramides were reduced in the mutant; the ER of the CerGT/GT embryos had twice as much ceramide as in the ER of age-matched CerT/+ wild-type controls (Fig. 2, C and D; Fig. S1 C shows minimal contamination of ER by mitochondria and vice versa). The total hexosylceramide (glucosylceramides and galactosylceramides) content was lower in extracts of CerGT/GT embryos compared with those of CerT/+ wild-type controls (Table S1).

A Drosophila melanogaster mutant lacking a functional CERT protein is defective in sphingolipid metabolism, and studies in mammalian tissue culture cells indicate that the biosynthesis of sphingomyelin is compromised when cells lacking CERT
are grown in serum-free media (Fukasawa et al., 1999; Rao et al., 2007). In Drosophila CERT-null mutants, both ceramide phosphoethanolamine (CPE; sphingomyelin analogue) and ceramide are decreased by >80%, and the decreased CPE in plasma membrane renders it more fluid and is responsible for the early death of these mutant flies. Because the plasma membrane sphingomyelin levels were decreased (Fig. 2E) in the Cer−/−Cer−embryos, albeit not as much as in Drosophila CERT mutant (dcert) animals, we isolated and analyzed plasma membrane preparations from the Cer−/− and Cer−/−embryos. There were no significant differences in the fluidity of the plasma membrane between the wild-type and mutant cells (Fig. 2F). The dcert plasma membrane was used as the positive control (unpublished data). The decrease in sphingomyelin levels (58%) in Cer−/−mutant embryos is less than that observed in dcert flies and might not be low enough to render the plasma membrane fluid.

Therefore, our data suggest that sphingomyelin-associated membrane fluidity was not contributing to the observed defects in the CERT-deficient mice. Thus, we investigated whether the accumulation of ceramide in the ER of Cer−/−embryos could affect its structure and function and thus compromise the viability of the cells.

ER and mitochondrial alterations in Cer−/−embryos

To evaluate whether the accumulation of ceramide affected the structure of the ER in the Cer−/−mutants, we examined sections from E8.5–10.5 embryos by transmission EM (TEM). Because the Cer−/−embryos exhibited cardiovascular defects (see section Cer−/−mutants die around E11.5...), we initially examined the hearts of E10.5 wild-type and mutant embryos. TEM analysis of cells from the endocardial, muscular, and epicardial regions showed proliferation, vesiculation, and even engorgement of the ER in the cells of the Cer−/−embryos (Fig. 3, top right). In many instances, these engorged ERs were accompanied by the accumulation of lipid bodies in their vicinity (Fig. 3, bottom right, white arrow). Surprisingly, the mitochondria of Cer−/−cells were abnormal as well, appearing pale and engorged (Fig. 3, middle and bottom). Many lacked cristae; several were undergoing gross structural changes and degenerating.

If indeed the CERT deficiency was responsible for these changes and CERT function is ubiquitous, we expect to see similar structural changes in other cell types of the developing embryo. To address this, we examined the cells of the developing optic cup, an easily identifiable area of the developing embryo, by TEM. Mitochondrial changes similar to the ones seen in the heart were predominant in these optic cup cells in the mutant E10.5 embryos (Fig. S2, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1). Although the ER and Golgi were the most visible structures in the wild-type Cer−/−cells, indicating healthy activity, the mitochondria in the mutant cells could be seen degenerating in the vicinity of lipid-filled structures.

To ascertain whether the compromised ER and mitochondria initiated the abnormal development of the CERT-deficient embryos, we also examined cardiovascular and optic cup cells from E9.5 embryos; that is, 48 h before the mutant embryos typically die. Although not as abundant as at E10.5, ER engagement, vesiculation, and mitochondrial changes were visible in the E9.5 embryos in differentiating cells of both the optic cup and the heart, including the myocardial cells (Fig. S3, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1).

Chronic ER stress in Cer−/−embryos

The morphological features of Cer−/−mutant cells are reminiscent of cells undergoing ER stress. ER stress manifests in cells as ER proliferation, dilation, and vesiculation (Scheuner and Kaufman, 2008). ER distension is a hallmark for cells that have defective protein folding in the ER lumen and is observed in response to the pharmacological induction of ER stress (Ermonval et al., 1997; Umebayashi et al., 1997; Scheuner et al., 2005). The ER is responsible for the synthesis of roughly a third of the proteins generated in a cell. Several hundred proteins, including those involved in lipid biosynthesis, are upregulated when the unfolded protein response (UPR) signaling pathway is activated in yeast upon ER stress (Travers et al., 2000; van Anken and Braakman, 2005). It has become increasingly clear that components of the UPR are also up-regulated during development and differentiation in animals (Reimold et al., 2000; Bertolotti et al., 2001; Zhang et al., 2005). The defective transport of ceramide in vivo may therefore stress the ER and affect the viability of the cell and of the organism as a whole. Although it has been proposed that the accumulation of ceramide in the ER could cause stress, this has not been demonstrated experimentally.

We used Western blot analysis to compare the steady-state levels of a panel of proteins implicated in the ER stress response, i.e., BiP, protein disulfide isomerase (PDI), IRE1-α, protein kinase–like ER kinase (PERK), eIF2-α, and C/EBP homologous protein, in E10.5 Cer−/− and Cer−/−embryos (Fig. 4A). IRE1, PERK, and ATF6 are considered the proximal sensors of the UPR signaling cascade (Malhotra and Kaufman, 2007; Ron and Walter, 2007). These proteins collectively monitor the quality of the proteins synthesized in the ER. Activation of these three proteins either in isolation or in concert when unfolded proteins accumulate in the ER or the ER is subjected to stress is thought to initiate a transcriptional and translational program. Acute or low-level chronic stress of the ER will initiate protective responses, and the cells adapt by regulating the induction of chaperones and modulating the capacity of the ER to synthesize and properly fold new proteins. However, severe or persistently toxic ER stress that cannot be resolved can activate components of the cell death pathway.

