SUMMARY

Dynamic processes such as fusion, fission, and trafficking are important in the regulation of cellular organelles, with an abundant literature focused on mitochondria. Mitochondrial dynamics not only help shape its network within cells but also are involved in the modulation of respiration and integrity. Disruptions of mitochondrial dynamics are associated with neurodegenerative disorders. Although proteins that directly bind mitochondria to promote membrane fusion/fission have been studied intensively, machineries that regulate dynamic mitochondrial processes remain to be explored. We have identified an interaction between the mitochondrial fission GTPase Dnm1/DRP1 and the actin-regulatory protein Srv2/CAP at mitochondria. Deletion of Srv2 causes elongated-hyperfused mitochondria and reduces the reserved respiration capacity in yeast cells. Our results further demonstrate that the irregular network morphology in Δsrv2 cells derives from disrupted actin assembly at mitochondria. We suggest that Srv2 functions as a pro-fission factor in shaping mitochondrial dynamics and regulating activity through its actin-regulatory effects.

INTRODUCTION

Mitochondria are critical organelles in eukaryotes. Among their known functions, the most significant is to produce energy for cells. Eukaryotic cells preferentially utilize mitochondria to produce ATP through oxidative phosphorylation, with oxygen as the final acceptor of electrons. In addition to its distinctive double membrane and undulating cristae structure, network dynamics also distinguish mitochondria from other organelles. The mitochondrial network is generated through continuous fusion, fission, trafficking, and anchoring. These complementary processes not only shape the network morphology but also aid in maintaining mitochondrial homeostasis and integrity. For instance, the fusion of mitochondria ameliorates functional defects and protects mitochondria from autophagic degradation during starvation (Gomes et al., 2011; Blackstone and Chang, 2011), and fission is critical for mitochondrial positioning and mitophagy (Youle and van der Bliek, 2012; Burman et al., 2017; Böckler et al., 2017).

Disruption of mitochondrial dynamics is correlated with mitochondrial disintegration. Neurons and muscle cells that require ATP for proper function are often prominently affected if mitochondrial function cannot be maintained. Models of Alzheimer, Parkinson, and Huntington diseases exhibit disrupted mitochondrial dynamics and irregular network morphology, prefiguring the importance of well-regulated mitochondrial dynamics (Cho et al., 2009; Shirendeb et al., 2012; Narendra et al., 2009).

Mitochondrial fusion and fission are evolutionarily conserved processes (Westermann, 2010), and large dynamin-related GTPases are required to drive both membrane fusion (MFN1/2 and OPA1) and fission (DRP1) in eukaryotes. In budding yeast, Fzo1 (yeast orthologue of mammalian mitofusins MFN1/2), Ugo1, and Mgm1 (yeast orthologue of OPA1) facilitate mitochondrial outer membrane fusion and inner membrane fusion cooperatively (Wong et al., 2000; Sesaki and Jensen, 2001; Hermann et al., 1998). Cytosolic Dnm1 (yeast orthologue of mammalian DRP1) is recruited to sites of mitochondrial fission by Fis1, Caf4, and Mdv1 to form a distinctive constriction ring (Griffin et al., 2005; Legesse-Miller et al., 2003; Chang and Blackstone, 2007). In addition to these proteins, the endoplasmic reticulum-mitochondria encounter structure (ERMES) is involved in the mitochondrial constriction process; the ER wraps around mitochondria at activated fission sites to facilitate mitochondrial division (Friedman et al., 2011). It appears

that not all Dnm1 foci on mitochondria are activated fission sites, and more information is needed to clarify the differences between inactive and active Dnm1 foci.

Mitochondrial transport in Saccharomyces cerevisiae is highly dependent on actin filaments (Hermann et al., 1998; Huckaba et al., 2004; Fehrenbacher et al., 2004). A genetic screen for the essential genes involved in mitochondrial morphogenesis identified multiple actin cytoskeleton-associated proteins (Altmann and Westermann, 2005). In mammalian cells, actin filaments also play a role in ER-mitochondria contact-mediated fission; the dynamic assembly and disassembly of actin is critical for regulating mitochondrial fission (Hatch et al., 2014, 2016; Ji et al., 2015; Gurel et al., 2015; Li et al., 2015; Moore et al., 2016). However, detailed mechanisms of how actin is involved in mitochondrial dynamics remain unclear.

Evidence suggests that unidentified factors of mitochondrial dynamics still exist (Koch et al., 2004; Legesse-Miller et al., 2003). For instance, mitochondrial network morphology upon double deletion of the fusion protein Fzo1 and fission protein Dnm1 is similar to that of wild-type yeast, although double deletions still affect mitochondrial inheritance and cell survival rate (Böckler et al., 2017). In mammalian cells, mitochondrial constriction also requires multiple steps mediated by both DRP1 and classical dynamin-2 (Lee et al., 2016). These results indicate that more factors regulating mitochondrial fusion, fission, or both remain to be identified.

In this study, we report that Srv2/CAP interacts with the mitochondrial fission protein Dnm1/DRP1 and functions as a pro-fission factor. Srv2 was initially identified as a factor involved in cAMP/PKA signaling and actin assembly; it binds monomeric actin to sequester available G-actin (Freeman et al., 1995; Vojtek et al., 1991; Gerst et al., 1991). We found that Srv2 deletion causes the mitochondrial network to become hyperfused, likely reflecting its function in regulating actin filament assembly. In addition, the irregularly hyperfused mitochondrial network in Δsrv2 cells is associated with lower reserve respiration capacity. Our finding that Srv2 functions as a pro-fission factor strengthens the argument for involvement of actin in mitochondrial fission and provides insight into the relationship between mitochondrial activity and network morphology.

