ABSTRACT. We study the regularization of an oriented 1-foliation $F$ on $M \setminus \Sigma$ where $M$ is a smooth manifold and $\Sigma \subset M$ is a closed subset, which can be interpreted as the discontinuity locus of $F$. In the spirit of Filippov’s work, we define a sliding and sewing dynamics on the discontinuity locus $\Sigma$ as some sort of limit of the dynamics of a nearby smooth 1-foliation and obtain conditions to identify whether a point belongs to the sliding or sewing regions.

1. INTRODUCTION

A 1-dimensional (singular) oriented foliation $F$ on a smooth manifold $M$ is defined by exhibiting an open covering of $M$ and a collection of smooth vector fields whose domains are the open sets of this covering, and which agree on the intersections of these open sets up to multiplication by a strictly positive function. A discontinuous 1-foliation on $M$ is given by a closed subset $\Sigma \subset M$ with empty interior and a 1-dimensional oriented foliation on $M \setminus \Sigma$.

To fix the ideas we start with the usual setting which was initially studied by Filippov [7]. The foliations considered are determined by flows of vector fields expressed by

\begin{equation}
X = \left(\frac{1 + \text{sgn}(f)}{2}\right)X_+ + \left(\frac{1 - \text{sgn}(f)}{2}\right)X_-
\end{equation}

for some smooth vector fields $X_+, X_-$ defined on $M$ and a function $f \in C^\infty(M)$ having 0 as a regular value. The discontinuity locus is the smooth codimension one submanifold $\Sigma = f^{-1}(0)$.

In this setting, we say that a point $p \in \Sigma$ is $\Sigma$-regular if $\mathcal{L}_{X_-}(f)\mathcal{L}_{X_+}(f) \neq 0$ and it is $\Sigma$-singular if $\mathcal{L}_{X_-}(f)\mathcal{L}_{X_+}(f) = 0$. Moreover the regular points are classified as sewing if $\mathcal{L}_{X_-}(f)\mathcal{L}_{X_+}(f) > 0$ or sliding if $\mathcal{L}_{X_-}(f)\mathcal{L}_{X_+}(f) < 0$.

According Filippov’s convention, the flow of $X$ is easily determined in the neighborhood of sewing points. Roughly speaking, it behaves like a constant vector field, as in Flow Box Theorem. However when a trajectory finds a sliding point, the orbit remains in $\Sigma$ up to a $\Sigma$-singular point. In the sliding
region of $\Sigma$ the trajectory follows the flow determined by a convex combination of $X^+$ and $X^-$, called \textit{sliding vector field}.

These concepts do not have a natural generalization when the discontinuity occurs in singular sets, that is when $\Sigma = f^{-1}(0)$ is the inverse image of a critical value. This is one of subjects which will be discussed in this article.

Our main tool in the study of discontinuous foliation is the \textit{regularization}. Basically, a regularization is a family of smooth vector fields $X_\varepsilon$ depending on a parameter $\varepsilon > 0$ and such that $X_\varepsilon$ converges uniformly to $X$ in each compact subset of $M \setminus \Sigma$ as $\varepsilon$ goes to zero. One of the most well-known regularization process was introduced by Sotomayor and Teixeira [18, 22]. It is based on the use of \textit{monotonic transition functions} $\phi : \mathbb{R} \to \mathbb{R}$ (1). The \textit{ST-regularization} of the vector field $X$ given in (1) is the one parameter family

\begin{equation}
X_\varepsilon = \frac{1}{2} \left( 1 + \phi \left( \frac{f}{\varepsilon} \right) \right) X_+ + \frac{1}{2} \left( 1 - \phi \left( \frac{f}{\varepsilon} \right) \right) X_-.
\end{equation}

The regularized vector field $X_\varepsilon$ is smooth for $\varepsilon > 0$ and satisfies that $X_\varepsilon = X_+$ on $\{ f > \varepsilon \}$ and $X_\varepsilon = X_-$ on $\{ f < -\varepsilon \}$. With this regularization process Sotomayor and Teixeira developed a systematic study of the singularities of these systems and also developed the Peixoto’s program about structural stability. In particular, Teixeira analyzed the singularity of the kind fold-fold, which was later known as $T$-singularity. We refer also [12, 13] for related problems.

In [2], the use of singular perturbation and blow-up techniques were introduced in the study of the ST-regularization. Let us briefly describe this procedure, assuming for simplicity that $M = \mathbb{R}^2$ and that $\Sigma = \{ y = 0 \}$. If

\footnote{by definition, this is a $C^\infty$ function such that $\phi(t) = -1$ for $t \leq -1$, $\phi(t) = 1$ for $t \geq 1$ and $\phi'(t) > 0$ for $-1 < t < 1$.}
we write $X_+ = a_+ \frac{\partial}{\partial x} + b_+ \frac{\partial}{\partial y}$ and $X_- = a_- \frac{\partial}{\partial x} + b_- \frac{\partial}{\partial y}$ then

$$X_\varepsilon = \frac{1}{2} \left( a_+ + a_- + \varphi \left( \frac{y}{\varepsilon} \right) (a_+ - a_-) \right) \frac{\partial}{\partial x} + \frac{1}{2} \left( b_+ + b_- + \varphi \left( \frac{y}{\varepsilon} \right) (b_+ - b_-) \right) \frac{\partial}{\partial y}.$$ 

Considering the directional blow-up $y = \bar{\varepsilon} \bar{y}, \varepsilon = \bar{\varepsilon}$ we get the vector field

$$\bar{X}_\varepsilon = \frac{1}{2} \left( a_+ + a_- + \varphi \left( \bar{y} \right) (a_+ - a_-) \right) \frac{\partial}{\partial x} + \frac{1}{2 \bar{\varepsilon}} \left( b_+ + b_- + \varphi \left( \bar{y} \right) (b_+ - b_-) \right) \frac{\partial}{\partial \bar{y}}$$

which corresponds to the singular perturbation problem (2).

\begin{equation}
\begin{cases}
\dot{x} = \frac{1}{2} \left( a_+ + a_- + \varphi \left( \bar{y} \right) (a_+ - a_-) \right) \\
\varepsilon \bar{y} = \frac{1}{2} \left( b_+ + b_- + \varphi \left( \bar{y} \right) (b_+ - b_-) \right)
\end{cases}
\end{equation}

For $\bar{\varepsilon} = 0$, the slow manifold of (3) is the set implicitly defined by

$$(b_+ + b_-) + \varphi \left( \bar{y} \right) (b_+ - b_-) = 0$$

with slow flow determined by

$$\frac{1}{2} \left( a_+ + a_- + \varphi \left( \bar{y} \right) (a_+ - a_-) \right) \frac{\partial}{\partial x}.$$

Silva et al [15] proved that the set of sliding points, according Filippov convention, is the projection of the slow manifold of (3) on $\Sigma$. Moreover they proved that the slow flow of (3) and the sliding vector field idealized by Filippov have the same equation.

For better visualization, we use the polar blow up $y = r \cos \theta, \varepsilon = r \sin \theta$ with $\theta \in (0, \pi)$. In this case the discontinuity $\Sigma$ is replaced by a semi-cylinder on which we draw the slow manifold and the fast and slow trajectories. See figure 2.

The singular perturbation problem which is obtained evidently depends on the choice of the regularization. The sliding vector field idealized by Filippov appears when we consider the ST-regularization, see for instance [14, 15, 16, 17]. However Novaes and his collaborators [21] have considered a slightly more general regularization, called non-linear regularization, which produces singular perturbation problem with slow manifold having fold points and thus not defining only one possible sliding flow. It seems evident that other regularizations may produce new sliding regions.

\[\text{System (3) is called slow system and it is equivalent, up to a time reparametrization, to the fast system}\]

$$x' = \frac{\varepsilon}{2} \left( a_+ + a_- + \varphi \left( \bar{y} \right) (a_+ - a_-) \right), \quad \bar{y} = \frac{1}{2} \left( b_+ + b_- + \varphi \left( \bar{y} \right) (b_+ - b_-) \right).$$
The techniques of singular perturbation have also been applied to deal with discontinuities on surfaces with singularities. Teixeira and his collaborators realized that in the case where $\Sigma$ has a transverse self-intersection a process of double regularization can be used, and that it generates systems with multiple time scales.

In this work we intend to unify the different approaches of the previous works. Let us briefly summarize the results proved in this paper.

Given a smooth manifold $M$, initially we introduce the concepts of 1-dimensional oriented foliation on $M$ and discontinuous 1-foliation on $M$ with discontinuity locus $\Sigma$. The first question we address is to get conditions so that the foliation can be smoothed by a sequence of blowing-ups.

Our first results are the following:

- If $\mathcal{F}$ is a piecewise smooth foliation and the discontinuity locus $\Sigma$ is a smooth submanifold of codimension one then the foliation $\mathcal{F}$ is blow-up smoothable. See Theorem 2.1.
- If the discontinuity locus $\Sigma$ is a globally defined analytic subset then there is a piecewise smooth 1-foliation which is related to the initial foliation by a sequence of blow-ups and whose discontinuity locus is smooth. Moreover if we further suppose that the discontinuity locus has codimension one then the foliation is blow-up smoothable. See Theorem 2.2 and Corollary 2.1.

The smoothing procedure defined in Section 2 does not allow to define the so-called sliding dynamics along the discontinuity locus. So, we define such sliding dynamics as the limit of the dynamics of a nearby smooth 1-foliations. This leads us to introduce a general notion of regularization for piecewise-smooth 1-foliations.