We found that phosphorylated PERK protein was slightly lower in the extracts of Cer−/−than in Cer/Cert mice (Fig. 4A), and a proapoptotic downstream effector of phosphorylated PERK, C/EBP homologous protein, was unaffected (not depicted). IRE1-α levels were unchanged, and ATF6 was only slightly increased in the mutant embryos. However, some of the downstream components of the UPR pathway displayed significant changes: the protective ER chaperones calnexin, PDI, and ATF4 were increased in the Cer−/−cells (Fig. 4B). In addition, phosphorylated eIF2-α, which is implicated in cell cycle arrest and attenuates the translation of general proteins
Ceramide is increased in mitochondrial preparations of CERT mutant embryos

The accumulating ceramide causes ER stress, and the ceramide might be transferred to the mitochondria via recently discovered regions of close contact between the ER and mitochondria (Copeland and Dalton, 1959; Ruby et al., 1969; Morre et al., 1971; Meier et al., 1978; Eggens et al., 1979; Vance, 1991; Rizzuto et al., 2004; Franzini-Armstrong, 2007). Such a finding would show a strong correlation between the altered sphingolipid metabolism and the observed phenotypes in CERT mutant embryos. Therefore, we prepared mitochondrial preparations under ER stress, leading to adaptation, was significantly up-regulated in the CERT mutant embryos (Fig. 4 B). It is worth noting that the phosphorylation of eIF2-α has been reported to increase significantly during the G2/M phase in Ba/F3 cells and at the G2/M boundary in human osteosarcoma cells (Datta et al., 2005; Tinton et al., 2005). These observations suggest that CERT mutant embryos are undergoing a state of chronic ER stress. The biochemical evidence correlating the structural alterations with functional changes in the ER prompted us to probe whether a similar situation existed in the mitochondria of CERT mutant embryos.

**Figure 3. EM evidence of ER and mitochondrial disorganization in CERT mutant embryos.** Cells from the three primary layers of the developing heart, namely endocardium, myocardium, and epicardium, of E10.5 CERT (+/+) and CERT mutants were examined under an electron microscope. The panels on the left are from the CERT (+/+) embryos, and the CERT (-/-) mutants are on the right. The black arrow shows a lipid-laden engorged rough ER in the endocardial layer of the mutant heart. The white arrows show lipid-laden structures found in the vicinity of swollen ER and mitochondria in the mutant cells. The arrowheads show mitochondria undergoing degeneration with discontinuous outer and inner mitochondrial membranes in the myocardial layer. In the epicardial cells, the arrowheads depict swollen and pale mitochondria with ruptured inner and outer mitochondrial membranes in the mutant heart. The mitochondria in the mutant are generally swollen, pale, and have fewer cristae. n, nucleus; mf, muscle fibers of the myocardial cells. Bars, 500 nm.
and lipoid degeneration observed in the CERT-deficient embryos than in wild-type embryos, indicating that the structural changes resulted in compromised functioning of the mitochondria in the CERT-deficient embryos.

Increased protein-folding efficiency of the ER such as ATF4, PDI, and calnexin were all increased in CERT-deficient embryos. As shown in Fig. 5A, the activity of cytochrome c oxidase was significantly lower in the mutant embryos than in wild-type embryos. The lack of CERT function caused abnormal ceramide accumulation in the mitochondria of those of the wild-type embryos. The increased levels of phosphorylated eIF2α are an indicator of the underlying ER stress. +/+ wild type; −/− homozygous mutant.

from the wild-type Cert+/+ and the mutant Cert−/− embryos and estimated ceramides in them. As shown in Fig. 5A, the mitochondria of the mutants contained 1.5-fold more ceramide than those of the wild-type embryos. The lack of CERT function caused abnormal ceramide accumulation in the mitochondria of CERT-deficient embryos.

To determine whether mitochondrial functioning was compromised in the Cert−/− embryos, we evaluated the level of cytochrome c oxidase, the terminal enzyme of the oxidative phosphorylation cascade. Mitochondria were prepared using density gradient centrifugation, and the cytochrome c oxidase activity was measured. As shown in Fig. 5B, the activity of cytochrome c oxidase was significantly lower in the mutant embryos than in wild-type embryos, indicating that the structural changes and lipoid degeneration observed in the CERT-deficient embryos resulted in compromised functioning of the mitochondria in these animals. Thus, the altered ceramide metabolism in the Cert−/− embryos not only affected the ER but also had a strong effect on mitochondrial integrity and function.

Cert−/− mutants die around E11.5 as a result of cardiovascular insufficiency

To correlate the underlying biochemical defects to the observed phenotype of the Cert−/− mutants, morphological assessment of embryos was performed. From the early head-fold stage (E7.5) to E10.5, the Cert−/− embryos were smaller than their wild-type Cert+/+ counterparts (more the size of wild-type animals that were 0.5–1 d younger), although their gross appearance was similar to wild type (Fig. S1A). To evaluate whether the growth defects began in early embryogenesis, we examined the outgrowth of Cert−/− blastocysts. E3.5 blastocysts were outgrown in ES media for 3 d, and no obvious developmental defect was found (Fig. S4, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1). The inner cell mass and the outgrowth of the polyploid trophectoderm cells in all three cultures were easily distinguished. We also followed cell proliferation in the blastocysts by incubating them with BrdU after 3 d of outgrowth. No significant differences were noted among the outgrowths of the three genotypes (unpublished data). Therefore, the changes leading to the observed size difference in Cert−/− mutants must manifest at a postimplantation stage.

CERT-deficient embryos obtained by caesarian section appeared normal at E8.5–10.5, although their growth was retarded. Gross examination of the mutant embryos at E10.5 did not reveal any major developmental defects, except in the heart. The heart is the first functional embryonic organ, one of the first to differentiate and begin to function in the developing mouse embryo around E10.5 (Sissman, 1970; Challlice and Viragh, 1974). In all of the mutant embryos examined, the bilateral heart tubes had migrated between E8.5 and E9.0 to the midline and fused to form a single heart tube. Heartbeats were established in the E10.5 mutants, indicating that they were all developmentally past E9.5. Closer examination of the dissected heart revealed that all of the Cert−/− embryos displayed a normal S-shaped loop. However, the truncus arteriosus region of the outflow tract of some Cert−/− mutants (Fig. 6A) was thin, transparent, and swollen, and the entire heart appeared swollen with thin and transparent walls in other embryos (Fig. 6A and B, bottom right). In one embryo, the walls of the primitive ventricle displayed a region of higher density (Fig. 6B, top).