RESULTS

Srv2/CAP Interacts with Dnm1/DRP1 at Mitochondria in Cells

To identify factors involved in mitochondrial dynamics, we performed yeast two-hybrid screening to search for potential factors that interact with the human mitochondrial fission protein DRP1 (splice variant 1, residues 1–736; Figure S1). Other than DRP1 itself, which is known to self-associate (Zhu et al., 2004), the only specific interactor identified was CAP2 (cyclase-associated protein 2). There are two CAP genes, CAP1 and CAP2, in mammalian cells. These two proteins have subtle differences in sequences along with different distributions (Peche et al., 2007). Based on phylogenetic analyses (Dereeper et al., 2010; Chevenet et al., 2006; Edgar, 2004; Guindon and Gascuel, 2003; Castresana, 2000), S. cerevisiae has only a single CAP orthologue, Srv2 (Figure 1A). Srv2 was originally identified as a protein required for RAS-activated adenylate cyclase activity and regulation of cAMP levels in yeast (Fedor-Chaiken et al., 1990). More recent studies have demonstrated that Srv2 binds actin and is required for normal actin turnover and organization (Chaudhry et al., 2010, 2014; Mattila et al., 2004; Balcerek et al., 2003). Both cAMP signaling and the actin cytoskeleton have previously been identified to play important roles in mitochondrial dynamics (Li et al., 2015; Chang and Blackstone, 2007). Since a single CAP ortholog in yeast (Srv2) facilitates functional studies, we decided to investigate the role of CAP/Srv2 in mitochondrial dynamics and function in S. cerevisiae first.

We performed co-precipitation studies to confirm the interaction between Srv2 and Dnm1 in yeast. C-terminal Srv2 was conjugated with Tandem Affinity Purification tag (TAP-tag) in a Dnm1-HA yeast strain (Ghaemmaghami et al., 2003). Using calmodulin-affinity resin to precipitate Srv2-TAP, we demonstrated that Dnm1 co-precipitates with Srv2 (Figure 1B). The Srv2/Dnm1 co-precipitation was not seen in the Dnm1-HA only strain. In addition, we applied split-GFP-based bimolecular fluorescence complementation (BiFC) (Skarp et al., 2008) to examine the spatial and temporal interaction of Srv2 and Dnm1 in vivo. Dnm1-GFP 1–10 and Srv2-GFP 11 were expressed in yeast cells, and upon complementation we detected that more than 50% of cells contain reconstituted GFP puncta on mitochondria (Figure 1C). When we used either N- or C-terminal fragments instead of full-length Srv2 in BiFC experiments, C-terminal
Srv2 demonstrated complementary fluorescence puncta at mitochondria in cells (Figure S2). The co-precipitation and BiFC results indicate that Srv2 and Dnm1 interact with one another on mitochondria in living cells.

SRV2 Deletion Causes a Hyperfused Mitochondrial Network

To elucidate the functional role of Srv2 in mitochondrial dynamics, we used direct gene replacement to construct an SRV2 deletion strain using the KanMX cassette (Figure 2A). Mitochondrial network morphology was used as an indicator for the status of mitochondrial dynamics. The mitochondrial network was labeled using mtGFP (Westermann and Neupert, 2000), and its morphology was classified into tubular, fragmented, and elongated-hyperfused categories by blinded observers. We found that 58% of Δsrv2 cells exhibited an elongated-hyperfused mitochondrial network. In addition, these elongated-hyperfused mitochondria in Δsrv2 cells had more branches as compared with the elongated mitochondria in fission-defect Δdnm1 cells. By contrast, <10% of wild-type cells had elongated-hyperfused mitochondria (Figure 2B). To verify that the elongated-hyperfused mitochondrial phenotype was due to SRV2 deletion, we examined mitochondrial morphology in an ectopic Srv2-expressing strain derived from the Δsrv2 strain. Ectopically-expressed Srv2 efficiently complemented the phenotype of the Δsrv2 deletion, and the ratio of cells with elongated-hyperfused mitochondria in cells ectopically expressing Srv2 approximated that of wild-type cells (Figures 2A and 2B). Next, we constructed a galactose-inducible Srv2 overexpression strain; the ratio of inducible Δsrv2 cells with elongated-hyperfused mitochondria was close to that of Δsrv2 cells in repressive dextrose medium. When yeasts were switched to galactose medium to induce Srv2 overexpression, the ratio of cells with elongated-hyperfused mitochondria was similar to that of the endogenously expressing cells (Figure 2C). Overexpression of Srv2 did not have any additional effects on mitochondrial structure or distribution. Together, these results demonstrate that the balance of mitochondrial fusion and fission in Δsrv2 cells is shifted toward excess fusion, resulting in elongated-hyperfused mitochondria. Thus, data from SRV2 deletion and galactose-induced overexpression of SRV2 suggest that Srv2 is a pro-fission factor in yeast cells, particularly when combined with the data showing a direct interaction between Srv2 and Dnm1.
To clarify further the role of well-known mitochondrial fusion/fission factors in generating the hyperfused mitochondrial phenotype in **Δsrv2** cells, we examined mitochondrial network morphology in several double-deletion yeast strains, **Δsrv2 Δdnm1** and **Δsrv2 Δfzo1**. Removal of the SRV2 gene in combination with the mitochondrial fission factor DNM1 or fusion factor FZO1 did not reveal synergic effects (Figure 2D); mitochondrial network morphology in double-deletion strains remained elongated-hyperfused in **Δsrv2 Δdnm1** cells and fragmented in **Δsrv2 Δfzo1** cells. Collectively, the mitochondrial morphologies in single- and double-deletion strains indicate that these conventional fusion/fission GTPases are decisive factors in generating mitochondrial morphology in **Δsrv2** cells.