Roughly speaking, the regularization is given by a new foliation depending on a parameter $\varepsilon$, which is smooth for $\varepsilon > 0$ and which coincides with the original discontinuous 1-foliation when $\varepsilon$ equals zero. We generalize the notion of ST-regularization to this global context and consider a larger family of regularizations (called of transition type) by dropping the condition of monotonicity of the transition function.

Basically, the sliding region associated to a given regularization is defined as the accumulation set of invariant manifolds of the regularized system. We prove the following results.

- The regularization of transition type is blow-up smoothable. See Theorem 4.1.
We obtain conditions on the transition function to identify whether a point lies in the sliding region. See Theorems 4.2 and 4.3.

The paper is organized as follows. In Section 2 we give the preliminary definitions and prove Theorems 2.1, 2.2 and Corollary 2.1. In Section 3 we study the regularization and in Section 4 we combine the blowing-up technique and the Fenichel’s theory to give sufficient conditions for identifying the sliding region.

Figure 3 is a pictorial representation of the blow-up smoothing process. It shows a piecewise smooth discontinuous foliation with analytic discontinuous set having a smooth part and a singular one. Applying a regularization of the kind transition we get a new foliation $\mathcal{F}^r$. In the figure we draw the level $\mathcal{F}^0$ of this foliation. The leaves displayed in $\mathcal{F}^0$ are the trajectories of the singular perturbation problem (3). The simple arrows correspond to the slow flow and the double arrows correspond to the fast flow, which is obtained after a time reparametrization.

2. DISCONTINUOUS 1-FOLIATIONS

In this section we present the preliminary definitions related to discontinuous 1-foliations. Also we enunciate and prove results related to blow-up smoothing of discontinuous 1-foliations.
2.1. **Smoothable discontinuous foliations.** We work in the category of manifolds with corners. We briefly recall that a manifold with corners of dimension \( n \) is a paracompact Hausdorff space with a smooth structure which is locally modeled by open subsets of \((\mathbb{R}^+)^k \times \mathbb{R}^{n-k}\). We refer the reader to [11, 20] for a careful exposition.

Let \( M \) be a smooth manifold (with corners). A smooth vector field defined on \( M \) will be called *non-flat* if its Taylor expansion is non-vanishing at each point of \( M \). From now on, all vector fields we will consider are non-flat.

We say that a pair \((V, Y)\) formed by an open set \( V \subset M \) and a smooth vector field \( Y \) defined in \( V \) is a local vector field in \( M \).

A *1-dimensional oriented foliation* on \( M \) is a collection
\[
\mathcal{F} = \{(U_i, X_i)\}_{i \in I}
\]
of local vector fields such that:
1. \( \{U_i\} \) is an open covering of \( M \).
2. For each pair \( i, j \in I \),
\[
X_i = \varphi_{ij}X_j
\]
for some strictly positive smooth function \( \varphi_{ij} \) defined on \( U_i \cap U_j \).
Remark 1. The importance to consider oriented foliations instead of globally defined vector fields in the manifold $M$ will become clear later. Roughly speaking, even if our initial object is a foliation globally defined by a smooth vector field, this property will not necessarily hold after the blowing-up operation.

We say that a local vector field $(V, Y)$ is a local generator of the foliation $\mathcal{F}$ if the augmented collection

$$\{(U_i, X_i)\}_{i \in I} \cup \{(V, Y)\}$$

also satisfies conditions 1. and 2. of the above definition. From now on, we will suppose that the collection $\mathcal{F}$ is saturated, meaning that it contains all such local generators.

Let $\psi : N \to M$ be a smooth diffeomorphism between two manifolds $N$ and $M$. We will say that two 1-dimensional oriented foliations $\mathcal{F}$ and $\mathcal{G}$ defined respectively in $M$ and $N$ are related by $\psi$ if for each local vector field $(V, Y)$ which is a generator of $\mathcal{G}$, the push-forward of this local vector field under $\psi$, namely

$$(U, X) := (\psi(V), \psi_*Y),$$

is a generator of $\mathcal{F}$.

A possibly discontinuous 1-foliation on a manifold $M$ is given by a closed subset $\Sigma \subset M$ with empty interior and a 1-dimensional oriented foliation $\mathcal{F}$ defined in $M \setminus \Sigma$.

The set $\Sigma$ is called the discontinuity locus of $\mathcal{F}$. We can write the decomposition

$$\Sigma = \Sigma^{\text{smooth}} \cup \Sigma^{\text{sing}}$$

where $\Sigma^{\text{smooth}}$ denotes the subset of points where $\Sigma$ locally coincides with an embedded submanifold of $M$. We shall say that $\mathcal{F}$ has a smooth discontinuity locus if $\Sigma = \Sigma^{\text{smooth}}$.

Example 1. The vector field in $\mathbb{R}^2$ given by

$$X = \frac{\partial}{\partial x} - \text{sgn}(y) \frac{\partial}{\partial y}$$

defines a discontinuous 1-foliation which has discontinuity locus $\Sigma = \{y = 0\}$.

Example 2. Consider the discontinuous 1-foliation defined in $\mathbb{R}^2$ by the vector field

$$X = \frac{x^2 - y^2}{x^2 + y^2} \left( -y \frac{\partial}{\partial x} + x \frac{\partial}{\partial y} \right) + \left( x \frac{\partial}{\partial x} + y \frac{\partial}{\partial y} \right)$$

with discontinuity locus $\Sigma = \{0\}$. Notice that $X$ is not smooth at the origin.
Example 3. Consider the discontinuous 1-foliation defined in $\mathbb{R}^3$ by the vector field

$$X = -\text{sgn}(x) \frac{\partial}{\partial x} - \text{sgn}(y) \frac{\partial}{\partial y} + \frac{\partial}{\partial z}$$

with has the (non-smooth) discontinuity locus $\Sigma = \{xy = 0\}$.

Figure 4. Discontinuity locus of the 1-foliation of the example 3.

More generally, let $f$ be an arbitrary smooth function on a manifold $M$ and let $X_+, X_-$ be two smooth vector fields defined on $M$. Then

$$X = \left(\frac{1 + \text{sgn}(f)}{2}\right) X_+ + \left(\frac{1 - \text{sgn}(f)}{2}\right) X_-$$

is a discontinuous 1-foliation with discontinuity locus $\Sigma = f^{-1}(0)$.

Example 4. The figure 5 illustrates a discontinuous 1-foliation in $M = \mathbb{R}^2$, where $f(x, y) = y^2 - x^2(x + 1)$, $X_+ = -y \frac{\partial}{\partial x} + x \frac{\partial}{\partial y}$ and $X_- = -X_+$.

Figure 5. Discontinuous 1-foliation of the example 4.
As the above examples show, there is no reason to expect that $\mathcal{F}$ can be extended smoothly (or even continuously) to $\Sigma$. In order to circumvent this difficulty, one possibility is to modify the ambient space $M$ by a blowing-up (or a sequence of blowing-ups) and to expect that the modified foliation extends smoothly to the whole ambient space. We refer the reader to [20], chapter 5 for a detailed definition of the blowing-up operation in the category of manifold with corners.

We will say that discontinuous 1-foliation $\mathcal{F}$ defined in $M$ and with discontinuity locus $\Sigma$ is blow-up smoothable if there exists a locally finite sequence of blowing-ups (with smooth centers)

$$M = M_0 \leftarrow \cdots \leftarrow \cdots \leftarrow \widetilde{M}$$

and a smooth 1-foliation $\tilde{\mathcal{F}}$ defined in $\widetilde{M}$ such that:

1. The map $\Phi : \widetilde{M} \to M$ is a diffeomorphism outside $\Phi^{-1}(\Sigma)$, and
2. $\tilde{\mathcal{F}}$ and $\mathcal{F}$ are related by $\Phi$, seen as a map from $\widetilde{M} \setminus \Phi^{-1}(\Sigma)$ to $M \setminus \Sigma$.

Let us show that the examples studied above are blow-up smoothable.

**Example 5.** Consider the discontinuous 1-foliation defined in $\mathbb{R}^2$ by the vector field in (5), which has discontinuity locus $\Sigma = \{y = 0\}$. If we denote by $S^0 = \{\pm 1\}$ the 0th-sphere, the blowing-up of $\Sigma$ is defined by the map

$$\Phi : \mathbb{R} \times (S^0 \times \mathbb{R}_{\geq 0}) \to \mathbb{R}^2 (u, (\pm 1, r)) \mapsto (x = u, y = \pm r).$$

The resulting 1-foliation in $\mathbb{R} \times (S^0 \times \mathbb{R}_{\geq 0})$, given by $\frac{\partial}{\partial u} \mp \frac{\partial}{\partial r}$ is clearly smooth.

**Example 6.** Consider the discontinuous foliation defined by (6). The blowing up of the origin is defined by the polar coordinates map

$$\Phi : S^1 \times \mathbb{R}_{\geq 0} \to \mathbb{R}^2 (\theta, r) \mapsto (x = r \cos(\theta), y = r \sin(\theta))$$

and an easy computation shows that this foliations is mapped to

$$\cos(2\theta) \frac{\partial}{\partial \theta} + r \frac{\partial}{\partial r}$$

which is clearly a $C^\infty$ vector field on $S^1 \times \mathbb{R}_{\geq 0}$.