Cert−/− embryos not only affected the ER but also had a strong effect on mitochondrial integrity and function.

Figure 4. Cert−/− embryos exhibit evidence of ER stress. (A) Western blot analysis of cell extracts of E10.5 wild-type and Cert−/− embryos probed for proximal sensors such as phosphorylated PERK, IRE1α, and ATF6 showing no or a slight increase in levels, a situation not different from cells in states of chronic stress. (B) Components of the UPR response implicated in the phosphorylation cascade. Mitochondria were prepared using density gradient centrifugation, and the cytochrome c oxidase was significantly lower in the mutant embryos than in wild-type embryos. The lack of CERT function caused abnormal ceramide accumulation in the mitochondria of those of the wild-type embryos. The increased levels of phosphorylated eIF2α are an indicator of the underlying ER stress. +/+ wild type; −/− homozygous mutant.

Figure 5. Increased ceramide content in mitochondria of Cert−/− compromises mitochondrial function. (A) CERT deficiency and lack of ceramide transfer out of the ER causes increased ceramide levels in the mitochondria. (B) The cytochrome c oxidase activity, the terminal reaction in ATP generation, was decreased by more than half in the mutant mitochondria (n = 3; error bars are very small and indicate the standard error of the mean). +/+ wild type; −/− homozygous mutant.
The contractions of the ventricles in the Cerf<sup>gt/gt</sup> embryos were obviously weaker than in normal embryos, and blood accumulated in the ventricles of some animals (Fig. 6 B, bottom left).

Upon examination in utero, some Cerf<sup>gt/gt</sup> embryos exhibited complete regurgitation of the blood into the heart during diastole, a phenomenon not observed in any of the wild-type or heterozygous embryos (Videos 1 and 2, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1). Although in rare instances bradycardia and atypical contractions caused a partial backflow of blood in a few wild-type hearts during dissection and sample preparation at room temperature, we never observed in them the extreme regurgitation of blood observed in the mutant embryos. Furthermore, the mutant embryos were well past the 20-somite stage when embryonic hearts normally establish unidirectional blood flow.

Histological analysis revealed an enlarged ventricular cavity and thin walls (Fig. 6 C). Closer inspection showed that the outflow tract was enlarged and had thinner and weaker walls than the heterozygote or wild-type hearts, and the width of the acellular cardiac jelly between the inner endocardial cells and...
the outer cardiomyocytes was also enlarged in many mutant hearts (Fig. 6 C, inset). In several mutant embryos, the ballooned and thin-walled heart chambers were so fragile that they were punctured during dissection, even with very gentle handling.

The combined gross and histological findings indicated that the Cert⁰⁰⁰ embryos die around E11.5 from failure to establish a fully functional cardiovascular system. The nonproductive cardiac contractions indicated that there was a cardiac pump failure that caused venous dilation, which could lead to low blood pressure, systemic hypoxia, and eventual embryonic death.

Cell proliferation changes in Cert⁰⁰⁰ embryos

At the cellular level, the growth defects of the Cert⁰⁰⁰ embryos could arise either from aberrant proliferation and differentiation or excessive cell death. Thus, we evaluated the proliferative potential of Cert⁰⁰⁰ embryonic cells by labeling dividing cells with BrdU (Fig. 7 A), which is incorporated during the S phase. The percentage of cells that incorporated BrdU was calculated in four different areas of each animal. The mutants had BrdU-positive indices that were significantly lower than those of wild-type Cert¹⁶ embryos (Fig. 7 B). These results suggested that the cell cycle patterns of the Cert⁰⁰⁰ embryos were aberrant, which could contribute to the observed defects in the growth and development of the mutant embryos.

To gain insight into the molecular changes affecting the cell cycle in the mutant embryos, we immunoblotted tissue extracts of E10.5 normal and mutant embryos for various cell cycle markers. As shown in Fig. 7 C, the levels of cyclin D1, a marker for G1 phase, and Cdc2, an essential cell cycle kinase and regulator of the G2/M transition, were decreased in the mutant embryos (Berthet and Kaldis, 2007; Satyanarayana et al., 2008). Moreover, the fraction of the inactive phosphorylated form of Cdc2 (Y15P-Cdc2) was higher in the mutant than in wild-type and mutant embryos (Fig. 7 B). These results suggested that the cell cycle patterns of the Cert⁰⁰⁰ embryos were aberrant, which could delay the entry of cells into the G2/M phase.

Active Akt has been implicated in the regulation of cardiac myocytes and the proliferation of cardiac progenitor cells (Sussman, 2007). Therefore, we measured the Akt levels in the wild-type and mutant developing embryos. As shown in Fig. 7 D, we found that the level of phosphorylated Akt was down-regulated in the Cert⁰⁰⁰ embryos, perhaps contributing, at least in part, to their decreased cell proliferation. Our findings show that the expression and regulation of key cell cycle proteins are affected in the mutant embryos, although further detailed studies will be required to understand the complexity of the deregulation. Furthermore, these results suggest that theCert⁰⁰⁰ proliferation deficiency occurs via a mechanism that is directly or indirectly linked to S- and M-phase entry.

Defects in Cert⁰⁰⁰ embryos are not caused by increased apoptosis

The complex pathways involved in sphingolipid metabolism have been implicated in the regulation of apoptosis. To learn whether the excessive loss of tissue and the developmental defects of the Cert⁰⁰⁰ embryos could be the result of apoptosis, cell death was measured by using TUNEL, as described in Materials and methods. As shown in Fig. 7 E, there was no difference in apoptotic cell death between mutant and wild-type embryos at E10.5, when all of the phenotypes described here were visible. The percentage of TUNEL-positive cells was determined by counting cells in at least six areas of each embryo and comparing results of corresponding areas in wild-type Cert¹⁶ and mutant Cert⁰⁰⁰ embryos. Our results indicated that the cellular death events that precede and contribute to heart failure do not include abnormal apoptotic cell death. We also did not observe cellular changes consistent with increased apoptosis among cells of the developing heart and optic cup of Cert⁰⁰⁰ embryo (unpublished data) while examining them for the aforementioned subcellular morphology.