**Dnm1 Localization Is Not Affected by SRV2 Deletion**

Dnm1 is a cytosolic protein recruited to fission sites on mitochondria to form a fission complex, constricting mitochondria and driving their fission (Kuravi et al., 2006; Griffin et al., 2005; Mozdy et al., 2000). The BiFC assay already demonstrated that Srv2 and Dnm1 interact with one another on mitochondria. To explore the possibility that deletion of SRV2 affects translocation of Dnm1 to mitochondria and reduces fission complex formation, we examined protein levels of Dnm1 in the mitochondrial fraction. Dnm1 protein levels in mitochondrial fractions isolated from both wild-type and **Δsrv2** cells were similar, although a slightly lower
molecular weight form of Dnm1 was more notable in the ∆srv2 cells (Figure 3A). We labeled mitochondria and Dnm1 with different fluorescence proteins, and the localization of Dnm1 foci at mitochondria was assayed using Mander’s colocalization coefficient method (Li et al., 2015; Dunn et al., 2011). We found that SRV2 deletion did not affect the colocalization of Dnm1 and mitochondria. On the other hand, FIS1 deletion dramatically decreased the localization of DNM1 puncta to mitochondria (Figure 3B). Thus, it is unlikely that Srv2 depletion affects Dnm1 recruitment to mitochondria.

Srv2 Function in Actin Dynamics Is Required for Shaping Mitochondria
Since Dnm1 levels and foci numbers at mitochondria are not affected by SRV2 deletion, it seemed more likely that the elongated-hyperfused mitochondrial phenotype in ∆srv2 cells emanated from loss of a specific Srv2 function. The N-terminal domain of Srv2 has been reported to be involved in cAMP/PKA signaling, and the C-terminal domain is involved in regulating actin dynamics. Overexpression of N-terminal and C-terminal Srv2 fragments can complement cAMP/PKA signaling and rescue defects in actin dynamics in ∆srv2 cells, respectively (Chaudhry et al., 2010, 2013; Mattila et al., 2004; Balcer et al., 2003; Fedor-Chaiken et al., 1990). Overexpression of N- or C-terminal Srv2 fragments in ∆srv2 cells was then used to examine which half of Srv2 could reverse the elongated-hyperfused phenotype and restore mitochondria to a more typical tubular morphology (Figure 4A). Overexpression of C-terminal Srv2 caused 36.67% cells to have elongated-hyperfused mitochondria. However, 57.67% of cells with empty vector and 60.33% of cells with overexpressed N-terminal Srv2 contained elongated-hyperfused mitochondria with the ∆srv2 background. The results demonstrated that overexpression of C-terminal Srv2 has the ability to rescue the mitochondrial phenotype in ∆srv2 cells (Figure 4B). These data also suggest that the function of Srv2 in actin assembly is important for mitochondrial dynamic processes.

To examine further the role of actin assembly in mitochondrial network shape, we overexpressed yeast profilin (Pfy1), an actin monomer-binding protein that is critical for actin organization, in ∆srv2 cells (Yoshida et al., 2013; Sagot et al., 2002; Haarer et al., 1990). Pfy1 overexpression compensates for defects of actin dynamics (Magdolen et al., 1993; Vojtek et al., 1991). When Pfy1 was expressed in ∆srv2 cells, 36.67% of cells contained elongated-hyperfused mitochondria. This number was reduced to a level similar to those cells overexpressing the C-terminal fragment of Srv2 (Figure 4B). Based on the complementation results of yeasts overexpressing the C-terminal domain of Srv2 and full-length Pfy1, Srv2-mediated mitochondrial dynamics appears closely associated with its role in regulating actin dynamics.

Disrupted Srv2-Mediated Actin Dynamics Cause Morphological Changes in the Mitochondrial Network
Two SRV2 mutant alleles, srv2-91 and srv2-98, cause actin severing and actin recycling defects, respectively (Chaudhry et al., 2010, 2013). To clarify how Srv2 affects mitochondrial dynamics through its
role in regulating actin dynamics, we examined mitochondrial network morphology in yeast strains harboring the srv2-91 and srv2-98 mutant alleles (Figure 5A). The ratio of cells with an elongated-hyperfused mitochondrial network in both strains (37.00% and 26.67%, respectively) was significantly higher than the 11.33% in wild-type yeast cells (Figure 5B). Another mutant allele, srv2-189 (Figure 5A), harbors mutant properties of both srv2-91 and srv2-98, and 63.00% of srv2-189 cells contained...
elongated-hyperfused mitochondria. This ratio in **srv2-189** was very similar to that of the \( D_{srv2} \) strain (Figure 5B).