**Example 7.** Consider the discontinuous foliation defined by (7). This foliation is blow-up smoothable by a sequence of three blowing-ups:

$$\mathbb{R}^3 = M_0 \Phi_1 M_1 \Phi_1 M_2 \Phi_1 M_3$$

with respective centers given by the $z$-axis, the strict transform of the hyperplane $\{x = 0\}$ and the strict transform of hyperplane $\{y = 0\}$.

Notice however that there are discontinuous 1-foliations which are not blow-up smoothable.
Example 8. Consider the discontinuous 1-foliation in $\mathbb{R}^2$ defined as in (8), where we take
\[ f(x, y) = y^2 - e^{-\frac{1}{x^2}} \sin^2 \left(\frac{1}{x}\right) \]
and $X_+ = \partial/\partial y$, $X_- = \partial/\partial x$. The set $\mathbb{R}^2 \setminus f^{-1}(0)$ has an infinite number of open connected components in any neighborhood of the origin, and this property cannot be destroyed by a locally finite sequence of blowing-ups.

![Figure 6. Discontinuous 1-foliation which is not blow-up smoothable.](image)

2.2. Piecewise smooth 1-foliations. A natural problem which arises is to establish conditions which guarantee that a discontinuous 1-foliation is blow-up smoothable. For this, we will introduce a particular class of discontinuous 1-foliations where, roughly speaking, we require that firstly each local vector field which defines such foliations extends smoothly to the discontinuity locus, and secondly that the discontinuity locus is an analytic subset of $M$.

More formally, let $\mathcal{F}$ be a discontinuous 1-foliation defined on a manifold $M$ and with discontinuity locus $\Sigma$. A local multi-generator of $\mathcal{F}$ is a pair $(U, \{X_1, \ldots, X_k\})$ satisfying the following conditions:

1. $U$ is an open set of $M$ and we can write $U \setminus \Sigma$ as a finite disjoint union
   \[ U \setminus \Sigma = U_1 \sqcup \cdots \sqcup U_k \]
   of open sets $U_1, \ldots, U_k$.
2. For each $i = 1, \ldots, k$, $X_i$ is a smooth vector field defined in $U$ and such that
   \[ (U_i, X_i|_{U_i}) \]
   is a local generator of $\mathcal{F}$.

We will say that $\mathcal{F}$ is piecewise smooth if there exists a collection $\mathcal{C}$ of local multi-generators as above whose domain forms an open covering of $\Sigma$ and the following compatibility condition holds: For each two local multi-generators
\[ (U, \{X_1, \ldots, X_k\}), \quad (V, \{Y_1, \ldots, Y_l\}) \]
belonging to $\mathcal{C}$, there exists a strictly positive smooth function $\varphi$ defined in $U \cap V$ such that
\[ X_i = \varphi Y_j \quad \text{on} \quad U_i \cap V_j \]
for each pair of indices $i = 1, \ldots, k$ and $j = 1, \ldots, l$.

Remark 2. In what follows, it will be important to require the transition function $\varphi$ to be the same on all intersections $U_i \cap V_j$. 

Example 9. The Example 1 exhibits a piecewise smooth 1-foliation, since $F$ is defined simply by restricting the constant vector fields

$$X_+ = \frac{\partial}{\partial x} - \frac{\partial}{\partial y} \quad \text{and} \quad X_- = \frac{\partial}{\partial x} + \frac{\partial}{\partial y}$$

to the subsets $U_+ = \{y > 0\}$ and $U_- = \{y < 0\}$, respectively. Similarly, the 1-foliation in Example 3 is piecewise smooth. On the other hand, the discontinuous vector field $X$ in Example 2 is not piecewise smooth. In fact, the vector field $X$ is not smooth at the origin and therefore the foliation cannot be smoothly extended to $\Sigma = \{(0,0)\}$.

A simple consequence of the definition of piecewise smooth 1-foliations is the following:

**Theorem 2.1.** Let $F$ be a piecewise smooth 1-foliation on a manifold $M$ whose discontinuity locus $\Sigma$ is an smooth submanifold of codimension one. Then, $F$ is blow-up smoothable.

*Proof.* We consider the smooth map $\Phi : N \to M$ defined by the blowing-up with center $\Sigma$, and exceptional divisor $D = \Phi^{-1}(\Sigma)$. The smooth foliation $G$ in $N$ is now defined by describing its local generator at each point $q \in N$. We consider separately the case where $q \in N \setminus D$ and $q \in D$. In the former case, we can choose a generator $(U, X)$ of $F$ defined in a sufficiently small neighborhood an of $p = \Phi(q)$ and decree that

$$(V, Y) = (\Phi^{-1}(V), \Phi^*Y)$$

is a local generator of $G$ near $q$. Notice that this construction defines unambiguously the 1-foliation on $N \setminus D$, since it is independent of the choice of $(U, X)$.

Suppose now that $q \in D$, i.e. that $p = \Phi(q)$ lies in $\Sigma$. Then, we can choose local coordinates $(x_1, \ldots, x_{n-1}, y)$ in a neighborhood $U$ of $p$ such that
\[ \Sigma = \{ y = 0 \} \text{ and the blowing-up map assumes the form} \]
\[
(\mathbb{S}^0 \times \mathbb{R}^+) \times \mathbb{R}^{n-1} \longrightarrow \mathbb{R}^n
\]
\[
(\pm 1, r), (u_1, \ldots, u_{n-1}) \mapsto y = \pm r, x_1 = u_1, \ldots, x_{n-1} = u_{n-1}.
\]

Up to reducing \( U \) to some smaller neighborhood of \( p \), we can assume that \( U \setminus \Sigma \) can be written as the disjoint union of connected subsets \( U_+ = \{ y > 0 \}, U_- = \{ y < 0 \} \) and that there exists two smooth vector fields \( X_+, X_- \) defined on \( U \) such that \( (U_+, X_+) \) and \( (U_-, X_-) \) are local generators of \( \mathcal{F} \).

Now, by the expression of the blowing-up map either \( V_+ = \Phi^{-1}(U_+) \) or \( V_- = \Phi^{-1}(U_-) \) is an open neighborhood of \( q \) in \( N \). Therefore, according to the choice of the \( \pm \) sign, we decree that the local vector field \( (V_\pm, \Phi^*X_\pm) \) is a local generator of \( \mathcal{G} \) at \( q \).

This procedure defines in an unambiguous way a smooth 1-foliation \( \mathcal{G} \) on \( N \), which is moreover related to \( \mathcal{F} \) by \( \Phi \).

A natural question which arises is whether the above result can be generalized to the case where \( \Sigma \) is a smooth submanifold of higher codimension.

**Example 10.** Consider the piecewise-smooth 1-foliation on \( \mathbb{R}^3 \) defined by
\[
X = z^k \frac{\partial}{\partial x} + \varphi \left( \frac{yz}{e^{-1/|z|}} \right) \frac{\partial}{\partial y} \quad \text{if } z \neq 0, \quad X = z^k \frac{\partial}{\partial x} + \text{sgn}(y) \frac{\partial}{\partial y} \quad \text{if } z = 0.
\]

where \( \varphi \) is a monotonic transition function as defined in the Introduction and \( k, l \in \mathbb{N} \) are arbitrary positive integers. Notice that \( X \) is smooth outside the discontinuity locus \( \Sigma = \{ y = z = 0 \} \), which is of codimension 2. A blowing up with center the origin will produce (in the \( z \)-directional chart) the same expression with the integer \( l \) replaced by \( l + 1 \). Similarly, a blowing-up with center \( \Sigma \) will produce exactly the same expression with \( k \) and \( l \) replaced by \( k + 1 \) and \( l + 1 \) respectively. Therefore, no sequence of blowing-ups will allow a \( C^\infty \) extension of this vector field to the exceptional divisor.

Our next goal is to obtain a similar result in the case where \( \Sigma \) is a codimension one singular subvariety. For this, we need to impose another regularity condition, which will allow us to use the Theorem of Resolution of Singularities.

We will say that \( \mathcal{F} \) has an analytic discontinuity locus if the ambient space \( M \) is an analytic manifold and the discontinuity locus \( \Sigma \) is a globally defined analytic subset of \( M \). In other words, we assume \( \Sigma = \Sigma(f) \) is the vanishing locus of a finite collection of global analytic functions \( f = (f_1, \ldots, f_m) \) defined on \( M \).

Under the above hypothesis, there exists an unique filtration by semianalytic sets (see [19])

\[
\Sigma^0 \subset \Sigma^1 \subset \cdots \subset \Sigma^d = \Sigma
\]

\[\text{[3]}\]According to [4], Proposition 15, and Grauert’s embedding theorem [8], this is equivalent to say \( \Sigma \) is the vanishing locus of a coherent sheaf of ideals \( I \) defined on \( M \).
where, for each $k = 1, \ldots, d$, the set $\Sigma^k \setminus \Sigma^{k-1}$ is a smooth manifold of dimension $k$. Using this decomposition, we say that $d$ is the dimension of $\Sigma$ and that $\Sigma^{\text{reg}} = \Sigma^d \setminus \Sigma^{d-1}$ is the regular part of $\Sigma$. The complementary set $\Sigma^{\text{exc}} = \Sigma \setminus \Sigma^{\text{reg}}$ is called the exceptional locus.