Activation of MAPK survival pathways and the inactivation of Akt/PKB and JNK signaling in Cert⁰⁰⁰ embryos

Our data suggested that the accumulation of ceramide caused by CERT deficiency led to the activation of ER stress and caused mitochondrial dysfunction. How do CERT-deficient cells cope with these defects and survive at E10.5? To profile the response of the CERT-deficient cells at the molecular level, we performed immunoblotting for a panel of proteins, phosphorylated and/or nonphosphorylated, that are implicated in stress-activated cell survival responses and apoptosis. MAPK and Akt/PKB signaling play critical roles in cell survival during stress. Therefore, we evaluated the steady-state levels of these proteins in wild-type and mutant embryos by Western blotting. Surprisingly, the levels of the phosphorylated form of Akt were down-regulated in the mutant extracts compared with total Akt (Fig. 7 D).

Although the difference in phosphorylated Akt could partly account for the cell cycle arrest/delay observed in CERT mutant cells, it could not fully explain the ability of the mutant cells to survive the ER stress. Therefore, we investigated the MAPK cell survival pathways. The MAPK signaling cascades are involved in stress-activated signaling responses. Extracellular signal-regulated kinase (ERK), JNK, and p38 MAPK are subgroups of the MAPK family. The dynamic balance between the activated ERK– and JNK–p38 signaling pathways is important in determining cell survival versus apoptosis. As shown in Fig. 8 A, the ERK survival pathway was significantly activated in the mutants, but the JNK–p38 pathway was down-regulated. Therefore, cellular survival under ER stress in Cert⁰⁰⁰ embryos involves a mechanism in which the ERK pathway is activated and the Akt, JNK, and p38 signaling pathways are suppressed.

A notable feature of the UPR is that it leads to the concomitant engagement of both adaptive and proapoptotic molecules. Thus, we extended our analysis to see whether such a phenomenon had been initiated in the Cert⁰⁰⁰ mice. We immunoblotted extracts from E10.5 embryos to look for the possible activation of cell death pathways (Fig. 8 B). Surprisingly, the proapoptotic proteins Bax and Bak were significantly elevated in the Cert⁰⁰⁰ embryos, and the antiapoptotic Bcl-2 and Bcl-xL were down-regulated. It is worth noting that the Bcl-2 family proteins also play important roles in ER physiology and regulate...
in the mitochondria (Fig. 8 C), supporting a nonmitochondrial role for the increased Bax protein. Also, the total level of cytochrome c, a key molecule released from mitochondria into the cytosol in the mitochondrial apoptotic pathways, was clearly decreased in the Cert gt/gt embryos. In contrast, the level of apoptosis-induced factor was not affected (Fig. 8 C). Because the mitochondrial morphogenesis (Karbowski et al., 2006). Bax and Bak were recently shown to act not only as essential gateway proteins to cell death pathways operating at the mitochondria but also to relocate to the ER to function in the regulation of UPR (Wei et al., 2001; Hetz et al., 2006; Oakes et al., 2006). Bax accumulated in postmitochondrial supernatant rather than
CERT embryos showed no sign of apoptosis, it was clear that several factors influenced the survival of the CERT-deficient cells, although the compensation was not vigorous enough to overcome the growth delays imposed on cells under chronic ER stress (Rutkowski et al., 2006).

Our data suggested that although activators of apoptosis were initiated in the CERT-deficient cells, the effectors were not deployed to execute apoptosis. One reason for the lack of deployment could be the low level of cytochrome c in the mutant embryos. In addition, the predominant activation of proteins in the cell survival pathways of the MAPKs could contribute to this effect. We have also confirmed that CERT deficiency does not inherently compromise the apoptotic potential of the mutant cells. Primary mouse embryonic fibroblasts (MEFs) can be derived and cultured from the mutant E9.5 embryos. Although they are slightly growth inhibited compared with similarly derived wild-type MEFs, they are capable of undergoing actinomycin D–induced apoptosis ex vivo (Fig. S5, available at http://www.jcb.org/cgi/content/full/jcb.200807176/DC1). A very high ADP/ATP charge ratio, an indicator of the inability to undergo apoptosis, was also not a contributing factor in the mutant embryos because these ratios were similar in the wild-type and the mutant embryos. Also, total ATP levels were comparable between the wild-type and mutant embryonic extracts, implying that insufficient ATP was not responsible for the failure to undergo apoptosis (unpublished data).

**Discussion**

In this study, we showed that CERT, a protein that transports ceramide from the ER to the Golgi, is essential for survival in mice. Mice lacking CERT die at E11.5 because of cardiac abnormalities manifesting as a result of underlying structural and functional defects in ER and mitochondria. Three in vivo significance of ceramide transfer from the ER to the Golgi was studied recently using a *Drosophila* model (Rao et al., 2007). Flies lacking a functional CERT protein are viable and fertile but die prematurely as a result of accelerated aging. The different outcomes in these organisms stem not only from the differences in their developmental programs but also from differences in the underlying biochemical changes accompanying the CERT deficiency.

CERT mutants in both organisms have decreased sphingomyelin levels (CPE in *Drosophila*). Although there is a fourfold decrease in the *Drosophila* adult, there is slightly more than a twofold decrease in the mutant mouse embryos. This is probably because the mouse embryos, unlike *Drosophila*, developed within the uterus of a heterozygous mother, where sphingomyelin, a component of plasma lipoprotein fraction, can be delivered to the developing embryos through the amniotic fluid (Liu et al., 1992; Subbaiah and Liu, 1993). In an analogous situation, CERT-deficient CHO cells (Ly-A), when grown in the presence of serum, do not show changes in steady-state sphingomyelin levels because they can incorporate the metabolites from the medium (Fukasawa et al., 1999; Hanada et al., 2003). However, experimental evidence for this explanation of the differences in sphingomyelin levels is lacking. In any case, the effects of the decrease differ in mice and *Drosophila*: the very significant decrease in the CPE levels of *Drosophila* CERT mutants affects plasma membrane fluidity and initiates oxidative stress; the smaller decrease in sphingomyelin in the CERT-deficient mouse embryo did not alter plasma membrane fluidity. In *Drosophila*, total ceramide levels decrease by 80%, whereas they remain unchanged in mice. However, in the mouse embryo, a 200% increase in ceramide levels in the ER instigates a series of pathophysiological changes and ultimately causes early embryonic lethality.