Our results thus far suggest that actin-related functions of Srv2 are critical for its modulation of mitochondrial dynamics. To clarify the role of actin in regulating mitochondrial fusion and fission, we treated wild-type yeast with latrunculin A, a compound that sequesters G-actin and inhibits actin polymerization. We found mitochondria network morphology has dose-dependent alteration in response to latrunculin A. Low dosage of latrunculin A treatment caused hyperfused mitochondrial network, whereas high dosage caused fragmented mitochondria. Treatment of cells with 0.5 \( \mu M \) latrunculin A caused three phenotypes—isotropic growth, fewer actin cables, and hyperfused mitochondria—all of which are reminiscent of \( \Delta_{srv2} \) phenotypes (Figure 5C). To our surprise, both co-precipitation and BiFC results demonstrated that the Srv2/Dnm1 interaction was not affected, whereas actin polymerization was inhibited under the

(B) Effects of \( srv2 \) mutant alleles on mitochondrial network morphology and F-actin assembly were examined using fluorescence microscopy. Ratios of cells with hyperfused mitochondria in \( SRV2 \), \( svr2-91 \), \( svr2-98 \), and \( svr2-198 \) strains were 10.33%, 37%, 26.67%, and 63.00%, respectively. **\( p < 0.001 \) vs. \( SRV2 \) cells.

(C) Analyses of mitochondrial morphology and F-actin in wild-type (WT) cells treated with latrunculin A along with mutant stains of \( \Delta_{tpm1} \), \( \Delta_{abp1} \), and \( \Delta_{sla1} \) cells were used to verify the effects of F-actin assembly on mitochondrial dynamics. Mitochondrial morphologies for each strain or condition were analyzed from three independent counts of 100 yeast cells. **\( p < 0.001 \) vs. dimethylsulfoxide-treated cells or WT cells. Mean values ±SE were obtained by averaging the percentages of three independent counts. Scale bars represent 5 \( \mu m \).
same latrunculin A treatment condition (Figure S3). Thus, our data demonstrate that actin filament/cable assembly at mitochondria is important for maintaining mitochondrial dynamics in yeast cells.

We next constructed a tropomyosin (TPM1) deletion strain; Tpm1 is a protein that binds to and stabilizes actin cables and filaments (Liu and Bretscher, 1989). In the Δtpm1 strain, we found that 56.67% cells exhibited an elongated-hyperfused mitochondrial network (Figure 5C). However, deletion of two cortical actin-binding proteins, ABP1 (Actin Binding Protein) and SLA1 (Synthetic Lethal with ABP1), did not cause elongated-hyperfused mitochondria (Figure 5C). Both Abp1 and Sla1 are important for actin patch formation. We examined actin cable in these mutant strains by phalloidin staining (Figure 5) and quantified actin cable numbers based on previous studies (Alioto et al., 2016; Higuchi-Sanabria et al., 2016). The Δtpm1 strain has almost no visible actin cables, whereas Δsrv2 and srv2-189 strains have similar actin cable counts that are lower than those of srv2-91 and srv2-98 strains. Both Δabp1 and Δsla1 strains demonstrated minor reduction of actin cable counts compared with wild-type cells (Figure S4). These results from genetic deletion strains, along with data from latrunculin A-treated cells and the Δsrv2 cells, demonstrate that Srv2-mediated actin filament/cable assembly rather than patch formation is more important for maintaining the balance of mitochondrial dynamics.

We also examined the effects of CAP2 deletion on mitochondria in SH-SY5Y cells. Applying CRISPR/Cas9 to delete both alleles of CAP2, we found that a majority of CAP2−/− cells bear a hyperfused mitochondrial network (Figure S5). The CAP2 knockout cells demonstrated that Srv2/CAP2 is important for mitochondrial fission in both mammalian and yeast cells.

**Deletion of SRV2 Affects Mitochondrial Activity**

Changes in mitochondrial dynamics are closely associated with adjustments in mitochondrial activity. For instance, Parkin/Pink1 respond to a reduced mitochondrial membrane potential to promote mitochondrial fission (Jin and Youle, 2012; Narendra et al., 2010), and elongation of mitochondria helps to preserve their membrane potential during nutrient starvation (Blackstone and Chang, 2011; Gomes et al., 2011). As SRV2 deletion causes elongation and hyperfusion of the mitochondrial network, it is plausible that mitochondrial activity would not be the same as that of wild-type cells. A high-resolution respirometer (Oroboros Oxygraph 2K) was used to examine the oxygen consumption rate, elucidating the mitochondrial reserve respiration capacity. We treated cells with compounds that inhibit oxidative phosphorylation at different stages of electron transport: triethyltin bromide (TET) to inhibit ATP synthase, carbonyl cyanide-4-(trifluoromethoxy)phenylhydrazone (FCCP) to increase proton permeability across the mitochondrial inner membrane, and antimycin to inhibit complex III. Oxygen consumption under the stress induced by these pharmacological agents was recorded throughout the procedure. Oxygen consumption rates during each step of the chemical treatments were normalized to flux control factor values to elucidate the reserve respiration capacity (Figure S6). Our results demonstrate that Δsrv2 and srv2-189 cells have a lower reserve respiration capacity as compared with wild-type and Δdnm1 cells (Figure 6A).