Remark 3. We observe that, in general, the inclusion $\Sigma^{\text{reg}} \subset \Sigma^{\text{smooth}}$ is strict. For instance, the Whitney umbrella $\Sigma = \{ z^2 - xy^2 = 0 \}$ is such that $\Sigma^{\text{exc}} = \{ y = z = 0 \}$ contains strictly $\Sigma^{\text{sing}} = \{ x \geq 0, y = z = 0 \}$. Taking the complementaries it follows that $\Sigma^{\text{reg}} \subset \Sigma^{\text{smooth}}$.

Under the above assumptions, we can apply the Theorem of Resolution of Singularities for globally defined real analytic sets (see e.g. [1]). As a result, we conclude that there exists a proper analytic map $\Phi : N \to M$, defined by a locally finite sequence of blowing-ups, such that:

1. $\Phi$ is a diffeomorphism outside $\Phi^{-1}(\Sigma^{\text{exc}})$.
2. $D = \Phi^{-1}(\Sigma^{\text{exc}})$ is a locally finite union of boundary components

$$
\bigcup_{i \in I} D_i \subset \partial N
$$

of codimension one.

3. The closure of $\Phi^{-1}(\Sigma^{\text{reg}})$ is a smooth submanifold $\Omega \subset N$.

The next result states that, under the above conditions, the foliation $\mathcal{F}$ pulls-back to a discontinuous foliation in $N$ which has a smooth discontinuity locus.

**Theorem 2.2.** Let $\mathcal{F}$ is a piecewise smooth 1-foliation with analytic discontinuity locus. Then, using the above notation, there is a piecewise smooth
1-foliation \( G \) defined on \( N \), which is related to \( F \) by \( \Phi \), and whose discontinuity locus is \( \Omega \).

Proof. We describe separately the local definition of \( G \) in points lying in \( N \setminus (D \cup \Omega) \), in points lying in \( D \setminus \Omega \), and then in points lying in \( \Omega \). If \( q \in N \setminus (D \cup \Omega) \) then choose a generator \((U,X)\) of \( F \) defined in a sufficiently small neighborhood of \( p = \Phi(q) \) and decree that

\[
(V,Y) = (\Phi^{-1}(V), \Phi^* Y)
\]

is a local generator of \( G \) near \( q \). Notice that this construction defines unambiguously the 1-foliation on \( N \setminus (D \cup \Omega) \), since it is independent of the choice of \((U,X)\).

Let us show now how to extend \( G \) smoothly to \( D \setminus \Omega \). By an induction argument, it suffices to consider the case where \( \Phi : N \to M \) is defined by a single blowing-up with center on an analytic submanifold \( C \subset M \), and such that \( D = \Phi^{-1}(C) \).

Given a point \( q \in D \setminus \Omega \), let \( p = \Phi(q) \) be its image in \( C \). According to the definition of piecewise smooth 1-foliation, choose a local multi-generator \((U,\{X_1,\ldots,X_k\})\) of \( F \) at \( p \). Then, considering the disjoint decomposition (9), there exists precisely one index \( i \in \{1,\ldots,k\} \), say \( i = 1 \), such that \( W = \Phi^{-1}(U_1) \) is an open neighborhood of \( q \).

Up to reducing these neighborhoods, we choose local trivializing coordinates \((y_1,\ldots,y_n)\) at \( W \) and \((x_1,\ldots,x_n)\) at \( U_1 \), respectively, such that \( C = \{x_1 = \cdots = x_d = 0\} \) and \( D = \{y_1 = 0\} \). Further, we can assume that, in these coordinates, the blowing-up map assumes the form

\[
x_1 = y_1, x_2 = y_1 y_2, \ldots, x_d = y_1 y_d, \quad \text{and} \quad x_{d+1} = y_{d+1}, \ldots, x_n = y_n.
\]

From the assumption that \( X_1 \) is non-flat, it follows that the set

\[
E = \{m \in \mathbb{Z} : y_1^m \Phi^* X_1 \text{ extends smoothly to } \{y_1 = 0\}\}
\]

has the form \( m_{\min} + \mathbb{N} \), for some minimal element \( m_{\min} \in \mathbb{Z} \). Indeed, if we expand the vector field \( X_1 \) as \( a_1 \frac{\partial}{\partial x_1} + \cdots + a_n \frac{\partial}{\partial x_n} \), with \( a_i \in C^\infty(U_1) \), then its pull-back under \( \Phi \) has the form \( \Phi^* X_1 = b_1 \frac{\partial}{\partial y_1} + \cdots + b_n \frac{\partial}{\partial y_n} \), where

\[
b_1 = \Phi^*(a_1), b_2 = \Phi^*((a_2 x_1 - a_1 x_2)/x_1^2), \ldots, b_d = \Phi^*((a_d x_1 - a_1 x_d)/x_1^2),
\]

\[
b_{d+1} = \Phi^*(a_{d+1}), \ldots, b_n = \Phi^*(a_n)
\]

In particular, \(-m_{\min}\) is algebraically defined as the minimum of all valuations

\[
\overline{val}_{y_1}(b_1), \ldots, \overline{val}_{y_1}(b_n)
\]

where \( \overline{b} \) denotes the formal series expansion of \( b \in C^\infty(W) \) in powers of the \( y_1 \)-variable, seen as element of the field \( C^\infty(W \cap D)(y_1) \) of formal Laurent series in \( y_1 \) with coefficients smooth functions in \( y_2, \ldots, y_n \) \(^4\). Using this

\(^4\)Notice that this minimum is well-defined by the non-flatness assumption. Furthermore, this shows that \( m_{\min} \) is uniform, i.e. independent of the choice of the point \( q \in W \cap D \).
we define \( Y = y_1^{m_{\min}} \Phi^* X_1 \) and decree that \((W,Y)\) is a local generator of \( \mathcal{G} \) at \( q \).

Let us show that this local definition is independent of the choice of the local multi-generator \((U, \{X_1, \ldots, X_k\})\). For this, suppose that we choose another local multi-generator \((U', \{X'_1, \ldots, X'_k\})\) of \( \mathcal{F} \) at \( p \). Then, up to a reordering of indices and a restriction to some possibly smaller neighborhood of \( p \), we can assume that \( U_1 = U'_1 \) and that

\[
X'_1 = \varphi X_1
\]

for some smooth function \( \varphi \) which is strictly positive in \( U \) (we use here the condition (11) in the definition of a piecewise smooth 1-foliation). Taking the pull-back of this relations through \( \Phi \), one obtains

\[
\Phi^* X'_1 = (\Phi^* \varphi) \Phi^* X_1,
\]

where \( \Phi^* \varphi \) is defined as \( \varphi \circ \Phi \)

which shows that the set \( E \) defined above coincides with the set \( E' = \{ m \in \mathbb{Z} : y_1^{m_{\min}} \Phi^* X'_1 \text{ extends smoothly } \{ y_1 = 0 \} \} \). Consequently,

\[
Y' = y_1^{m_{\min}} \Phi^* X_1 = y_1^{m_{\min}} (\Phi^* \varphi) \Phi^* X'_1 = (\Phi^* \varphi) Y
\]

which shows that the foliation \( \mathcal{G} \) is well defined at \( q \).

\[\Phi\]

\[\Sigma\]

\[\Sigma^{\text{sing}}\]

\[\Omega\]

\[D\]

\[\Phi\]

\[y_1\]

\[\text{Figure 9. Eliminating } \Sigma^{\text{exc}}.\]

It remains to construct a local generator of \( \mathcal{G} \) in each point \( q \in \Omega \). The reasoning is very similar to the previous cases, and is left to the reader.

Let us show that the previous two Theorems can be combined to give a general smoothing procedure which extends Theorem 2.1 to the case where \( \Sigma \) is singular.

**Corollary 2.1.** Under the assumptions of the Theorem 2.2, suppose further that the discontinuity locus of \( \mathcal{F} \) has codimension one. Then, \( \mathcal{F} \) is blow-up smoothable.

\[\text{Notice that this construction is a slight generalization of the blowing-up of local foliated vector fields defined in [5].}\]
3. Regularization and sliding dynamics for piecewise smooth foliations

One disadvantage of the smoothing procedure defined in the previous subsection is that it does not allow to define the so-called sliding dynamics along the discontinuity set.

Our present goal is to define such sliding dynamics as some sort of limit of the dynamics of a nearby smooth 1-foliations. This leads us to introduce the notion of regularization. Later on, we shall see that the blow-up smoothing and the regularization can be combined in a fruitful way.

Let \( F \) be a discontinuous 1-foliation on a manifold \( M \), with discontinuity locus \( \Sigma \). A regularization of \( F \) (with \( p \)-parameters) is a discontinuous 1-foliation \( F_r \) defined in the product manifold \( M \times ((\mathbb{R}^+)^p, 0) \) which satisfies the three following conditions:

1. \( F_r \) is tangent to the fibers of the canonical projection \( \pi : M \times ((\mathbb{R}^+)^p, 0) \to ((\mathbb{R}^+)^p, 0) \)
2. The restriction \( F_r^0 \) of \( F_r \) to the fiber \( \pi^{-1}(0) \) coincides with \( F \),
3. The discontinuity locus \( \Sigma^r \) of \( F_r \) is a subset of \( \Sigma \times \{ \prod_i \varepsilon_i = 0 \} \), where \( (\varepsilon_1, \ldots, \varepsilon_p) \) are the coordinates in \( ((\mathbb{R}^+)^p, 0) \).