The most important finding of this study is the impact of deficient ceramide transport on mitochondrial structure and function in mice. Mass spectrometric data indicated increased levels of ceramide in the mitochondria and ER, and electron micrographic pictures showed progressive degeneration of the mitochondria. The changes in ceramide levels and in the structure and function of mitochondria that accompany the CERT deficiency in mice support the idea that ceramide is normally directly transferred from the ER to the mitochondria. Studies have demonstrated a close functional link between the ER and

---

**Figure 8.** Cell survival pathways are activated in E10.5 *Cert<sup>+/–</sup>* embryos. (A) Components of the cell survival pathway p42/44 ERK are strongly activated in the mutant, whereas MAPK components that mediate stress-mediated response are suppressed. SAPK, stress-activated protein kinase. (B) Components of the apoptotic machinery such as Bak and Bax that also have roles in mediating UPR are activated, whereas antiapoptotic components Bcl-2 and Bcl-x are down-regulated. (C) The total cytochrome c levels in *Cert<sup>+/–</sup>* embryos are decreased significantly in the mutant embryos. Although most of the cytochrome c is in the mitochondria in the wild type, in the mutant we see it in both cytosol (C) and mitochondria (M). Also, the increased Bax in *Cert<sup>+/–</sup>* embryos is in the cytosol, whereas mitochondrial levels seem unaffected. AIF, apoptosis-induced factor.
mitochondrial physiology (Copeland and Dalton, 1959; Ruby et al., 1969; Morre et al., 1971; Meier et al., 1978; Eggens et al., 1979; Vance, 1991; Rizzuto et al., 2004; Franzini-Armstrong, 2007). Several of these studies have even demonstrated a physical link between the ER and mitochondria. ER membranes called mitochondria-associated membranes are physically and functionally allied with mitochondria and have been implicated in the integration of several aspects of ER and mitochondrial function. Mitochondria-associated membranes are also involved in multiple mechanisms of the cooperative synthesis by the two organelles of the mitochondrial cytochrome c oxidase and phospho- and glycerosphingolipids (Shore and Tata, 1977; Vance, 1991; van Meer and Lisman, 2002). A recent electron tomography study demonstrated the existence of 10-nm and 25-nm tethers connecting smooth and rough ER, respectively, to mitochondria (Csordas et al., 2006). Furthermore, although sphingolipid levels are low in mitochondria, some enzymes involved in the de novo steps of the sphingolipid biosynthetic pathway, including ceramide synthase and ceramidase, have been reported to localize to mitochondria (Bionda et al., 2004). Our data support the idea that some mechanism exists for the transfer of ceramide from the ER to the mitochondria, either by physical continuity between the organelles or by a transfer protein. Although delivering sphingolipid metabolites to the mitochondria may serve a useful function in healthy cells, it might also serve to mitigate the effect of the sphingolipids accumulating in the ER during stressful or pathological conditions.

In a recent study probing the mechanism of drug resistance in tumor cells, it was shown that down-regulation of CERT sensitized these cells to the cytotoxic effects of paclitaxel and potentiated paclitaxel-induced ER stress (Swanton et al., 2007). However, in this study, we demonstrate that under physiological conditions, in vivo loss of CERT induces a state of chronic stress in the ER and, most importantly, compromises mitochondrial structure and function. The state of chronic stress in CERT mutant embryos is comparable with that of cells that are exposed to chronic ER stress but that have adapted to the stress. In a study of different states of ER stress, cells exposed to low concentrations of tunicamycin showed UPR activation and ER perturbation, but the cells still proliferated, although at a slower rate than untreated cells, and did not show any signs of apoptosis (Rutkowski et al., 2006). The chronically stressed cells achieved confluence and could be passaged for as long as their untreated counterparts (and they eventually achieved a near-normal growth rate) despite the continued presence of tunicamycin in the culture. Thus, the decreased proliferation of the tunicamycin-treated cells was caused by a growth delay, and chronic ER stress by exogenous pharmacological manipulation does not necessarily result in cell death, although death could be caused by a secondary mitigating event. Similarly, physiological activation of the UPR is observed in B lymphocytes as a result of increased demands of protein secretion (Wu and Kaufman, 2006).

The lack of CERT function in mice did not result in cell death. The biochemical data suggest that the cells mounted an adaptation response to the ER and mitochondrial stress in the mutant embryos. Because CERT performs a fundamental function in sphingolipid metabolism, it is present in all cells and tissues. Perhaps surprisingly, although none of the cells in the Cert−/− mice could transport ceramide, they could still divide at a compromised rate, and they progressed through a nearly normal developmental program until about E10–11.5.

This stage is a remarkable period in mouse development. Beginning around E8 and lasting until around E11.5, there is a sudden increase in the growth and complexity of the embryo (Viragh and Challice, 1973). The sudden shift in the pace of division and differentiation imposed on the CERT mutant cells at these stages apparently outstrips the ability of these compromised cells to respond to developmental signals. This notion is partly supported by our EM data that showed at E9.5 the beginnings of changes to the mitochondria and ER that were much more obvious at E10.5. That the animals died of cardiovascular defects is very reasonable in this context. During the 24-h window between E8.0 and E9.0, the linear dimensions of the heart increase four- to fivefold, which apparently pushed the mutant cells beyond their capacity to adapt. Because a functional circulatory system is an early requirement for survival and growth, its developmental failure resulted in early death attributable to the lack of CERT function. However, the underlying pathology existed in all of the embryonic cells, as indicated by the similar mitochondrial and ER changes observed in the cells of the developing eye.