Owing to catabolite repression in the presence of dextrose, mitochondrial activity would be de-repressed when yeast cells switch to a non-dextrose medium (Gancedo, 1998). To verify further the reserve respiration capacity results, we examined the routine oxygen consumption rate of wild-type, Δdnm1, Δsrv2, and srv2-189 cells in both dextrose and non-dextrose (raffinose) medium (Figure 6B). All four strains had higher oxygen consumption rates in raffinose than dextrose. We then examined the mitochondrial membrane potential in both dextrose and raffinose media, applying DiOC6 to detect the mitochondrial membrane potential using flow cytometry. Cells cultured in raffinose had a higher membrane potential than those cultured in dextrose (Figure 6C). An intriguing finding was that raffinose-related increases in the levels of oxygen consumption and membrane potential in both Δsrv2 and srv2-189 strains were lower than in wild-type and Δdnm1 cells (Figures 6B and 6C). These membrane potential and oxygen consumption rate results are consistent with the reserve respiration capacity results. Together, these data demonstrate that Srv2 defects not only change the mitochondrial network morphology but also impact mitochondrial activity, especially the reserve respiration capacity.

**DISCUSSION**

SRV2 deletion and mutant alleles cause elongated-hyperfused mitochondria, and this phenotype can be reverted by the overexpression not only of Srv2 but also of Pfy1, indicating that Srv2 modulates...
mitochondrial dynamics through its function in actin assembly. Deletion of SRV2 not only changed the network morphology of mitochondria but also affected mitochondrial activity; Δsrv2 cells with hyperfused mitochondria have a lower spare respiration capacity when compared with wild-type cells. Furthermore, Δsrv2 cells are unable to increase oxygen consumption and mitochondrial membrane potential as much as wild-type cells when cultured in non-dextrose medium. Based on these findings, we propose that Srv2 serves as a dual-function modulator of both mitochondrial dynamics and activity.

Srv2 was previously known to regulate actin recycling and severing. Both polarized actin cable assembly and patch formation are the major regulatory functions of Srv2/CAP (Toshima et al., 2016). Our results of SRV2 deletion and mutant alleles bring the regulatory mechanisms of mitochondria and actin dynamics together. The yeast two-hybrid, co-precipitation and BiFC results demonstrated the interaction between Dnm1 and Srv2. The interaction was even preserved under the condition when actin cable assembly was inhibited by latrunculin A. However, deletion of SRV2 did not affect Dnm1 localized to mitochondria. This result ruled out the possibility that Srv2 involves in mitochondria dynamics by affecting Dnm1 recruitment to mitochondria.

Over-expressed C-terminal Srv2 and the Pfy1-compensated SRV2 deletion phenotypes demonstrated the involvement of actin in the formation of hyperfused mitochondria in Δsrv2 cells. Mutant alleles that caused...
minor reduction of actin cable numbers (srv2-91 and srv2-98) led to lower ratio of cells with hyperfused mitochondria than the one caused severe reduction of actin cable numbers (srv2-189). These disrupted actin cable counts in mutant cells along with latrunculin A treatment and TPM1 deletion resulted in hyperfused mitochondria in wild-type cells, suggesting that actin cable formation plays a critical role in mitochondrial dynamics in yeast cells. This notion was further supported by the fact that the hyperfused-elongated mitochondrial network morphology was not seen in Δabp1 or Δsla1 strains that bear actin patch formation defects. However, mitochondrial network morphology in double-deletion strains is elongated-hyperfused in Δsrv2 Δdnm1 cells and fragmented in Δsrv2 Δfzo1 cells. These phenotypes of double-mutant strains suggested that actin cable plays different roles in mitochondrial fusion and fission processes and that Srv2 may be responsible for the differences. The Dnm1/Srv2 interaction may facilitate actin cable assembly on mitochondria. Loss of Srv2 may not only affect actin assembly but also lead to loss of the interaction between mitochondria and actin. Mitochondrial dynamics and activity would be affected either by their interaction with actin cable or when actin assembly at mitochondria is disrupted. We favor a model in which Srv2 mediates mitochondrial dynamics through its function in promoting actin polymerization and stabilizing actin filaments in conjunction with its ability to interact with the fission protein Dnm1 (Figure 7). Potentially, disrupted actin/ mitochondria interaction under SRV2 deletion causes either mitochondrial transporting defect or incomplete mitochondrial division. We still have not collected enough results to distinguish between the two possibilities.

Both SRV2 and DNM1 deletion yeasts possess hyperfused mitochondria with less reserve respiration capacity compared with wild-type cells. The reserve respiration capacity results are in agreement with the mitochondrial membrane potentials measured under conditions without catabolite repression (Figure 6). These data strongly suggest that well-maintained mitochondrial dynamics are required for the proper function of oxidative phosphorylation complexes.

Unexpectedly, the reserve respiration capacities were different in the Δsrv2 and Δdnm1 strains, although both strains contained an elongated-hyperfused mitochondrial network. Even so, we found that the morphology of the mitochondrial network was different between Δsrv2 cells and Δdnm1 cells. The
mitochondria in Δsrv2 cells formed an elongated and branched network, whereas in Δdnm1 cells the mesh form of hyperfused mitochondria dominated. The different network morphologies indicate that unidentified factors are involved in the dynamic balance in these strains. A previous study suggested that the machinery of mitochondrial dynamics is correlated with the wild-type and mutant mtDNA expansion rates (Karavaeva et al., 2017; Osman et al., 2015). We speculate that this may underlie the differential reserve respiration capacities of Δsrv2 cells and Δdnm1 cells. However, impacts of different shapes of the network on activity require further study.