The last condition implies that, for each \( \varepsilon \in ((\mathbb{R}^+)^p, 0) \) such that \( \prod_i \varepsilon_i \neq 0 \), the restriction \( F_r^\varepsilon \) of \( F_r \) to the fiber \( \pi^{-1}(\varepsilon) \) is a smooth 1-foliation. Furthermore, by the smoothness assumption,

\[
\lim_{\varepsilon \to 0} F_r^\varepsilon = F_r^0
\]

uniformly (in the \( C^\infty \) topology) on each compact subset of \( M \setminus \Sigma \).

**Example 11.** In [9] section 1.4, Hörmander constructs a regularization by convolution. For simplicity, let us assume that \( F \) is defined in \( \mathbb{R}^n \) by a smooth vector field \( X \) which extends as a locally bounded measurable function to the discontinuity set \( \Sigma \). Given a function \( 0 \leq \chi \in C^\infty_0(\mathbb{R}^n) \) such that \( \int \chi(y)dy = 1 \), we define

\[
X_\varepsilon(x) = \int_{\mathbb{R}^n} X(x - \varepsilon y)\chi(y)dy
\]

Then, it is easy to see that \( X_\varepsilon \) is a smooth vector field for each \( \varepsilon > 0 \) and that the one-parameter family of 1-foliations \( F_\varepsilon \) defined by these vector fields is a regularization of \( F \).

---

\(^{6}\)We use the notation \( ((\mathbb{R}^+)^p, 0) \) to indicate in abridged form some open neighborhood of the origin in \( (\mathbb{R}^+)^p \).

\(^{7}\)More precisely, given a point \( q \in M \setminus \Sigma \), there exists an open neighborhood \( U \) of \( q \) and a \( p \)-parameter family of smooth vector field \( X_\varepsilon \) defined on \( U \times ((\mathbb{R}^+)^p, 0) \) (and depending smoothly on \( \varepsilon \)) such that \( X_\varepsilon \) is a local generator of \( F_\varepsilon|_U \) for each \( \varepsilon \).
One disadvantage of this regularization by convolution is that some important features of the dynamics of $\mathcal{F}$ which appears outside the discontinuity locus can be destroyed by small perturbations, and thus not be seen in $\mathcal{F}_\varepsilon$. For instance, the saddle connection illustrated in figure 10 would be broken by a generic choice of convolution kernel $\chi$ (although it lies outside the discontinuity locus).

![Saddle connection for $X_0$ is broken by the regularization by convolution.](image)

In the next subsection, we will describe two regularization methods which keep $\mathcal{F}$ unchanged outside $O(\varepsilon)$-neighborhoods of the discontinuity set. As such, we expect to see the full dynamics of $\mathcal{F}$ outside $\Sigma$ to be reflected at $\mathcal{F}_\varepsilon$, for each sufficiently small $\varepsilon$.

### 3.1. Sotomayor-Teixeira regularization and its generalizations

Suppose that the discontinuity locus of $\mathcal{F}$ is a smooth submanifold $\Sigma \subset M$ of codimension one and that we fix the following data:

1. A tubular neighborhood map $f: N\Sigma \to M$, which maps the normal bundle $N\Sigma$ diffeomorphically to an open neighborhood $W = f(N\Sigma)$ of $\Sigma$.
2. A smoothly varying metric $|\cdot|$ on the fibers of the bundle $N\Sigma \to \Sigma$ (such that $|p| = 0$ iff $p \in \Sigma$).
3. A monotone transition function $\phi: \mathbb{R} \to [-1, 1]$.

Using the map $f$, we pull-back $\mathcal{F}$ to a discontinuous 1-foliation $\mathcal{G}$ on the normal bundle $N\Sigma$, with discontinuity locus given by the zero section $\Sigma \subset N\Sigma$.

Without loss of generality, we can assume that $N\Sigma$ is covered by local trivialization charts where the bundle map assumes the form

$$V \times \mathbb{R} \to V$$

$$(x, y) \mapsto x$$

for some open set $V \subset \Sigma$, and that $\mathcal{F}$ has a local multi-generator of the form $(V \times \mathbb{R}, \{X_+, X_\mp\})$, where $X_+$ (resp. $X_-$) is a smooth vector field in $V \times \mathbb{R}$ which generate $\mathcal{G}$ on $U_+ = \{y > 0\}$ (resp. $U_- = \{y < 0\}$). Furthermore, we can assume that the norm on the fibers of $N\Sigma$ is simply the absolute value $|y|$ on $\mathbb{R}$.
For each $\varepsilon > 0$, we now define a smooth vector field $X_\varepsilon$ in $V \times \mathbb{R}$ as follows

$$X_\varepsilon \overset{\text{def}}{=} \frac{1}{2} \left( 1 + \phi \left( \frac{y}{\varepsilon} \right) \right) X_+ + \frac{1}{2} \left( 1 - \phi \left( \frac{y}{\varepsilon} \right) \right) X_-$$

Notice that, by construction

$$X_\varepsilon (x, y) = \begin{cases} X_+ (x, y) & \text{if } y \geq \varepsilon, \\ X_- (x, y) & \text{if } y \leq -\varepsilon, \end{cases}$$

Moreover, if we choose another multi-generator of $\mathcal{G}$, say $(V \times \mathbb{R}, \{Y_+, Y_-\})$ then it follows from the condition (11) in the definition of piecewise smooth 1-foliation that $Y_+ = \varphi X_+$ and $Y_- = \varphi X_-$, for some strictly positive smooth function $\varphi$. Therefore, if we define a family $Y_\varepsilon$ exactly as above but replacing $X_\pm$ by $Y_\pm$, we conclude that

$$Y_\varepsilon = \varphi X_\varepsilon, \quad \forall \varepsilon > 0$$

In other words, the $X_\varepsilon$ and $Y_\varepsilon$ define precisely the same smooth 1-foliation in the domain $V \times \mathbb{R}$.

By considering an open covering of $N\Sigma$ by these local trivializations, one defines, for each $\varepsilon > 0$, a smooth foliation $\mathcal{G}_\varepsilon$. By construction, such foliation coincides with the original foliation $\mathcal{G}$ outside the region $\{p \in N\Sigma : |p| < \varepsilon\}$.

The **Sotomayor-Teixeira regularization** of $\mathcal{F}$ is the discontinuous 1-foliation $\mathcal{F}_\varepsilon^r$ defined in the product space $M \times (\mathbb{R}^+, 0)$ as follows: For $\varepsilon = 0$, we let $\mathcal{F}_0^r = \mathcal{F}$. For $\varepsilon > 0$, we define the foliation $\mathcal{F}_\varepsilon^r$ in $M$ by

$$\mathcal{F}_\varepsilon^r = \begin{cases} \mathcal{F} & \text{on } M \setminus W, \\ f_* \mathcal{G}_\varepsilon & \text{on } W \end{cases}$$

It follows from the remark made at the previous paragraph that this defines a globally smooth 1-foliation in $M$. It is easy to verify that the conditions 1.-3. of the definition of a regularization are satisfied.

![Figure 11. The Sotomayor-Teixeira regularization.](image-url)

More generally, under the same assumptions of the previous example, we can define regularization of $\mathcal{F}$ by dropping the assumption of monotonicity and $x$-independence of the transition function. Namely, by replacing the choice of function $\phi$ in item 3. by the choice of a smooth function

$$\psi : \Sigma \times \mathbb{R}_+ \to [-1, 1]$$
such that \( \psi(x, t) = -1 \) if \( t \leq -1 \) and \( \psi(x, t) = 1 \) if \( t \geq 1 \). Correspondingly, we replace the expression of \( X_\epsilon \) given above by

\[
X_\epsilon \overset{\text{def}}{=} \frac{1}{2} \left( 1 + \psi \left( x, \frac{y}{\epsilon} \right) \right) X_+ + \frac{1}{2} \left( 1 - \psi \left( x, \frac{y}{\epsilon} \right) \right) X_-
\]

All the remaining steps in the construction remain the same. The resulting regularization will be called a regularization of transition type.

### 3.2. Double regularization of the cross

Let us show a situation where it is natural to consider a multi-parameter regularization. Consider a discontinuous 1-foliation \( F \) in \( \mathbb{R}^3 \) with discontinuity locus \( \Sigma = \{ xy = 0 \} \) (like in Example 3). In other words, \( F \) is defined by four smooth vector fields \( X_\pm, \pm \), where the first and the second \( \pm \) sign correspond respectively to the sign of the \( x \) and \( y \) coordinates. In other words, each \( X_\pm, \pm \) is a generator of \( F \) in one of the four quadrants \( U_\pm, \pm = \{ (x, y, z) : \text{sgn}(x) = \pm, \text{sgn}(y) = \pm \} \).

Choosing monotone transitions functions \( \phi, \psi \) as above, we consider the two-parameter family of smooth vector fields

\[
Y_{\epsilon, \eta} \overset{\text{def}}{=} \sum_{\alpha, \beta \in \{ +, - \}} \left( 1 + \alpha \phi \left( \frac{x}{\epsilon} \right) \right) \left( 1 + \beta \psi \left( \frac{y}{\eta} \right) \right) X_{\alpha, \beta}
\]
defined for \( \epsilon, \eta > 0 \). Similarly, we define the two one-parameter families of discontinuous vector fields

\[
Z_{\pm, \eta} \overset{\text{def}}{=} \sum_{\beta \in \{ +, - \}} \left( 1 + \beta \psi \left( \frac{y}{\eta} \right) \right) X_{\pm, \beta}
\]

\[
W_{\epsilon, \pm} \overset{\text{def}}{=} \sum_{\alpha \in \{ +, - \}} \left( 1 + \alpha \phi \left( \frac{x}{\epsilon} \right) \right) X_{\alpha, \pm}
\]
declared respectively for \( \eta > 0 \) and \( \epsilon > 0 \). Notice that the discontinuity locus of \( Z_{\pm, \eta} \) and \( W_{\pm, \eta} \) is given respectively by \( \{ x = 0 \} \) and \( \{ y = 0 \} \).