Our study clearly demonstrates that manipulation of sphingolipid flux in vivo and the consequent accumulation of ceramide within cellular compartments do not necessarily end in apoptotic cell death. In the present study, it leads to defects in cell cycle and differentiation caused by the stress imposed on the ER and mitochondria. In sum, our combined approach has identified the essential role of CERT in mammalian embryogenesis and provided molecular insight into the role of the de novo sphingolipid biosynthetic pathway in influencing the ER-dependent structure/function of mitochondria.

Materials and methods

Generation of CERT knockout mice

The BayGenomics mouse (strain 129/Ola) ES cell line RRF047 was obtained and confirmed by RT-PCR. The gene trap vector (pGT2Lx) was inserted in the Cert gene between exons 3 and 4 (26 kb). These cells were injected into C57Bl/6 blastocysts, which were then implanted into pseudo-pregnant foster mothers. High contribution chimeras were obtained. Heterozygous mice were backcrossed to C57Bl/6 mice and kept in a 129/Ola cross C57Bl/6 background. Therefore, all of the following experiments were performed with mice of the mixed genetic background. All mice were held in accordance with institutional policies and federal guidelines.

Mice were genotyped by a three-primer PCR using mouse tail DNA as a template. The primer sequences used were as follows: forward, 5’-CTCATGATCATCGTGGTAGAGAGAC-3’; reverse mutant, 5’-CCTACATAGTGGGAGTGTTTTGG-3’; and wild-type reverse, 5’-GATGTGGTACCTGAGAGAGGC-3’. These primers amplified bands of 319 bp and 481 bp for the mutant and wild-type allele, respectively. PCR reactions began with a denaturing step at 95 °C for 3 min followed by 35 cycles of 95°C for 30 s, 55°C for 30 s, and 72°C for 30 s.

Embryo dissection and histological and EM analyses

Timed mating was performed with Cert−/− (+−/) mice on a mixed genetic background (C57Bl/J129). Females with copulation plugs were considered to be at day 0.5 of gestation, and embryos present in this pregnant female were designated at E0.5. Pregnant females were dissected at various times of gestation, and the dissected embryos were photographed under a normal inverted light microscope (Axioskop, Carl Zeiss, Inc.)
connected to a digital camera (Powershot S50; Canon), and DNA for genotyping was isolated from small pieces of yolk sac by hot-start PCR (lysis buffer (25 mM NaOH and 0.2 mM EDTA) and neutralization buffer (40 mM Tris-HCl)). Genotyping was performed by the aforementioned 3 primer short PCR. For histological analysis, embryos were fixed with 4% paraformaldehyde (HCl solution), embedded in paraffin, sectioned, and stained with hematoxylin and eosin (H&E). Photomicrographs were taken using a microscope (Carl Zeiss, Inc.) and a digital camera (Q-imaging, Inc.) and processed using Photoshop (Adobe). For EM analysis, embryos were fixed in 4% HClO and 2% glutaraldehyde in 0.1 M sodium cacodylate buffer and processed as described previously (Acharya et al., 2006). Serial sections were viewed on an electron microscope (EM300; Philips Electronic Instruments, Inc.).

For blastocyst outgrowths, heterozygous 4–6-wk-old female mice were superovulated by intraperitoneal injection of a pregnant mare’s serum (5 IU per animal) and human chorionic gonadotropin (5 IU per animal) 48 h later and were subsequently mated with Cert+/+ males. Plugged female mice were killed, and their uteri were dissected and flushed with ES cell medium at 3.5 d after coitus. Single blastocysts were seeded onto gelatinized 96-well plates containing 200 μl of medium and incubated at 37°C and 5% CO2. After 3 d, wash by PBS and blastocyst DNA was isolated by lysis buffer with proteinase K. The 3 primer PCR was performed.

LacZ staining was performed on E9.5 embryos dissected from the intercross of Cert+/+ in PBS, and embryos were transferred to 4% HClO in PBS at 4°C and incubated in the dark for 1 h. Embryos were washed with rinse buffer (5 mM EGTA, 0.01% deoxycholate, 0.02% NP-40, and 2 mM MgCl2 in PBS) at room temperature for 15 min. The embryos were incubated in the dark with protocols with some modifications (Bozidis et al., 2007). In brief, the homogenate was centrifuged at 152,000 g for 70 min. The ER that appears as a band at the interface of the 1.3-M sucrose solutions in Hepes-EDTA buffer. The contents were centrifuged at 152,000 g for 15 min. The pellet enriched in mitochondria was mixed 1:2 with Opti-prep, resulting in a 40% solution. 30 and 5% nolic KOH solution was added to each of the tubes followed by incubation overnight. Tissue sections were rinsed and stored in PBS and observed under a dissection microscope (Stemi DV4; Carl Zeiss, Inc.).

For BrdU, TUNEL staining, and immunohistochemistry, pregnant mice at E10.5 were injected intraperitoneally with BrdU (100 mg/kg) and human chorionic gonadotropin (5 IU per animal) 48 h prior to sacrifice. Embryos were washed thoroughly in PBS containing 0.5% Triton X-100 and 0.2% sodium chloride, and 0.2 mM EGTA with protease inhibitor mixture. The homogenate was centrifuged at 1,000 g for 10 min to get rid of cell debris. The postnuclear supernatant was mixed 1:2 with Opti-prep, resulting in a 40% solution. 30 and 50% Opti-prep solutions were overlaid on the top. The tubes were centrifuged for 3 h at 100,000 g. Plasma membrane appeared as a white dense band at 30–50% interface.