Based on phylogenetic analyses, two orthologous CAP proteins in mammalian cells, CAP1 and CAP2, serve similar functions as Srv2 in yeast cells. Although microtubules have been emphasized in mitochondrial dynamics, the role of actin filaments in mitochondrial dynamics in mammalian cells requires further study.

In summary, we have characterized Srv2 as a pro-fission factor that modulates mitochondrial activity. Our work brings the regulatory pathways of actin and mitochondrial dynamics together. As the roles of mitochondrial dynamics in the pathogenesis of neurodegenerative diseases and other diseases are emerging, returning the disrupted equivalence of mitochondrial dynamics to normal will be a potential therapeutic target in the future.

Limitations of the Study
Cytoskeletal systems definitely play a role in mitochondrial dynamics, and mammalian cells have much more sophisticated cytoskeleton systems than yeasts. In addition, mitochondrial transport largely relies on microtubules in mammalian cells. Although we have demonstrated that CAP2-knockout mammalian cells also possess elongated-hyperfused mitochondria, further study is required to clarify how actin assembly on mitochondria is involved in fission and transportation in mammalian cells.

METHODS
All methods can be found in the accompanying Transparent Methods supplemental file.

SUPPLEMENTAL INFORMATION
Supplemental Information includes Transparent Methods, six figures, and two tables and can be found with this article online at https://doi.org/10.1016/j.isci.2018.12.021.

Supplemental Information

Srv2 Is a Pro-fission Factor that Modulates Yeast Mitochondrial Morphology and Respiration by Regulating Actin Assembly

Ying-Chieh Chen, Tzu-Hao Cheng, Wei-Ling Lin, Chang-Lin Chen, Wei Yuan Yang, Craig Blackstone, and Chuang-Rung Chang
Figure S1. Yeast two-hybrid analysis to identify Srv2-Dnm1 interaction, related to Figure 1.

Yeast two-hybrid system LexABD/ Gal4AD was used to assess protein interaction. The interaction between proteins fused with LexABD and Gal4AD drives reporter gene “HIS3” expression. Yeast cells expressing fusion protein LexABD-Dnm1 and Gal4AD-Srv2 were assayed for growth on SD-His plate (serial dilution as indicated at the top).
Supplemental Figure 2.

Figure S2. BiFC analysis for assessing interaction between truncated/ mutated Srv2 and Dnm1, related to Figure 1.

Bimolecular fluorescence complementation (BiFC) experiments were used to analyze interaction between N/C-terminal Srv2 and srv2-189 and Dnm1. Yeast transformed with DNM1-GFP1~10+ NSRV2-GFP11, DNM1-GFP1~10+ CSRV2-GFP11, or DNM1-GFP1~10+ srv2-189-GFP11 were examined using BiFC assays. To improve the poor BiFC signals, NSRV2-GFP11/ CSRV2-GFP11/ srv2-189-GFP11 were expressed by pRS425 vector (2-micron plasmid). mt-DsRed was expressed to label mitochondria. Scale bars denote 5 μm.
Supplemental Figure 3.

Figure S3. Latrunculin A treatment does not disrupt Srv2-Dnm1 interaction, related to Figure 5.

Co-Immunoprecipitation (Co-IP) and bimolecular fluorescence complementation (BiFC) combined with latrunculin A (Lat-A) were used to assess Srv2 Dnm1 interaction upon disrupted actin dynamics. (A) The same strains and materials as in Figure 1B combined with 0.5 μM Lat-A were used to perform Co-IP experiments. (B) Yeast transformed with SRV2-GFP11 and DNM1-GFP1~10 combined 0.5 μM Lat-A were used to perform BiFC experiments. The results indicated that 0.5 μM Lat-A does not disrupt Srv2-Dnm1 interaction.
Supplemental Figure 4.

Figure S4. Actin cable counts in different yeast strains, related to Figure 5.

WT, srv2 mutants, actin cable mutant (Δtpm1) and actin patch mutants (Δabp1 and Δsla1) were grown at 30 °C in YPD, fixed and stained with rhodamine phalloidin. Visible actin cables in mother cell were counted (n≥50 cells per strain).
Figure S5. Mitochondrial elongation and hyperfusion in CAP2-/- Human neuroblastoma SH-SY5Y cell line, related to Figure 2.

The CAP2-/- SH-SY5Y cell line was generated by CRISPR/Cas9 system. Mitochondrial network morphology in wild-type (WT) and CAP2-/- cells expressing mito-EYFP was examined by fluorescence microscopy. The ratios of WT and CAP2-/- cells with hyperfused mitochondria were: WT, 2.67 % and CAP2-/-, 76.83 %. Statistical data for each strain were obtained from three trials of 100 cells. The mean values ± SE were obtained by averaging the percentages of three counts. ***p<0.001 vs. WT group. Scale bars denote 10 μm.
Figure S6  Oxygen consumption rates (OCR) are different among yeast strains, related to Figure 6.