The double-regularization of \( F \) is the discontinuous 1-foliation \( F^\star \) defined in the product space \( \mathbb{R}^3 \times ( (\mathbb{R}^+)^2, 0 ) \) as follows. For each parameter value \( \epsilon, \eta \geq 0 \), the foliation restricted to fiber \( \pi^{-1}(\epsilon, \eta) \) is generated by a discontinuous vector field \( K_{\epsilon, \eta} \) chosen as follows

\[
K_{\epsilon, \eta} = \begin{cases} 
X_{\pm, \pm} & \text{if } \epsilon = 0 \text{ or } \eta = 0, \\
Z_{\pm, \eta} & \text{if } \epsilon = 0 \text{ and } \eta > 0, \\
W_{\epsilon, \pm} & \text{if } \epsilon > 0 \text{ and } \eta = 0, \\
Y_{\epsilon, \eta} & \text{if } \epsilon > 0 \text{ and } \eta > 0.
\end{cases}
\]

More generally, assuming that a discontinuous foliation \( F \) in \( \mathbb{R}^n \) has a discontinuity locus given by the union of \( p \) coordinate hyperplanes, say

\[
\Sigma = \left\{ \prod_{i=1}^{p} x_i = 0 \right\}
\]

we can define \( p \)-parameter regularization of \( F \) by an easy generalization of the above construction.
3.3. Sliding regions. Let $\mathcal{F}$ be a discontinuous 1-foliation defined on a manifold $M$ and with discontinuity locus $\Sigma$. Given a $p$-parameter regularization $\mathcal{F}_r$ of $\mathcal{F}$, our present goal is to define a subset $\text{Slide}(\mathcal{F}_r)$ of $\Sigma$ where it will be reasonable to study a limit dynamics with respect to such given regularization.

Our definition is local. We will say that point $p \in \Sigma$ is a point of sliding for $\mathcal{F}_r$ if there exists an open neighborhood $U \subset M$ of $p$ and a family of smooth manifolds $S_\varepsilon \subset U$ defined for all $\varepsilon \in \left(\mathbb{R}^*, 0\right)$ such that:

1. For each $\varepsilon$, $S_\varepsilon$ is invariant by the restriction of $\mathcal{F}_r^\varepsilon$ to $U$.
2. For each compact subset $K \subset U$, the sequence $S_\varepsilon \cap K$ converges to $\Sigma \cap K$ as $\varepsilon$ goes to zero in some given Hausdorff metric $d_H$ on compact sets of $M$. (8)

The set of sliding points for $\mathcal{F}_r^\varepsilon$ is a relatively open subset of $\Sigma$, which we denote by $\text{Slide}(\mathcal{F}_r^\varepsilon)$.

\(\text{Figure 12. The double regularization and the discontinuity locus}\)
Example 12. Consider the Sotomayor-Teixeira regularization of the discontinuous foliation described in Example 1. Then, an easy computation with the expression of $X_\varepsilon$ defined in the previous subsection (and taking $|y|$ to be the usual absolute value) gives

$$X_\varepsilon = \frac{\partial}{\partial x} - \phi \left( \frac{y}{\varepsilon} \right) \frac{\partial}{\partial y}.$$ 

Let $t_0 \in (-1, 1)$ be the zero of $\phi$ (which is unique by the monotonicity hypothesis on $\phi$). Then, the family of one-dimensional manifolds

$$S_\varepsilon = \{ y = t_0 \varepsilon \}$$

satisfies the above conditions 1. and 2. locally at each point of $\Sigma$. Consequently, $\text{Slide}(\mathcal{F}^r) = \Sigma$.

Example 13. Consider the discontinuous foliation in $\mathbb{R}^2$ defined by the vector field

$$X = \frac{\partial}{\partial x} + \left( (x+1) + \text{sgn}(y)(x-1) \right) \frac{\partial}{\partial y}.$$ 

Then, the Sotomayor-Teixeira regularization is defined by the vector field

$$X_\varepsilon = \frac{\partial}{\partial x} - \left( (x+1) + \phi \left( \frac{y}{\varepsilon} \right) (x-1) \right) \frac{\partial}{\partial y}.$$
Therefore for each $x \in \mathbb{R}$, the coefficient of the $\partial/\partial y$ component of $X_\varepsilon$ vanishes if and only if

$$y = \varepsilon t_x$$

where $t_x$ is a solution of the equation $\phi(t_x) = (x + 1)/(1 - x)$. By the assumptions on $\phi$, this equation has a solution (which is necessarily unique) if and only if $x \leq 0$. As we shall prove in the next section, it follows that $\text{Slide}(\mathcal{F}^r) = \Sigma \cap \{x < 0\}$.

**Example 14.** Let us consider the same discontinuous vector field of the previous Example but now use a different regularization. Namely, we let $\mathcal{F}^r$ be a regularization of transition type, with transition function $\psi$ having a graph as illustrated in the figure below.

![Figure 15. A non-monotone transition function.](image)

As a consequence of the results of the next section, we have $\text{Slide}(\mathcal{F}^r) = \Sigma \cap \{x < \frac{1}{3}\}$ (because $\frac{1/3+1}{1-1/3} = 2$).

**Remark 4.** (Stratified Sliding for analytic discontinuity locus) Assume that the discontinuity locus $\Sigma$ is an analytic subset, of dimension $d$. Then, we can define a more refined notion of sliding by considering different strata of $\Sigma$.

More precisely, using the decomposition $\Sigma^0 \subset \Sigma^1 \subset \cdots \subset \Sigma^d = \Sigma$ defined in (12), we say that point $p \in \Sigma^k \setminus \Sigma^{k-1}$ is a *stratified point of sliding* for $\mathcal{F}^r$ if the conditions 1. and 2. of the above definition holds, when we replace the convergence condition in 2. by

$$d_H(S_\varepsilon \cap K, \Sigma^k \cap K) \to 0$$

as $\varepsilon$ goes to zero. The set of all points $\Sigma^k \setminus \Sigma^{k-1}$ satisfying the above condition is called *sliding region of dimension* $k$, and denoted by $\text{Slide}^k(\mathcal{F}^r)$.

**Example 15.** Let us apply the double regularization described in subsection 3.2 to the discontinuous 1-foliation defined in Example 3. An easy computation shows that the regularized vector field is given by

$$X_{\varepsilon,\eta} = -\phi \left( \frac{x}{\varepsilon} \right) \frac{\partial}{\partial x} - \psi \left( \frac{y}{\eta} \right) \frac{\partial}{\partial y} + \frac{\partial}{\partial z}$$
where \( \phi, \psi \) are monotone transition functions.

\[
\begin{align*}
\phi, \psi & \text{ are monotone transition functions.} \\
\epsilon, \eta > 0 & \text{ respectively, then the one-dimensional curve} \\
S_{\epsilon, \eta} & = \{ x = \epsilon t_0, \ y = \eta u_0 \}
\end{align*}
\]

is invariant by \( X_{\epsilon, \eta} \) and clearly converges to \( \Sigma^1 \) as \( \epsilon, \eta \) converges to zero.

4. Regularizations of transition type: blowing-up and conditions for sliding

Consider the one dimensional stratum \( \Sigma^1 \subset \Sigma \) given by \( \Sigma_1 = \text{axis } z \). We claim that each point of \( \Sigma^1 \) is a stratified point of sliding. Indeed, if we denote by \( t_0, u_0 \in (-1, 1) \) the unique roots of \( \phi(t) = 0 \) and \( \psi(u) = 0 \) respectively, then the one-dimensional curve

\[
S_{\epsilon, \eta} = \{ x = \epsilon t_0, \ y = \eta u_0 \}
\]

is invariant by \( X_{\epsilon, \eta} \) and clearly converges to \( \Sigma^1 \) as \( \epsilon, \eta \) converges to zero.

Theorem 4.1. Let \( \mathcal{F}^r \) be a regularization of transition type of \( \mathcal{F} \). Then, \( \mathcal{F}^r \) is blow-up smoothable.

Proof. We will show that a single blowing-up suffices to obtain a smooth foliation. More precisely, consider the blowing up

\[
\Phi : N \to M \times (\mathbb{R}^+, 0)
\]
with center on $\Sigma$. We claim that there exists a smooth foliation in $G$ in $N$ which is related to $F^r$ by $\Phi$.