Mitochondria and ER were isolated by following previously published protocols with some modifications (Bazid et al., 2007). In brief, the embryos were homogenized in homogenization buffer A (20 mM NaHepes, 0.1 mM EDTA, and 0.2 M sucrose) with protease inhibitors. The homogenate was centrifuged at 1,000 g for 10 min and the resulting supernatant B was collected and suspended in Opti-prep buffer and used for cytchrome c oxidase assay. The supernatant B (postmitochondrial supernatant) was centrifuged at 150,000 g for 2 h, and the pellet was suspended in Hepes-EDTA buffer (20 mM Hepes and 0.1 mM EDTA) and loaded on top of the sucrose gradient tube (discontinuous gradient made with 2%, 1.5%, and 1.3-M sucrose solutions in Hepes-EDTA buffer). The contents were centrifuged at 152,000 g for 70 min. The ER appears as a band at the interface of the 1.3-M sucrose gradient was collected into a new tube. The admixing of ER and mitochondrial fractions were monitored by evaluating the ER resident protein BiP and mitochondrial marker protein Grp 75 in the preparations. There was <5% mixing of mitochondrial resident protein Grp 75 in ER preparation and, likewise, <1% of ER protein BiP in mitochondrial preparation (Fig. S1 C).

Sphingolipid standards were purchased from Sigma-Aldrich and Avanti Polar Lipids, Inc. The ceramide/sphingolipid internal standard mixture (LM0001; Avanti Polar Lipids, Inc.) contains a mixture of 10 sphingolipids, each present at a concentration of 25 μM, was purchased from Avanti Polar Lipids, Inc.

Plasma membrane was isolated by density gradient centrifugation, and fluidity measurement Subcellular fractionation for sphingolipid analysis and membrane fluidity measurement was performed.

Mitochondrial Dysfunction in CERT Mutant Mice • Wang et al. 155

Flow cytometry and cell death analysis E9.5 embryos were separated from the yolk sac, washed twice with PBS, pH 7.2, and trypsinized for 10 min. The cells were disaggregated by pipetting several times and suspended in 1 ml of prewarmed (37°C) DMEM supplemented with 10% FBS. The suspension was allowed to stand for 2–3 min at room temperature, and visible clumps were removed. The suspension was further centrifuged at 500 g for 3 min, and the cell pellet was suspended in MEF media (DMEM + 10% FBS) and plated on a 48-well plate. The plates were incubated at 37°C with 3% oxygen and 5% carbon dioxide as described previously (Parrinello et al., 2003). The medium was replaced the next day, and the cells were cultured for 4–5 d. For induction of apoptosis, the cells were treated with 10 μM actinomycin D for 12 h, after which the cell death was assessed using Vybrant apoptosis assay kit #2 (Invitrogen) according to the manufacturer’s instructions. The images were obtained on a microscope (Axioplan 2) at a magnification of 40 using Axiovision 4.2 (Carl Zeiss, Inc.) and pseudocolored using Photoshop (Adobe). For induction of apoptosis, the cells were treated with 10 μM actinomycin D for 12 h, after which the cell death was assessed using Vybrant apoptosis assay kit #2 (Invitrogen) according to the manufacturer’s instructions. The images were obtained on a microscope (Axioplan 2) at a magnification of 40 using Axiovision 4.2 (Carl Zeiss, Inc.) and pseudocolored using Photoshop (Adobe). Tabulation reported in Fig. S5, 68–218 cells were counted from three separate primary MEFs derived from Certr−/− E9.5 embryos, and between 52 and 157 cells were counted for three primary MEF lines derived from E9.5 Certr−/− embryos.

Sphingolipid estimation

Preparation of lipid extracts from tissues. Lipid extracts were prepared, and sphingolipids were estimated according to the method described previously (Merrill et al., 2005; Merrell et al., 2005). In brief, each of the samples was extracted with a mixture of 50–100 μl of sample having a protein concentration of ~3–4 mg/ml. 0.5 ml CH3OH, 0.25 ml CHCl3, 50–100 μl of water, and 30 μl of a 25 μM solution of LM6002 internal standard was added. The lipid aggregates in the mixture were dispersed by either sonicating four times using a tip sonicator (Bronson) at an amplitude of 30% for a period of 10 s or using a water bath sonicator for ~15–30 min. After sonication, the samples were incubated overnight at 48°C with shaking. After cooling, 75 μl of 1 M methanoic KOH solution was added to each of the tubes followed by incubation at 37°C for 2 h with shaking. Each of the samples was then divided into two equal aliquots.

One of the aliquots was evaporated to a volume of ~25 μl using a Speed Vac Concentrator (Savant Instruments, Inc.) and reconstituted with 300–400 μl of 1:1 (vol/vol) reverse phase solution A and reverse phase solution B. After vortexing for 1 min, centrifugation, the supernatant was collected.

The other aliquot was neutralized by an addition of 3–4 μl CH3COOH followed by the addition of 2 ml of water and 1 ml CHCl3. The biphasic solution was vortexed for 1 min, and the lower organic phase was collected. This extraction procedure was repeated once more. The combined organic fractions were evaporated using a heating block set at 50°C. Samples were reconstituted in 300–400 μl of 1.4 (vol/vol) CHCl3–nonpolar mobile phase solution A. Ceramides and sphingomyelins were analyzed from this sample by normal phase LC-MS.

Quantitation of ceramide and sphingomyelin molecular species by LC electron spray tandem MS. LC-MS analyses were performed using a mass spectrometer (LTQ Discovery LC-MS; Thermo Electron Corp.) consisting of a Quantum triple stage quadrupole mass spectrometer equipped with an ESI source. The mass spectrometer was coupled to a high-performance LC system (1100 series; Agilent Technologies).

Complex sphingolipids (such as ceramides and sphingomyelins) were separated by normal phase high-performance LC using a binary system and a Supelcosil LC-CN18 column (internal diameter = 3 mm, length = 7 cm, and mean particle size of the medium = 3 μm) operating at a flow rate of 250 μl/min. The column was maintained at 37°C. Mobile phase A consisted of 20 ml MeOH, 5 mM NH4OAc, 15 ml CH3COOH, 270 ml MeCN, 295 ml EIOAc, and 400 ml hexanes. Mobile phase B consisted of 99:1 (vol/vol) CH3OH:CH3COOH containing 5 mM NH4OAc. The LC gradient run time for the analyses of ceramides and sphingomyelins was 18 or 21 min.
The mass spectrometer (TSQ Quantum Discovery; Thermo Electron Corp.) was calibrated using a solution of polytylene-1,3,6 as recommended by the manufacturer. The tune file for calibrations, sphenoglycolines, etc. was obtained by optimizing ESI source conditions at an LC flow rate of 250 µl/min and using calibrations and sphenoglycoline reference compounds. The optimized source parameters used were as follows: sheath gas pressure, 20 psi; auxiliary gas pressure, 3 (arbitrary units); ion spray needle voltage, 4,500 V; capillary temperature, 377 °C; skimmer offset, 5 V. No source fragmentation was observed when direct infusion of reference compounds was made at this skimmer potential, thus ensuring that maximum sensitivity is obtained. For sphenoglycoline, the collision energy and tube lens values were obtained through compound optimization. For ceramides, tuned values for the tube lens were used, and application of universal 28–30 V of continuous extraction gave the best [M+H]+ → 264 or 266 product ion fragments for all of the ceramides.