OCR in different yeast strains under basal conditions or the addition of TET (ATP synthetase inhibitor), FCCP (uncoupler, proton carrier), and Antimycin A (complex III inhibitor) were measured by high resolution respirometry. Routine denotes OCR in the basal condition. LEAK denotes OCR with TET treatment, which reflects futile oxygen consumption even though ATP synthesis is blocked. ETS denotes OCR after FCCP titration, which causes proton loss and drive mitochondria consume more oxygen to replenish the proton gradient. ROX denotes OCR in Antimycin A treatment, which depletes OCR derived from mitochondria respiration and reveals oxygen consumption in this system other than mitochondria.
**Supplemental Table 1.** Yeast strains and their genotypes used in this study, related to Figure 1, 2, 3, 4, 5 and 6.

Transparent Methods

Yeast Strains and Genotypes

All yeast strains and genotypes used in this study are listed in Supplemental Table 1. Gene deletion strains and DNM1-GFP tag-related strains were constructed based on S. cerevisiae W303-1A (RRID: SCR_003093). Gene deletion strains were constructed mainly by PCR-based gene replacement with a KanMX4 cassette that was amplified from the yeast deletion collection. For double-gene deletion strains, the KanMX4 cassette was replaced by HIS3MX6 or HphMX4 cassettes from a yeast GFP collection or pAG32. The KanMX4 cassette was then used again to construct the second gene deletion. For DNM1-GFP fusion strains, GFP with a HIS3MX6 cassette was integrated proximal to the stop codon of DNM1 by PCR-mediated homologous recombination. For construction of strains CYC005, CYC016, CYC018, and CYC046, the integrative plasmids pRS403-pSRV2, pRS403-psrv2-91, pRS403-psrv2-98, and pRS403-GalSpSRV2 were linearized by restriction digestion for integration at the HIS3 locus after yeast transformation.

Plasmid Constructions

All plasmids used in this study are listed in Supplemental Table 2. pRS425-ADH1 was constructed by amplifying the ADH1 promoter from pGAD424 and cloning into
pRS425. Subsequently, DNA fragments encoding N-SRV2 (residues 1-259), C-SRV2 (residues 253-526), and PFY1 were amplified from yeast genomic DNA and then cloned into pRS425-ADH1 to generate pRS425-ADH1-N-SRV2, pRS425-ADH1-C-SRV2, and pRS425-ADH1-PFY1. pRS403-psrv2 was constructed by amplifying the open reading frame (ORF) of the SRV2 gene along with the upstream 490 base pairs from yeast genomic DNA and cloning into the pRS403 vector. Based on previous studies (Chaudhry et al., 2010, Chaudhry et al., 2013), pRS403-psrv2-91 and pRS403-psrv2-98 were generated by PCR-mediated mutagenesis from pRS403-psrv2 using primers (srv2-91: CACAGTTTTGGACTAATGCTATTGCTGCTGCTTACAGAGAGTCTGATC and GATCAGACTCTCTGTAAGCAGCAGCAATAGCATTAGTCCAAAAACTGTG/srv2-98: GAAAATATCATAAGGGTGCTGCTGCTGCTGACAAATCCCAACAAAC and GTTTGTTGGGATTTGTCAGCAGCAGCAGCACCCTAGTGATATTTTC). pRS403-psrv2-189 was generated by PCR-mediated mutagenesis with both sets of primers. For construction of pRS403-GalSpSRV2, the DNA fragment containing the GalS promoter and SRV2 ORF was amplified from pRS414-GalSpSRV2. For pVT100U-mtDsRed construction, the GFP in pVT100U-mtGFP was replaced by a DsRed sequence amplified from DCY2370 (the yeast strain containing DNM1-GFP).
and mtDsRed, a gift of Dr. David Chan, California Institute of Technology). For plasmids used in the bimolecular fluorescence complementation (BiFC) assay, DNA fragments of split-GFP (GFP1-10/ GFP11) were amplified from pcDNA3.1-MFN2-sfGFP11 and pcDNA3.1-sfGFP1~10 (gifts from Dr. Tzu Kang Sang, National Tsing Hua University). DNA fragments encoding individual proteins and native promoters were ligated to either GFP1-10 or GFP11 DNA fragments. Ligated DNA fragments were cloned into pRS413 and pRS414 (low-copy vectors), as shown in Supplemental Table 2.

Microscopy

Yeasts were examined during the log phase of growth in medium containing either glucose or galactose. Fluorescence images were captured using an inverted microscope (Zeiss/Observer.Z1) with a 63× objective lens (Zeiss Plan-ApoChromat 63×) and AxioVs40 software. Mitochondria were visualized by expressing matrix-targeted Su9-EGFP from pVT100-mtGFP (Westermann and Neupert, 2000) or matrix-targeted Su9-DsRed from pVT100-mtDsRed. For colocalization analysis of Dnm1 and mitochondria, z-section images captured by fluorescence microscopy were projected (orthogonal projection, maximum) using ZEN 2012 image acquisition software. Each individual yeast cell in the projected image was analyzed separately.
with ImageJ software (NIH) and the plugin “Manders Coefficients”. For actin cable
and patch staining, yeasts were fixed in medium containing 3.7% formaldehyde for 15
min at room temperature, washed with phosphate buffered saline (PBS), and stained in
PBS containing 0.165 μM rhodamine phalloidin. Actin cable counts were based on
the previous published paper (Alioto et al., 2016, Higuchi-Sanabria et al., 2016). For
latrunculin A treatment, yeast cells were incubated with medium containing 0.5 μM
latrunculin A for 6 h. For galactose induction, CYC005 was inoculated in SC medium
containing 2% raffinose until the log phase of growth. The yeast cells were then
transferred to YP medium containing 2% galactose for 3 h.