To prove this, we use the trivialization of $\Sigma$ given by the local charts $(x, y) \in V \times \mathbb{R}$ described in subsection 3.1 and the expression for $X_\varepsilon$ defined at the end of that subsection. Using these coordinates, the blowing-up map can be written (up to restriction to an appropriate subdomain) as

$$V \times S^1 \times \mathbb{R}^+ \longrightarrow V \times \mathbb{R} \times \mathbb{R}$$

$$x, (\theta, r) \longmapsto x, y = r \sin(\theta), \varepsilon = r \cos(\theta).$$

In order to make the computations easier, it is better to cover the domain in $S^1 \times \mathbb{R}^+$ by three directional charts, with domains $E = \{\theta \neq 0 (\text{mod } \pi \mathbb{Z})\}$ and $F_\pm = \{\theta \neq \pm \pi/2 (\text{mod } 2\pi \mathbb{Z})\}$. In these charts, the blowing-up map assumes respectively the form

$$V \times \mathbb{R} \times \mathbb{R}^+ \longrightarrow V \times \mathbb{R} \times \mathbb{R}$$

$$x, (\bar{y}, \bar{\varepsilon}) \longmapsto x, y = \bar{\varepsilon} \bar{y}, \varepsilon = \bar{\varepsilon},$$

$$V \times \mathbb{R}^+ \times \mathbb{R}^+ \longrightarrow V \times \mathbb{R} \times \mathbb{R}$$

$$x, (\tilde{y}, \tilde{\varepsilon}) \longmapsto x, y = \pm \tilde{y}, \varepsilon = \tilde{\varepsilon}.$$

Let us compute the pull-back of $X_\varepsilon$ in each one of these charts.

In the $E$-chart, we have the following transformation rules for the basis vectors of $T(M \times \mathbb{R})$:

$$\frac{\partial}{\partial x_i} = \frac{\partial}{\partial \bar{x}_i}, \quad \frac{\partial}{\partial y} = \frac{\partial}{\partial \bar{y}}, \quad \frac{\partial}{\partial \varepsilon} = \frac{\partial}{\partial \bar{\varepsilon}} - \frac{\bar{y}}{\bar{\varepsilon}} \frac{\partial}{\partial \bar{y}}.$$

Thus, for instance the vector field $f(x, y, \varepsilon) \frac{\partial}{\partial y}$ is mapped to $\frac{f(x, \bar{y}, \varepsilon)}{\bar{\varepsilon}} \frac{\partial}{\partial \bar{y}}$ and so on. Therefore, using the expression in (14), we obtain

$$\Phi^* X_\varepsilon = \frac{1}{2} \left( 1 + \psi(x, y) \right) \Phi^* X_+ + \frac{1}{2} \left( 1 - \psi(x, y) \right) \Phi^* X_-.$$
Therefore, from the above transformation rules, it is clear that the vector field

$$Y \overset{\text{def}}{=} \bar{\varepsilon} \Phi^* X_{\varepsilon}$$

has a smooth extension to the exceptional divisor \( \{ \bar{\varepsilon} = 0 \} \). We take \( Y \) to be a local generator of \( G \) on this domain.

Similarly, in the \( F_{\pm} \)-chart, we have the following transformation rules

$$\frac{\partial}{\partial x_i} = \frac{\partial}{\partial x_i}, \quad \frac{\partial}{\partial \varepsilon} = \pm \frac{1}{\bar{y}} \frac{\partial}{\partial \bar{\varepsilon}}, \quad \frac{\partial}{\partial y} = \pm \left( \frac{\partial}{\partial \bar{y}} - \bar{\varepsilon} \frac{\partial}{\partial \bar{\varepsilon}} \right).$$

And the pull-back of \( X_{\varepsilon} \) in this chart has the form

$$\Phi^* X_{\varepsilon} = \frac{1}{2} \left( 1 + \psi(x, \pm \frac{1}{\varepsilon}) \right) \Phi^* X_+ + \frac{1}{2} \left( 1 - \psi(x, \pm \frac{1}{\varepsilon}) \right) \Phi^* X_-.$$

Notice that, for all \( 0 < \varepsilon \leq 1 \), one has \( \psi(x, \pm \frac{1}{\varepsilon}) \equiv \pm 1 \) identically, and we can extend this function smoothly to \( \varepsilon = 0 \) as being equal to \( \pm 1 \), according to the domain. Therefore, similarly to the previous case, the vector field

$$Z \overset{\text{def}}{=} \bar{y} \Phi^* X_{\varepsilon}$$

has a smooth extension to the exceptional divisor \( \{ \bar{y} = 0 \} \), and we choose it as a generator of \( G \) on the corresponding domain. This concludes the proof. \( \square \)

Now, we will study the sliding regions. The criterion that we are going to describe needs one additional definition: Using the notation introduced above, the height function of \( \mathcal{F}_\varepsilon \) is the smooth function \( h^\varepsilon \) with domain \((x,t) \in \Sigma \times \mathbb{R} \) defined by

$$h^\varepsilon = \psi \mathcal{L}_{(X_+-X_-)}(y) + \mathcal{L}_{(X_+X_-)}(y)$$

where \( \psi(x,t) \) is the transition function and \( \mathcal{L}_X(f) \) denotes the Lie derivative of a function \( f \) with respect to a vector field \( X \). We remark that the Lie derivative of \( X_+-X_- \) and \( X_+X_- \) needs to be evaluated only at points of \( \Sigma \).

More explicitly, if we write \( X_+ \) and \( X_- \) in terms of the local trivializing coordinates \((x,y)\) described above as

$$X_\pm = a_\pm \frac{\partial}{\partial y} + \sum_{i=1}^{n-1} b_{i,\pm} \frac{\partial}{\partial x_i}$$

(for some smooth functions \( a_\pm \) and \( b_{i,\pm} \)) then the height function is given by

$$h^\varepsilon(x,t) = \psi(x,t) \left( a_+(x,0) - a_-(x,0) \right) + \left( a_+(x,0) + a_-(x,0) \right).$$

Notice that the function \( h^\varepsilon \) is independent of the choice of local coordinates \((x,y)\) and local generators \((X_+,X_-)\) up to multiplication by a strictly positive function. More precisely, if we replace the local generators \((X_+,X_-)\)
by local generators \((Y_+, Y_-)\) such that \(Y_\pm = \varphi X_\pm\) then \(h^r\) is transformed to \(\varphi h^r\).

Based on the height function, we define the following subsets in \(\Sigma \times \mathbb{R}\):

\[
Z^r = \{ h^r(x, t) = 0 \}, \quad W^r = \{ \frac{\partial h^r}{\partial t}(x, t) \neq 0 \}, \quad \text{and} \quad NH^r = Z^r \cap W^r.
\]

The main result of this section can now be stated as follows:

**Theorem 4.2.** Let \(F^r\) be a regularization of transition type of \(F\), defined by a transition function \(\psi\) as above. Then,

\[
\pi(NH^r) \subset \text{Slide}(F^r) \subset \pi(Z^r).
\]

where \(\pi : \Sigma \times \mathbb{R} \to \Sigma\) is the canonical projection.

**Proof.** Let us compute in more details the expression of the blowing-up of \(X_\varepsilon\) in the \(E\) chart described in the proof of Theorem 4.1. If we write the transformed vector field \(Y\) in the form

\[
Y = \alpha \frac{\partial}{\partial y} + \bar{\varepsilon} \sum_{i=1}^{n-1} \beta_i \frac{\partial}{\partial x_i}
\]

then, using the expansions of \(X_+\) and \(X_-\) given in (16), we conclude that, for \(i = 1, \ldots, n - 1\),

\[
\beta_i = \frac{1}{2} \left( \psi(b_{i,+} - b_{i,-}) + (b_{i,+} + b_{i,-}) \right),
\]

and

\[
\alpha = \frac{1}{2} \left( \psi(a_+ - a_-) + (a_+ + a_-) \right)
\]

where \(\psi\) is the transition function evaluated at \((x, t) = (x, \bar{y})\) and all functions \(a_\pm\) and \(b_{i,\pm}\) are computed by replacing the variable \(y\) by \(\bar{\varepsilon}\bar{y}\). Notice that the restriction \(Y|_D\) of \(Y\) to the exceptional divisor \(D = \{ \bar{\varepsilon} = 0 \}\) is simply given by

\[
Y|_D = \frac{1}{2} h^r(x, \bar{y}) \frac{\partial}{\partial \bar{y}}
\]

where \(h^r\) is the height function defined above.

Suppose now that the coordinates \((x, y, \varepsilon)\) are centered in a point \(p \in \Sigma \times \{0\}\) lying in \(\pi(NH^r)\). Then, it follows from the above definition of the sets \(Z^r\) and \(W^r\) that there exists a \(\bar{y}_0 \in \mathbb{R}\) lying in the open interval \((-1, 1)\) such that

\[
h^r(0, \bar{y}_0) = 0, \quad \text{and} \quad \frac{\partial h^r}{\partial \bar{y}}(0, \bar{y}_0) \neq 0.
\]

Looking at the expression of \(Y|_D\) given above, it follows from the implicit function theorem that the point \(q = (0, \bar{y}_0, 0) \in \Phi^{-1}(p)\) lies in a locally defined smooth codimension one submanifold \(H_0\) contained in the divisor \(D = \{ \bar{\varepsilon} = 0 \}\) such that

1. Each point of \(H_0\) is an equilibrium point of \(Y|_D\).
(2) $H_0$ is a normally hyperbolic invariant submanifold of $Y|_D$.

From Fenichel theory [6] it follows that there exists a local smooth manifold $W \subset N$ of codimension one defined near $p$ which is invariant by the flow of $Y$ and such that $W \cap D = H_0$.

Let $S = \Phi(W)$. Then, it follows that, for each sufficiently small $\varepsilon > 0$, the set $S_\varepsilon = S \cap \pi^{-1}(\varepsilon)$ is an invariant submanifold of $\mathcal{F}_\varepsilon$ and $S_\varepsilon$ accumulates on $\Phi(H_0)$ as $\varepsilon$ goes to zero. Therefore, $p \in \text{Slide}(\mathcal{F}^r)$.