Nitrogen gas was used for collisionally induced dissociations in Q2, which was offset from Q1 by 10 V. SRM scans were acquired by setting Q1 and Q3 to pass the precursor [M+H]+ and product ions 184 for sphenoglycoline and 264 or 266 for ceramides containing sphingosine and sphinganine, respectively. The acquisition parameters common to all analyses were scan width (mass/charge ratio), 0.050 D; scan time, 0.10 s for each transition; peak width (full width half maximum), 0.70 D for both Q1 and Q3; and collision pressure, 1.5 mtorr.

For experiments conducted in SRM mode, a segmented tandem MS method was constructed based on the chromatographic retention times of the sphingolipids. For each class of sphingolipids such as ceramides and sphingomyelins, two or three methods were built, and, in each method, only five to six analyte SRM transitions were present that also included the respective ceramide or sphingomyelin internal standard precursor-to-product ion transitions. Experiments were performed in triplicate. Data acquisition and analysis were accomplished using Xcalibur software version 2.0.5 (Thermo Electron Corp.).

Quantitation data were corrected for the carbon number difference between a given molecular species and the selected internal standard (different in degrees because of varying carbon chain lengths, which results in different ionization efficiencies) according to the following formula (Han and Gross, 2005): 

\[ z_1 = \frac{1 + 0.011n + 0.0112n^2}{n - 1}/2 + 0.011s \]

**Antibodies**

The following antibodies were used: mouse monoclonal anticard [AC-15], rabbit polyclonal anti–calnexin ER marker, chicken polyclonal anti–CO-LA33BP (M-150), secondary antibody goat anti–chicken IgY, HRP linked (Abcam), rabbit polyclonal anti–Akt, phospho-Akt (Ser473), CDC-2, phospho-PDK1 (Ser415), phospho-GSK-3 (Abcam), rabbit polyclonal anti-Akt, phospho-Akt (Ser473), CDC-2, phospho-PDK1 (Ser415), phospho-GSK-3 (Abcam), rabbit polyclonal anti-Akt, phospho-Akt (Ser473), CDC-2, phospho-PDK1 (Ser415), phospho-GSK-3 (Abcam), mouse monoclonal anti–Bak (Ab-2), rabbit polyclonal anti–Bax (Ab-1), Bcl-2 (Ab-2), Bcl-x (Ab-1), EMD, mouse monoclonal anti–cyclin B (Invitrogen), rabbit polyclonal anti–cyclin D1 (Thermo Fisher Scientific), mouse monoclonal anti–cytochrome c (Assay Designs), rabbit monoclonal anti–phospho–elf2α (pS51), Epitomics, mouse monoclonal anti–GADD 153 (B-3), secondary antibody goat anti–mouse IgG, and HRP linked (Santa Cruz Biotechnology, Inc.).

**Immunoblotting**

Immunoblot analysis of cell protein lysates was performed according to the instructions of Santa Cruz Biotechnology, Inc. In brief, frozen tissue (embryos) was thawed in ice-cold radioimmunoprecipitation assay buffer with freshly added inhibitors (1x PBS, 1% Igepal, 0.5% sodium deoxycholate, 0.1% SDS, 10 mg/ml PMSF, 50 mg/ml apronitin, and 1 mM/liter sodium orthovanadate [Sigma-Aldrich]) and homogenized on ice with a polytron device followed by centrifugation at 10,000 g for 20 min at 4°C. The concentration of supernatant protein was quantified using protein assay (Bio-Rad Laboratories). Samples were mixed with 2x Laemml buffer (Bio-Rad Laboratories) and denatured at 100°C for 5 min, and 50 µg of denatured protein per lane was separated by Novex 4–12% Bis-Tris gel (Invitrogen). Separated proteins were transferred to polyvinylidene difluoride membrane (Millipore) and subjected to immunoblotting with various primary antibodies. Positive antibody reactions were visualized with an HRP-conjugated secondary antibody and a chemiluminescence detection system (PerkinElmer) according to the manufacturer’s instruction. The membrane was deprobed and reprobed with an anticanine antibody to confirm that all samples contained similar amounts of proteins. TTS (TBS with 0.05% Tween 20) was used as a washing buffer, and 5% nonfat dry milk (Bio-Rad Laboratories) was dissolved in TBS and used as a blocking solution.

**RT-PCR analysis**

Total RNA was extracted using the TRIZOL reagent (Invitrogen), and cDNAs were generated with reverse transcription (Superscript; Invitrogen) according to the manufacturer’s instructions. 2 µl cDNA was amplified in the PCR Master Mix solution (Promega).

**Online supplemental material**

Fig. S1 shows that the gene trap vector efficiently traps the Cert gene. Fig. S2 shows EM evidence of defects in the ER and mitochondria in cells from the developing embryonic optic cup of Cerf+/- embryos. Fig. S3 shows that ER and mitochondrial defects can be noticed even at E9.5. Fig. S4 shows that blastocysts from the preimplantation stage do not show gross abnormalities. Fig. S5 shows that Cerf+/- derived primary MEFs are capable of undergoing apoptosis. Videos 1 and 2 compare the cardiac output from E10.5 embryos of Cerf+/- and Cerf+/-, demonstrating the circulation defects in the mutant heart. Table S1 shows the detailed quantification of the different species of sphenoglycoline and ceramides estimated in the whole embryos and plasma membrane preparations of Cerf+/- and Cerf+/- at E10.5.