*Tandem affinity purification (TAP) tag co-precipitation*

Yeasts with TAP tag grown to mid-log phase were harvested by centrifugation. Pellets
were washed with ddH₂O and resuspended with extraction buffer (10 mM Tris-Cl, pH
8.0, 1 mM dithiothreitol (DTT), 150 mM NaCl, 1 mM magnesium acetate, 1 mM
imidazole, 2 mM CaCl₂, 0.1% NP-40). Glass beads were added to break the yeast
cells during vortexing for 15 min at 4 °C. Supernatants were collected thoroughly
from cell lysates by centrifugation at 15,000 g. Aliquots (150 μL) of the resulting
supernatant were incubated with 25 μL of bovine serum albumin pre-coated calmodulin
Sepharose beads for 3 hr at 4 °C. After incubation, the Sepharose beads were washed
three times with wash buffer (10 mM Tris-Cl, pH 8.0, 1 mM DTT, 500 mM NaCl, 1 mM magnesium acetate, 1 mM imidazole, 2 mM CaCl₂, 0.1% NP-40). The Sepharose beads were incubated with elution buffer (10 mM Tris-Cl, pH 8.0, 1 mM DTT, 150 mM NaCl, 1 mM magnesium acetate, 1 mM imidazole, 2 mM EGTA, 0.1% NP-40) for 5 min. The Sepharose beads with elution buffer and protein sample buffer were boiled for 5 min and cooled. The supernatants were collected for further western blot analysis.

**BiFC Assay**

To detect specific interaction between Srv2 and Dnm1 in yeasts, plasmids pRS413-pSRV2-GFP11 and pRS414-pDNM1-GFP1-10 were transformed in the specific strains described; the plasmids were constructed with low-copy vectors (yeast centromere plasmids) and native promoter. To avoid the titration effects of endogenous protein (without the split-GFP moiety), the indicated gene deletion strains were used in these experiments. For example, the ∆srv2 ∆dnm1 yeast strain transformed with pRS413-pSRV2-GFP11 and pRS414-pDNM1-GFP1-10 was used to detect the interaction of Srv2 and Dnm1. pVT100-mtDsRed was also used for labeling mitochondria.
Mitochondrial Fractionation

Mitochondria crude extracts were obtained by yeast cell fractionation (Meisinger et al., 2006). Briefly, yeast cells grown to mid-log phase were harvested by centrifugation at 1,500 g and suspended in DTT buffer at 30 °C for 20 min. The cells were washed and resuspended in buffer containing zymolyase for 30 min. Zymolyase-treated yeasts (spheroplasts) were collected by centrifugation, resuspended in homogenization buffer, and homogenized with 15 strokes of a glass-Teflon homogenizer. The homogenates were centrifuged at 1,500 g to pellet cell debris and nuclei, and the supernatants were collected and centrifuged at 4,000 g and then at 12,000 g. The pellets were denoted as the “crude mitochondria fraction”, and supernatants were denoted as the “cytosolic fraction”. Protein in both fractions were then analyzed by western blotting.

Flow Cytometry

Mitochondrial membrane potential was evaluated by DiOC6(3) staining (Cat. D273, Life Technology). Yeasts were incubated in medium containing 175 nM DiOC6 (3) for 20 min at 30 °C in the dark. Samples were evaluated using an Accuri C6 flow cytometer (BD Bioscience) following the protocol provided by the company. Data were analyzed using Cellquest software from BD Bioscience.
**High-resolution Respirometry**

Yeasts oxygen consumption rates were determined using an Oxygraph-2K (Oroboros). Data was analyzed by DatLab software provided by the company. Yeasts grown to stationary phase in Yeast Extract Peptone Dextrose Medium (YPD) were subcultured (160× dilution) in YPD/YPR (raffinose as carbon source) until an optical density at 600 nm of 0.6. The inoculates were then mixed with YPD/ YPR at a concentration of $5 \times 10^6$ cells per mL. The examination was done using $10^7$ cells. Triethyltin bromide (TET, 150 μM), carbonilcyanide p-trifluromethoxyphenylhydrazone (FCCP, < 4 μM), and 2 μM antimycin A were added stepwise. Mitochondrial basal respiration (R), proton leakage (L), and maximal respiration (E) can be evaluated by determining oxygen consumption rates with these mitochondrial inhibitors. To compare the mitochondrial functionality of yeast strains with different basal respiration (routine oxygen consumption), the oxygen consumption rates were transferred to comparable values, designated as the reserve capacity, by calculating $(E-R)/E$.

**Phylogenetic Analysis**

Protein sequences of the indicated species were obtained from the Uniprot website (http://www.uniprot.org/). These sequences were aligned, curated, and
phylogenetically analyzed using the MUSCLE online software, Gblocks, and PhyML, respectively (Edgar, 2004, Castresana, 2000, Dereeper et al., 2010, Guindon and Gascuel, 2003). The phylogenetic tree was generated using TreeDyn (Chevenet et al., 2006). Software was accessed at http://www.phylogeny.fr/.

**Statistical Analysis**

All experiments were conducted with at least three independent trials. To classify mitochondrial morphology, more than 100 cells were examined in each trial. Data are expressed as mean values. All error bars in the figures represented standard error unless otherwise specified. Significance was determined using two-tailed, unpaired Student’s t tests.