**Figure 18.** The normally hyperbolic manifold $H_0$.

We have just proved that $\pi(\text{NH}^r) \subset \text{Slide}(\mathcal{F}^r)$. We postpone the proof of the inclusion $\text{Slide}(\mathcal{F}^r) \subset \pi(\mathcal{Z}^r)$ to the end of this section. □

Let us now describe the behavior of a regularization in the complement of the sliding set. For this, we introduce the so-called sewing region.

Keeping the above notation, we will say that a point $p \in \Sigma$ is a point of sewing for the regularization $\mathcal{F}^r$ if there exists an open neighborhood $U \subset M$ of $p$ and local coordinates $(x,y)$ defined in $U$ such that

1. $\Sigma = \{y = 0\}$ and,
2. For each sufficiently small $\varepsilon > 0$, the vertical vector field $\frac{\partial}{\partial y}$ is a generator of $\mathcal{F}_\varepsilon^r$ in $U$.

We will denote the set of all sewing points by $\text{Sew}(\mathcal{F}^r)$.

**Remark 5.** Notice that the intersection of the regions $\text{Sew}(\mathcal{F}^r)$ and $\text{Slide}(\mathcal{F}^r)$ is empty. Indeed, if $p$ lies in $\text{Sew}(\mathcal{F}^r)$ then in the coordinates $(x,y)$ described above, each smooth manifold $S_\varepsilon$ which is invariant by $\mathcal{F}_\varepsilon^r$ should have necessarily the form

$$S_\varepsilon = \{f_\varepsilon(x) = 0\}$$

for some smooth function $f_\varepsilon$ which is independent of the $y$ variable. In particular, $S_\varepsilon$ cannot tend to the discontinuity locus $\Sigma = \{y = 0\}$ as $\varepsilon$ goes to zero. Therefore $p \notin \text{Slide}(\mathcal{F}^r)$. 

Theorem 4.3. Let $\mathcal{F}^r$ be a regularization of transition type of $\mathcal{F}$, defined by a transition function $\psi$. Then,
\[ \pi(\mathcal{Z}^r)^C \subset \text{Sew}(\mathcal{F}^r) \]
where $\pi(\mathcal{Z}^r)^C$ denotes the complement of $\pi(\mathcal{Z}^r)$ in $\Sigma$.

Proof. Suppose that the coordinates $(x, y, \varepsilon)$ described in the proof of Theorem 4.1 are centered in a point $p \in \Sigma \times \{0\}$ which lies in $\pi(\mathcal{Z}^r)^C$. We claim that there exists a constant $\mu > 0$ and an open neighborhood $U \subset M \times (\mathbb{R}^+, 0)$ of $p$ such that the function
\[ g = \mathcal{L}_{X_\varepsilon}(y) \]
(which is defined only for $\varepsilon > 0$) satisfies $|g| > \mu$ on $U \cap \{\varepsilon > 0\}$. Once we prove this claim, the result is an immediate consequence of the flow-box theorem.

To prove this, we use the following fact: If $f$ and $X$ are respectively a smooth function and vector field defined in an open set $V \subset \mathbb{R}^n$ and $\Psi : W \mapsto V$ is a diffeomorphism from another open set $W$ into $V$, then
\[ (\mathcal{L}_X(f)) \circ \Psi = \mathcal{L}_{\Psi^\star X}(f \circ \Psi). \]
In other words, the Lie derivative operation commutes with the pull-back operation.

We apply this to the vector field $X_\varepsilon$ and to blowing-up map $\Phi$ defined in the proof of the Theorem 4.1. Recall that $\Phi$ is a diffeomorphism outside the exceptional divisor $D$, and therefore by the above identity,
\[ g \circ \Phi = \mathcal{L}_{\Phi^\star X_\varepsilon}(y \circ \Phi). \]
We are going to compute this expression explicitly using the directional charts. Recall that, in $E$ chart, we have
\[ \Phi^\star X_\varepsilon = \frac{1}{\varepsilon} Y \quad \text{and} \quad y \circ \Phi = \tilde{\varepsilon} \tilde{y} \]
where $Y$ is the vector field in (15). Using the basic properties of the Lie derivative, we get

$$g \circ \Phi = \mathcal{L}_Y(\bar{\varepsilon}\bar{y})$$

$$= \frac{1}{\bar{\varepsilon}} \mathcal{L}_Y(\bar{\varepsilon}\bar{y}) \quad \text{(because $\mathcal{L}_fX(g) = f\mathcal{L}_X(g)$)}$$

$$= \frac{1}{\bar{\varepsilon}} (\bar{\varepsilon}\mathcal{L}_Y(\bar{y}) + \bar{y}\mathcal{L}_Y(\bar{\varepsilon})) \quad \text{(by Leibniz’s rule)}$$

$$= \mathcal{L}_Y(\bar{y}) \quad \text{(because $\mathcal{L}_Y(\bar{\varepsilon}) = 0$).}$$

Now, using the expression of $Y$ given in (17), we obtain

$$\mathcal{L}_Y(\bar{y}) = \frac{1}{2}(\psi(x,\bar{y})(a_+ - a_-) + a_+ + a_-).$$

where $a_+$ and $a_-$ are computed by replacing $x,y$ by $x,\bar{\varepsilon}\bar{y}$, respectively.

By restricting this expression to the divisor $D = \{\bar{\varepsilon} = 0\}$ and using the expression (18), we easily see that $|g \circ \Phi| > \mu$ for some $\mu > 0$, uniformly in sufficiently small neighborhood $U_1$ of $\Phi^{-1}(p)$ in the domain of the $E$-chart.

![Figure 20. The regions $U_1$ and $U_2$.](image)

Let us now compute $g \circ \Phi$ in the $F_{\pm}$ chart. Analogous computations gives

$$g \circ \Phi = \frac{1}{\bar{y}} \mathcal{L}_Z(\bar{y}).$$

On the other hand, a simple application of the transformation rules described in the proof of Theorem 4.1 shows that

$$\mathcal{L}_Z(\bar{y}) = \pm \frac{\bar{y}}{2}(\psi(x,\frac{1}{\bar{\varepsilon}})(a_+ - a_-) + a_+ + a_-)$$

where $a_+$ and $a_-$ are now computed by replacing $x,y$ by $x,\pm\bar{y}$, respectively.

Again, by restricting this expression to the divisor $D = \{\bar{y} = 0\}$ it is easy to see that $|g \circ \Phi| > \mu$ uniformly in a sufficiently small neighborhood $U_2$ of $\Phi^{-1}(p)$ in the domain of the $F_{\pm}$-chart.

Since the domains of the $E$ and $F_{\pm}$ charts covers an entire neighborhood of $\Phi^{-1}(p)$ in the blowed-up space, it follows that $U_1 \cup U_2$ is a neighborhood of $\Phi^{-1}(p)$ in which $|g \circ \Phi| > \mu$. Hence the inequality $|g| > \mu$ holds in the neighborhood $U = \Phi(U_1 \cup U_2)$ of $p$. This concludes the proof of Theorem 4.3. □
We are now ready to conclude the proof of Theorem 4.2.

Proof. (end of proof of Theorem 4.2) It remains to prove that $\text{Slide}(\mathcal{F}^r) \subset \pi(Z^r)$. From the Remark 5, we know that $\text{Slide}(\mathcal{F}^r) \cap \text{Sew}(\mathcal{F}^r) = \emptyset$. Combining with the result of the above Theorem, we conclude that $\text{Slide}(\mathcal{F}^r) \cap \pi(Z^r)^C = \emptyset$. This concludes the proof. \qed

Remark 6. Recall that in the case of the Sotomayor-Teixeira regularization we require the transition function $\psi$ to be strictly monotone in the interval $(-1, 1)$. In this case, the set $\pi(Z^r)$ can be alternatively described by the condition

$$a_+ \cdot a_- \leq 0$$

In other words, we recover the usual sliding condition of Filippov. Correspondingly, in this case $\pi(Z^r)^C$ is defined by

$$a_+ \cdot a_- > 0$$

which corresponds to the Fillipov’s sewing condition.

Remark 7. Notice that in the limit dynamics defined in the sliding region can be highly dependent on the choice of the transition function used in the regularization. To illustrate this, consider the following simple example. Let $\mathcal{F}$ be the discontinuous 1-foliation in $\mathbb{R}^2$ defined by the vector field

$$X = (x^2 + y) \frac{\partial}{\partial x} - \text{sgn}(y) \frac{\partial}{\partial y}$$

with discontinuity locus $\Sigma = \{y = 0\}$. Given a monotone transition function $\phi$, the Sotomayor-Teixeira regularization $\mathcal{F}^r$ is defined by the vector field

$$X_\varepsilon = (x^2 + y) \frac{\partial}{\partial x} - \phi(y) \varepsilon \frac{\partial}{\partial y}$$

and it is easy to see that the sliding region coincides with $\Sigma$. Explicitly, if $t_0 \in (-1, 1)$ denotes the unique zero of the transition function $\phi$ then the curve $S_\varepsilon = \{y = t_0 \varepsilon\}$ is invariant by the flow of $X_\varepsilon$, for each $\varepsilon > 0$. Notice that the flow of $X_\varepsilon$ restricted to $S_\varepsilon$ is defined by the one-dimensional vector field

$$(x^2 + t_0 \varepsilon) \frac{\partial}{\partial x}.$$ 

In particular, we have three completely distinct topological behaviors depending on the sign of $t_0$.
